Contents

PREFACE	xxvii
I. INTRODUCTION	1
1. CHANGES IN QUANTITATIVE TRAITS OVER TIME	3
A Brief History of the Study of the Evolution of Quantitative Traits	4
The fusion of population and quantitative genetics	4
The ongoing fusion of molecular and quantitative genetics	7
The common thread between breeding and evolution in natural populations	9
Detecting selection in natural populations	10
The Theoretical Foundations of Evolutionary Biology	11
The completeness of evolutionary theory	11
Nonadaptive hypotheses and our understanding of evolution	14
Overview and Pathways Through This Volume	16
Evolution at one and two loci	17
Drift and quantitative traits	18
Short-term response on a single character	18
Selection in structured populations	19
Population-genetic models of trait response	20
Measuring selection on traits	20
Appendices	21
Volume 3	21
Notation	22
II. EVOLUTION AT ONE AND TWO LOCI	23
2. NEUTRAL EVOLUTION IN ONE- AND TWO-LOCUS SYSTEMS	25
The Wright-Fisher Model	26
Loss of Heterozygosity by Random Genetic Drift	28
Probabilities and Times to Fixation or Loss	31
The age of a Neutral Allele	33
Allele-frequency Divergence Among Populations	35
Buri's Experiment	36
Higher-order Allele-frequency Moments	40
Linkage Disequilibrium	43
Mutation-drift Equilibrium	44
The Detailed Structure of Neutral Variation	48
The infinite-alleles model and the associated allele-frequency spectrum	48
The infinite-sites model and the associated site-frequency spectrum	50
The Genealogical Structure of a Population	52
Mutation-migration-drift Equilibrium	54
Quantifying population structure: F_{ST}	54
Mutation-migration-drift equilibrium values of F_{ST}	55
3. THE GENETIC EFFECTIVE SIZE OF A POPULATION	59
General Considerations	60
Monoecy	61
Dioecy	63
Age Structure	65
Variable Population Size	67

Partial Inbreeding	68
Special Systems of Mating	69
Population Subdivision	72
Selection, Recombination, and Hitchhiking Effects	74
Effects from selection at unlinked loci	74
Selective sweeps and genetic draft	75
Background selection	77
4. THE NONADAPTIVE FORCES OF EVOLUTION	81
Relative Power of Mutation and Genetic Drift	82
Nucleotide diversity	82
Number of segregating sites	83
Alternative approaches	84
Empirical observations	85
Relative Power of Recombination and Genetic Drift	86
Number of recombinational events in a sample of alleles	87
Other approaches for narrow genomic intervals	89
Large-scale analysis	90
Empirical observations	92
Effective Population Size	94
Temporal change in allele frequencies	94
Single-sample estimators	96
Empirical observations	97
Mutation Rate	98
Divergence analysis	98
Short-term enrichment	100
Evolution of the mutation rate	103
Recombination Rate	106
Evolution of the recombination rate	107
General Implications	109
5. THE POPULATION GENETICS OF SELECTION	113
Single-locus Selection: Two Alleles	113
Viability selection	114
Expected time for allele-frequency change	116
Differential viability selection on the sexes	117
Frequency-dependent selection	118
Fertility/fecundity selection	118
Sexual selection	119
Wright's Formula	119
Adaptive topographies and Wright's formula	122
Single-locus Selection: Multiple Alleles	122
Marginal fitnesses and average excesses	122
Equilibrium frequencies with multiple alleles	124
Internal, corner, and edge equilibria and basins of attraction	125
Wright's formula with multiple alleles	126
Changes in genotypic fitnesses, W_{ij} , when additional loci are under selection	127
Selection on Two Loci	128
Dynamics of gamete-frequency change	129
Gametic equilibrium frequencies, linkage disequilibrium, and mean fitness	130
Results for particular fitness models	131
Phenotypic stabilizing selection and the maintenance of genetic variation	132
Selection on a Quantitative Trait Locus	135
Monogenic traits	136
Many loci of small effect underlying the character	136

A population-genetic derivation of the breeder's equation	138
Correct quadratic terms for s_i	141
6. THEOREMS OF NATURAL SELECTION:	
RESULTS OF PRICE, FISHER, AND ROBERTSON	145
Price's General Theorem of Selection	146
The life and times of George Price	146
Price's theorem, $R_z = \sigma(w_i, z_i) + E(w_i \bar{\delta}_i)$	147
The Robertson-Price identity, $S = \sigma(w, z)$	150
The breeder's equation, $R = h^2 S$	151
Fisher's Fundamental Theorem of Natural Selection	154
The classical interpretation of Fisher's fundamental theorem, $R_w = \sigma_A^2(w)$	154
What did Fisher really mean?	157
Implications of Fisher's Theorem for Trait Variation	158
Traits correlated with fitness have lower heritabilities	160
Traits correlated with fitness have higher levels of both	
additive and residual variance	162
Nonadditive genetic variance for traits under selection	164
Robertson's Secondary Theorem of Natural Selection	165
1968 version: $R_z = \sigma_A(w, z)$	165
1966 version: $R_z = \sigma(w, A_z)$	166
Accuracy of the secondary theorem	166
Connecting Robertson's results with those of Price, Fisher, and Lush	167
The Breeder's Equation Framed Within the Price Equation	168
Partial covariance and the spurious response to selection	168
Parent-offspring regressions before and after selection	171
Heywood's decomposition of response	172
7. INTERACTION OF SELECTION, MUTATION, AND DRIFT	175
Selection and Mutation at Single Loci	175
Selection and Drift at Single Loci	179
Probability of fixation under additive selection	180
Probability of fixation under arbitrary selection	185
Fixation of overdominant and underdominant alleles	187
Expected allele frequency in a particular generation	190
Joint Interaction of Selection, Drift, and Mutation	191
Haldane's Principle and the Mutation Load	194
Fixation Issues Involving Two Loci	197
The Hill-Robertson effect	197
Mutations with contextual effects	199
Stochastic tunneling	200
8. HITCHHIKING AND SELECTIVE SWEEPS	207
Sweeps: A Brief Overview	207
Hitchhiking, sweeps, and partial sweeps	207
Selection alters the coalescent structure at linked neutral sites	208
Hard vs. soft sweeps	211
The Behavior of a Neutral Locus Linked to a Selected Site	212
Allele-frequency change	212
Reduction in genetic diversity around a sweep	217
The Messer-Neher estimator of s	220
Recovery of variation following a sweep	220
Effects of sweeps on the variance in microsatellite copy number	221
The site-frequency spectrum	222
The pattern of linkage disequilibrium	224

Age of a sweep	226
Partial sweeps	226
Impacts of inbreeding	227
Summary: Signatures of a hard sweep	227
Soft Sweeps	227
Signatures of a soft sweep	229
Sweeps using standing variation	230
How likely is a sweep using standing variation?	231
“Hardening” and “softening” of a sweep	235
Recurrent mutation of the favorable allele cannot be ignored	236
Impact of geographic structure	239
Polygenic Adaptation	242
Genome-Wide Impact of Repeated Selection at Linked Sites	243
Association between levels of variation and localized recombination rates	244
Impact of recurrent hard sweeps on levels of neutral variation	245
A few large or many small sweeps?	247
Selective interference and the Hill-Robertson effect	250
Background selection: Reduction in variation under low recombination or selfing ..	251
Background selection vs. recurrent selective sweeps	254
Sweeps, background selection, and substitution rates	255
Sweeps, background selection, and codon usage bias	257
A paradigm shift away from the neutral theory of molecular evolution?	262
9. USING MOLECULAR DATA TO DETECT SELECTION: SIGNATURES FROM RECENT SINGLE EVENTS	265
An Overview of Strategies Based on Segregating Variation	266
Attempts to account for departures from the equilibrium model	268
SNP ascertainment bias	268
SNP polarity assignment errors	269
Background selection as the more appropriate null?	269
Structure of the remainder of this chapter	269
Allele-Frequency Change in a Single Population	269
Allele-frequency change over two sample points: The Waples adjusted test	270
Allele-frequency change over a time series: The Fisher-Ford test	272
Schaffer’s linear trend test	274
Scans and simulation-based approaches	275
Birthdate selection mapping (<i>BDSM</i>)	275
Divergence Between Populations: Two-population Comparisons	277
Divergence Between Populations: F_{ST} -based Tests	278
Outlier approaches	279
Tests based on F_{ST} -generated branch-lengths	280
The Lewontin-Krakauer test: Basics	280
Second-generation Lewontin-Krakauer tests: Model-based adjustments	282
Third-generation Lewontin-Krakauer tests: Correcting for population structure	283
Allele-Frequency Correlations With Environmental Variables	284
Joost’s spatial analysis method (<i>SAM</i>)	284
Accounting for population structure: Coop’s <i>Bayenv</i> and Fritchot’s <i>LFMM</i>	286
Changes in the Chromosomal Pattern of Neutral Variation	289
Simple visual scans for changes in nucleotide and STR diversity	289
Tests based on STR variation across populations	291
Tests of sweeps using bottleneck models	292
Tests of sweeps using genomic positional information: <i>CLRT-GOF</i>	293
Tests of sweeps using genomic positional information: “ <i>SweepFinder</i> ”	295
Tests of sweeps using genomic positional information: <i>XP-CLR</i>	297
Ascertainment issues	299

Model fragility: Demography, mutation, recombination, and gene conversion	299
Tests Based on Site-frequency Spectrum Statistics	300
Summary statistics based on infinite-sites models	300
Tajima's D test	303
Achaz's Y and Y^* tests	305
Fu and Li's D^* and F^* tests	305
Fay and Wu's H test	306
Zeng et al.'s E test	307
Adjusting the null to account for nonequilibrium populations	307
Support via a preponderance of evidence	309
Recombination makes site-frequency tests conservative	311
Haplotype-based Tests	311
Defining and inferring haplotypes	312
Overview of haplotype-based tests	312
The Ewens-Watterson test	314
Other infinite-alleles tests: Conditioning on $\hat{\theta}$	315
Other infinite-alleles tests: Conditioning on S	316
Garud et al.'s H_{12} and H_2 tests	318
Recombination and infinite-alleles-based tests	318
Pairwise disequilibrium tests: Kelly's Z_{nS} and Kim and Nielsen's ω_{max}	319
Contrasting allele-frequency vs. intra-allelic estimates of haplotype age	320
Long haplotype tests using within-population data: $rEHH$, LLD , iHS , nS_L , SDS , and $DIND$	324
Long haplotype tests using between-population data: $XP-EHH$, Rsb , rHH , $rMHH$, and χ_{MD}	328
Summary: Tests based on haplotype/LD information	330
Searches for Selection: Humans	330
Recent and current selection in humans	331
Balancing selection in humans	333
Searches for Selection: Domesticated Organisms	334
The process of domestication	335
Finding domestication and improvement genes in crops	336
Domestication and improvement genes in rice	338
Domestication and improvement genes in maize	338
Relative strengths of selection on domestication vs. improvement genes	340
Silkmoths and flies	341
Constraints on finding domestication and improvement genes through selective signals	341
10. USING MOLECULAR DATA TO DETECT SELECTION: SIGNATURES FROM MULTIPLE HISTORICAL EVENTS	343
Brief Overview of Divergence-based Tests	344
A history of selection alters the ratio of polymorphic to divergent sites	344
A history of positive selection alters the ratio of silent- to replacement-site substitution rates	345
Divergence-based tests are biased toward conservative sites	346
What fraction of the genome is under functional constraints?	346
The HKA and McDonald-Kreitman Tests	347
The Hudson-Kreitman-Aguadé (HKA) test	347
The McDonald-Kreitman (MK) test: Basics	350
The McDonald-Kreitman test: Caveats	356
Dominance in fitness and the MK test	359
Fluctuating selection coefficients and MK tests	359
Recombinational bias in extended MK tests	360
Estimating Parameters of Adaptive Evolution	360

Estimating the fraction, α , of substitutions that are adaptive	360
How common are adaptive substitutions?	365
Estimating the rate, λ , of adaptive substitutions	367
The Sawyer-Hartl Poisson Random Field Model	369
Basic structure of the model	369
Bayesian extensions	374
INSIGHT analysis of human transcription factors	376
Phylogeny-based Divergence Tests	377
The K_a to K_s ratio, ω	378
Parsimony-based ancestral reconstruction tests	379
Maximum-likelihood-based codon tests	380
Bayesian estimators of sites under positive selection	383
Connecting the Parameters of Adaptive Evolution	384
The Search for Selection: Closing Comments	385
Caution is in order when declaring positive selection	386
Curbing our enthusiasm	387
III. DRIFT AND QUANTITATIVE TRAITS	389
11. CHANGES IN GENETIC VARIANCE INDUCED BY DRIFT	391
Response of Within-population Genetic Variance to Drift	391
Complete additivity	391
The effects of dominance	392
Quadratic components for inbred populations	393
One- and two-locus identity coefficients	395
Impact of drift under nonadditive variance	397
The effects of epistasis	399
Sampling error	403
Empirical data	405
Covariance Between Inbred Relatives	411
REML estimates	416
Empirical observations	417
Drift-mutation Equilibrium	419
Subdivided populations	422
12. THE NEUTRAL DIVERGENCE OF QUANTITATIVE TRAITS	425
Short-term divergence	426
Sampling error	427
Sample variance confidence intervals	429
Empirical observations	431
Estimating the among-group variance	432
Lande's constant variance test, F_{CV}	433
Long-term Divergence	434
Effectively neutral divergence and the estimation of rates of mutational variance	436
Testing the Null Hypothesis of Neutral Phenotypic Divergence: Rate-based Tests	438
Rate tests	439
Lande's Brownian-motion model of neutral trait evolution	439
Tests based on the Brownian-motion model	441
Ornstein-Uhlenbeck models	445
Divergence in morphological traits	446
Time Series Divergence Tests	446
Tests for departures from symmetric random walks	447
Hunt's approach for comparing different models	448
Population Structure Based-tests: Q_{ST} versus F_{ST}	452
Q_{ST} : Partitioning additive variance over populations	452

<i>P_{ST}</i> : Approximating <i>Q_{ST}</i> with phenotypic data	454
Testing <i>Q_{ST}</i> versus <i>F_{ST}</i>	455
Empirical data	458
Closing comments: <i>Q_{ST}</i> , <i>F_{STQ}</i> , and linkage disequilibrium	460
Trait-augmented Marker-based Approaches: Tests Using QTL Information	462
Leveraging QTL studies	462
Orr's <i>QTLST</i> and <i>QTLST-EE</i> sign tests	462
Applications of QTL sign tests	465
Trait-augmented Marker-based Approaches: Tests Using GWAS Information	467
Approaches based on combining signals	467
Tests based on <i>tSDS</i> scores	467
The Berg and Coop <i>Q_x</i> test	468
Divergence in Gene Expression	469
Level of gene expression as a quantitative trait	469
Rate-based tests for neutrality in divergence of gene expression	470
Largely neutral evolution of expression levels in primates?	473
Transcriptional <i>Q_{ST}</i> , <i>tQ_{ST}</i>	474
<i>Cis</i> vs. <i>trans</i> , local vs. distant, and allele-specific expression (ASE)	474
Applications of sign-based tests to expression data	475
Evolution of expression levels: Drift, directional, or stabilizing selection?	477
IV. SHORT-TERM RESPONSE ON A SINGLE CHARACTER	479
13. SHORT-TERM CHANGES IN THE MEAN:	
1. THE BREEDER'S EQUATION	481
Single-generation Response: The Breeder's Equation	482
The breeder's equation: A general approximation for response	482
The importance of linearity	482
Response is the change in mean breeding value	483
Response under sex-dependent parent-offspring regressions	484
The selection intensity, \bar{t}	486
The Robertson-Price identity, $S = \sigma(w, z)$	486
Correcting for reproductive differences: Effective selection differentials	487
Expanding the Basic Breeder's Equation	488
Accuracy	489
Reducing environmental noise: Stratified mass selection	493
Reducing environmental noise: Repeated-measures selection	494
Adjustments for overlapping generations	496
Maximizing response under the breeder's equation	497
Maximizing the economic rate of response	499
Mean- versus variance-standardized response	499
BLUP Selection	500
The Multivariate Breeder's Equation	500
Response with two traits	501
Accounting for phenotypic correlations: The selection gradient	501
Accounting for genetic correlations: The Lande equation	502
Selection gradients and mean population fitness	503
Limitations of the Breeder's Equation	504
14. SHORT-TERM CHANGES IN THE MEAN:	
2. TRUNCATION AND THRESHOLD SELECTION	507
Truncation Selection	507
Selection intensities and differentials under truncation selection	507
Correcting the Selection Intensity for Finite Sample Sizes	509

Response in Discrete Traits: Binary Characters	512
The threshold/liability model	512
Direct selection on the threshold, T	516
The logistic regression model for binary traits	516
BLUP selection with binary data: Generalized linear mixed models	520
Response in Discrete Traits: Poisson-distributed Characters	522
15. SHORT-TERM CHANGES IN THE MEAN:	
3. PERMANENT VERSUS TRANSIENT RESPONSE	525
Why all the Focus on h^2 ?	525
Genetic Sources of Transient Response	526
Additive epistasis	526
Dominance in autotetraploids	529
Ancestral Regressions	530
Response due to Environmental Correlations	534
Selection in the Presence of Heritable Maternal Effects	537
Decomposing maternal effects	537
Selection response under Falconer's dilution model	538
Separate direct and maternal traits	543
Maternal selection vs. maternal inheritance	545
16. SHORT-TERM CHANGES IN THE VARIANCE:	
1. CHANGES IN THE ADDITIVE VARIANCE	549
Changes in Variance due to Gametic-Phase Disequilibrium	549
Changes in Variance Under the Infinitesimal Model	552
Within- and among-family variance under the infinitesimal model	554
Accounting for inbreeding and drift	556
Changes in Variance Under Truncation Selection	557
Changes in correlated characters	560
Directional truncation selection: Theory	561
Directional truncation selection: Experimental results	563
Effects of epistasis: Does the Griffing effect overpower the Bulmer effect?	563
Double truncation selection: Theory	564
Double truncation selection: Experimental results	565
Response under Normalizing Selection	567
Selection with Assortative Mating	569
Results using the infinitesimal model	569
Assortative mating and enhanced response	570
Disruptive selection, assortative mating, and reproductive isolation	572
17. SHORT-TERM CHANGES IN THE VARIANCE:	
2. CHANGES IN THE ENVIRONMENTAL VARIANCE	573
Background: Heritable Variation in σ_E^2	573
Scales of environmental sensitivity	573
Environmental vs. genetic canalization	574
Evidence for heritable variation in the environmental variance	575
Modeling Genetic Variation in σ_E^2	576
The multiplicative model	577
The exponential model	578
The additive model	580
The heritability of the environmental variance, h_v^2	581
Selection on σ_E^2	583
Translating the response in A_v into response in σ_E^2	583
Response from stabilizing selection on phenotypic value, z	584

Response from directional selection on z	585
Direct selection on σ_E^2 using repeated records	588
18. ANALYSIS OF SHORT-TERM SELECTION EXPERIMENTS:	
1. LEAST-SQUARES APPROACHES	591
Variance in Short-term Response	591
Expected variance in response generated by drift	592
Variance in predicted response versus variance in actual response	595
Realized Heritabilities	595
Estimators for several generations of selection	596
Weighted least-squares estimates of realized heritability	598
Standard errors of realized heritability estimates	600
Power: Estimation of h^2 from relatives or selection response?	601
Empirical versus predicted standard errors	603
Realized heritability with rank data	604
Infinitesimal-model corrections for disequilibrium	604
Experimental Evaluation of the Breeder's Equation	606
Most traits respond to selection	606
Sheridan's analysis	607
Realized heritabilities, selection intensity, and inbreeding	608
Asymmetric selection response	611
Reversed response	615
Control Populations and Experimental Designs	616
Basic theory of control populations	616
Divergent selection designs	618
Variance in response	618
Control populations and variance in response	619
Optimal Experimental Designs	620
Nicholas' criterion	621
Replicate lines	621
Line-cross Analysis of Selection Experiments	622
The simple additive model	622
The Hammond-Gardner model	623
Accounting for inbreeding depression and drift	628
19. ANALYSIS OF SHORT-TERM SELECTION EXPERIMENTS:	
2. MIXED-MODEL AND BAYESIAN APPROACHES	631
Mixed-model vs. Least-squares Analysis	631
BLUP selection	632
Basics of Mixed-model Analysis	633
REML estimation of unknown variance components	636
REML often returns variance estimates unbiased by selection	637
Animal-model Analysis of Selection Experiments	638
The basic animal model	638
Response is measured by change in mean breeding values	639
Fixed effects alter heritabilities	642
Model validation	642
Separating genetic and environmental trends	643
Validation that a trend is indeed genetic	645
Replicate lines	647
Estimating the additive variance at generation t	647
The Relationship Matrix, A , Accounts for Drift and Disequilibrium	648
Modifications of the Basic Animal Model	651
Models with additional random effects	652
Common family and maternal effects	654

Treating certain breeding values as fixed effects	655
Dominance	656
Bayesian Mixed-model Analysis	659
Introduction to Bayesian statistics	659
Computing posteriors and marginals: MCMC and the Gibbs sampler	662
Bayesian analysis of the animal model	665
Application: Estimating selection response in pig litter-size components	666
LS, MM, or Bayes?	668
20. SELECTION RESPONSE IN NATURAL POPULATIONS	671
Evolution in Natural Populations: What Is the Target of Selection?	672
Direct and correlated responses	672
Environmentally generated correlations between fitness and traits	674
The Fisher-Price-Kirkpatrick-Arnold Model for Evolution of Breeding Date	676
Modifying the Breeder's Equation for Natural Populations	677
Complications in the absence of environmental change	678
Additional complications from environmental change	682
Is a Focal Trait the Direct Target of Selection?	682
Robertson's theorem: Response prediction without regard to the target of selection ..	682
Robertson consistency tests	683
Rausher's consistency criteria	684
Morrissey et al.'s consistency criteria	686
The breeder's equation versus the secondary theorem	687
Applying Mixed Models to Natural Populations: Basics	688
Animal-model analysis in natural populations: Overview	689
Obtaining the relationship matrix: Direct observation of the pedigree	691
Obtaining the relationship matrix: Marker data	691
Consequences of pedigree errors	696
Model selection	697
Applying Mixed Models to Natural Populations	698
Consistency tests: Accuracy, reliability, and caveats when using PBVs	698
Bivariate animal models: REML estimates of $\sigma(A_z, A_w)$, S_A , and S_z	702
Next-generation analysis: Generalized mixed models	703
Next-generation analysis: Modeling missing data	704
Detecting genetic trends	706
Causes of Apparent Failures of Response in Natural Populations	709
Cryptic evolution: Genetic change masked by environmental change	711
Antler size in red deer: The focal trait is not the target of selection	713
Lower heritabilities in environments with stronger selection?	713
Fitness tradeoffs and multivariate constraints	714
V. SELECTION IN STRUCTURED POPULATIONS	717
21. FAMILY-BASED SELECTION	719
Introduction to Family-based Selection Schemes	719
Overview of the different types of family-based selection	720
Plant versus animal breeding	720
Among- versus within-family selection	722
Details of Family-based Selection Schemes	722
Selection and recombination units	722
Variations of the selection unit	723
Variations of the recombination unit	725
Theory of Expected Single-cycle Response	727
Modifications of the breeder's equation for predicting family-based response	727

The selection unit-offspring covariance, $\sigma(x, y)$	731
Variance of the selection unit, σ_x^2	733
Response for Particular Designs	736
Overview of among- and within-family response	736
Among-family selection	737
Among-family selection: Which scheme is best?	740
Within-family selection	741
Realized heritabilities	743
Accounting for epistasis	744
Response with autotetraploids	745
Efficiency of Family-based Vs. Individual Selection	749
The relative accuracies of family-based vs. individual selection	749
Comparing selection intensities: Finite size corrections	753
Within-family selection has additional long-term advantages	754
Response when Families are Replicated Over Environments	755
Among-family variance under replication	755
Ear-to-row selection	758
Modified ear-to-row selection	758
Selection on a Family Index	761
Response to selection on a family index	762
Lush's optimal index	763
Correcting the selection intensity for correlated variables	766

PREFACE

One hundred years ago, Sir Ronald Aylmer Fisher (1918), in a paper that was rejected by the Royal Society of London, laid the foundations for the field that has come to be known as quantitative genetics. This paper, and subsequent work by Fisher and others (often in the search of biologically motivated problems), also gave birth to much of modern statistics. The past century has seen quantitative genetics flourish, and indeed, the field has never been stronger or more vibrant as it moves seamlessly into the post-genomics era with an ever-broadening reach. If Fisher were alive today, we believe that he would be fascinated, and somewhat pleased, both at how much the field has grown, and also at how much it remains very familiar to him, even after all these years.

This text is the second part (out of three) of our treatment of the modern field of quantitative genetics from its humble, but path-breaking, beginnings 100 years ago. Some 20 years ago, we remarked in the introduction to the first part of our treatment (Lynch and Walsh 1998) that “today’s quantitative genetics is not the science that it was 25 (or even 10) years ago,” a statement that is even truer today. Our further comment that “the current machinery of quantitative genetics stands waiting (and its practitioners willing) to incorporate the fine genetic details of complex traits being elucidated by molecular and developmental biologists” has certainly been proven true over the past two decades. Modern quantitative genetics is the glue that connects many disciplines, especially given its ability to model uncertainty while fully accounting for known genetic and genomic features.

The first part of our treatment (Volume 1) dealt with genetics, which is the underpinning of complex traits. While we also remark on some recent developments in this area in this volume, our main focus is on the evolution of such traits, with applied evolution (plant and animal breeding) as an important application. To address these concerns, we have attempted to merge modern population-genetics theory with quantitative genetics and genomics. As a result, some of our treatment is more technical than was presented in Volume 1, as it provides a much fuller development of mathematical models of evolution. We have strived to present a holistic treatment, showing the interplay between theory and data, with extensive discussions on statistical issues relating to the estimation of the biologically relevant parameters for these models. We view quantitative genetics as the bridge between complex mathematical models of trait evolution and real-world data, and have tried to frame our treatment as such.

As with our first volume, a key goal in producing this volume is to increase communication among the various disciplines that make up the very diverse field of quantitative genetics. Twenty years ago, this included plant and animal breeders, evolutionary biologists, human geneticists, and statisticians. This list has only grown with the advent of genomics, which attracts an ever-widening array of those who use quantitative genetics (many of whom may not even be aware of it).

Given a project of this size and scope, and despite our own best efforts, excellent copy editors, and wonderful colleagues, it is likely that errors have escaped scrutiny. Hopefully, most will be obvious and trivial, but the posterior for this process often has a long tail, and, therefore, the potential for some interesting outliers. Please report any errors you find to BW (jbwalsh@email.arizona.edu). Likewise, we have a facebook group, **Quantitative Genetics Book**, whose file section will contain updated pdf files for current errata, as well as a forum for discussing issues related to the book. Finally, the final part of our treatment, which deals largely with multivariate issues, will be forthcoming in a more timely manner than this volume!

Acknowledgments

As numerous seasoned readers will know, various components of this book have been in the works for over three decades. For a project of this magnitude, there is a host of people to thank, and we have undoubtedly forgotten to credit individuals who provided us with critical feedback in the earliest years. We profusely apologize for any such slights and blame our slowly fading memories.

As we moved into the field of quantitative genetics in earnest in the 1980s, critical foundational support in the development of our ideas was provided by our colleagues and teachers Stevan Arnold, Reinhard Burger, James Crow, Joe Felsenstein, Wilfried Gabriel, Daniel Gianola, Thomas Hansen, William Hill, Elizabeth Housworth, Alex Kondrashov, Russell Lande, Bill Muir, Tom Nagylaki, Tim Prout, Monty Slaktin, Michael Turelli, and Michael Wade.

We have also greatly benefited from all past and current members of our labs for their comments over the years. These especially include Ph.D. students: Matthew Ackerman, Desiree Allen, Stephan Baehr, David Butcher, Chi Chun Chen, Hong-Wen Deng, Suzanne Estes, Allan Force, Jean-François Pierre Gout, Kyle Hagner, Parul Johri, Vaishali Katju, Weiyi Li, Timothy Licknack, Hongan Long, Samuel Miller, Kendall Morgan, Angela Omilian, Michael Pfrender, Taylor Raborn, Sarah Schaack, Ryan Stikeleather, and Ken Spitze; and post-doctoral associates: Charles Baer, Melania Cristescu, Dee Denver, Thomas Doak, Jeffrey Dudycha, Suzanne Edmonds, Jean Francois Gout, Kevin Higgins, David Houle, Sibel Kucukyildirim, Niles Lehman, Hong-An Long, Takahiro Maruki, Martin O'Hely, Susan Ratner, Barrie Robison, Stewart Schultz, Douglas Scofield, and John Willis.

BW also wishes to thank the thousands of students who have attended his short courses on various aspects of quantitative genetics over the past two decades, during which he has taught over 5000 students from roughly 60 countries at various locations around the world (25 countries at last count). This international interaction and feedback have greatly sharpened our ability to present the material in this book to a truly universal audience.

We have been exceptionally blessed with outstanding feedback throughout this project from a long list of colleagues, who directly engaged with the manuscript. Sally Otto and Michael Morrissey read whole parts of the manuscript, while critical comments on specific chapters were provided by Steve Arnold, Nick Barton, Peter Bijma, Mark Kirkpatrick, Bill Muir, Shinichi Nakagawa, Guilherme Rosa, Ruth Shaw, John Storey, and Michael Turelli.

We especially want to acknowledge Bill Hill, who has been a major force throughout this project, and in many ways could be considered its third author. Bill read all of both Volume 1 (Lynch and Walsh) and the current volume, offering very detailed and critical comments, and saving us from much embarrassment. Our goal throughout the project was to present the field with the breadth and depth that Bill carries around in his head. He also kept us going by constantly ending his emails with the reminder to “keep writing!” Hence, we are very pleased to codecide this volume to Bill.

With respect to the production end, we have greatly enjoyed working with the highly professional staff at Sinauer Associates through the bulk of the editing process, and then with their new colleagues at Oxford during the final phase. Copy editor Nicole Balant and production editor Martha Lorantos faced the thankless task of trying to catch typos in a 1400-page technical manuscript where the lead author is rather dyslexic.

Elizabeth Morales and Ann Chiara did a wonderful job with the illustrations and patiently dealt with us, as we frequently changed our minds on how to best illustrate various concepts, while Michele Beckta dealt with copyright issues regarding the figures. Last, but certainly not least, production manager Chris Small thoughtfully guided us through the typesetting of both this and the previous volume (both of which were typeset by BW using Textures). Any less-than-professional appearance of aspects of this volume are there despite the best efforts of Chris!

We save very special thanks for our publisher and friend, Andy Sinauer. Andy initially started this project in the mid-1980s when we (BW and ML) discovered (via Andy) that

we were both working on separate books on the same subject and he logically queried whether it might be better if we worked together. Indeed it was! Andy has shown incredible patience over the past three decades on the pace of this project, and we hope that he will be pleased with the final outcome, despite its long gestation. We are thus extremely pleased to codedicate this volume to Andy for his long and outstanding service as one of the preeminent publishers of biological science textbooks. Upon his retirement, he has left a gap that will be hard to fill, and his impact on a number of fields, particularly evolutionary biology, is hard to overstate.

In closing, ML is especially grateful to the administration and colleagues at the University of Illinois, his place of first employment, for providing him with a safe environment for making an early (and risky) career transition from limnology to evolutionary genetics. And we both thank NSF and NIH for continuing support for research related to the subject matter of the book.

Finally, and especially, we wish to thank our incredible wives, Emília Martins (ML) and Lee Fulmer (BW), for their enduring patience during this long project.

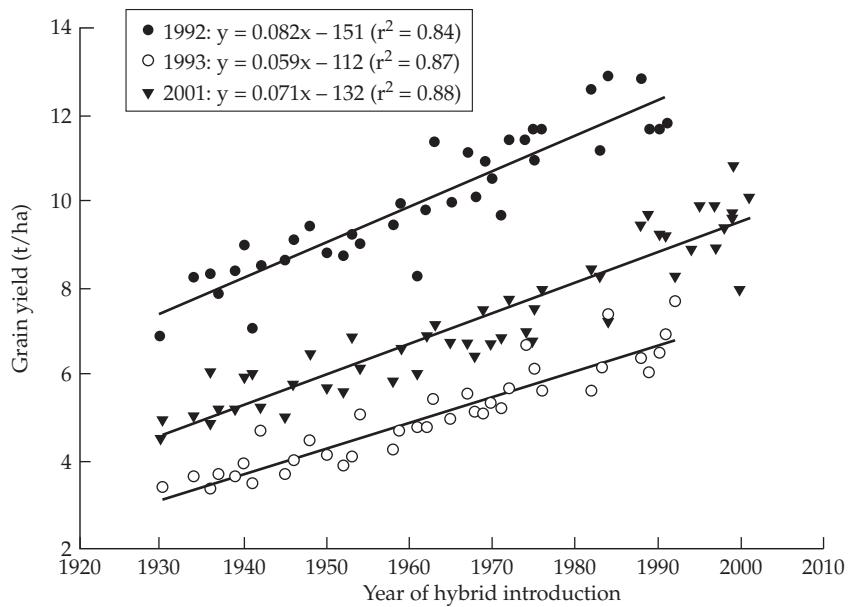

Bruce Walsh, Tucson

Michael Lynch, Tempe

March 2018

I

Introduction

1

Changes in Quantitative Traits Over Time

The tendency of modern scientific teaching is to neglect the great books, to lay far too much stress upon relatively unimportant modern work, and to present masses of detail of doubtful truth and questionable weight in such a way as to obscure principles. Fisher and Stock (1915)

Quantitative traits—be they morphological or physiological characters, aspects of behavior, or genome-level features such as the amount of RNA or protein expression for a specific gene—usually show considerable variation within and among populations. A central (perhaps *the* central) question in evolution is the nature of the underlying forces generating this variation, be it the standing variation within a population or the divergence between species. Fully interwoven into this question is the corollary of how best to achieve targeted changes in organisms exploited for human welfare, namely breed improvement (Figures 1.1 and 1.2). The importance of this applied aspect cannot be overstated. The most important technology developed by humans is agriculture, as all of our other impressive advances rest upon the foundation of a stable and sustainable food system. At present, despite significant improvements in yield (e.g., Evenson and Gollin 2003; Thornton 2010), there is considerable uncertainty about our ability to keep pace with projected global needs (Ray et al. 2012, 2013).

It is against this background that we attempt to present a modern, unified theory of quantitative genetics. Such a theory must draw heavily from population genetics, statistical theory, mathematical modeling, genetics, and genomics. It must also be built upon empirical observations from a very wide range of fields. As such, it must consider changes in complex traits in populations of organisms ranging from long-term laboratory studies on viral and bacterial evolution, much shorter-term selection experiments on metazoans, the exhaustive experience of breeders of a wide range of domesticated plants and animals, recent information from human biology, and a growing number of model (and also non-model) species in wild populations. Quantitative-genetics theory also needs to consider the full range of mating systems: inbred and outbred populations of sexual species and the clonal populations of asexual species, and it must also be applicable to haploids, diploids, and polyploids. It should be flexible and extensible, being able to incorporate new sources of information as they become available (e.g., functional-genomics features). Finally, such a theory should be empirically testable, making predictions (such as selection response) based on quantities that we have some hope of estimating.

Given the vast diversity of stakeholders in quantitative genetics, it is not surprising that very useful ideas, results, and machinery developed in one subfield may only slowly (if at all) migrate out into the broader community of users. A critical goal of this book is to facilitate this dissemination. For example, it is not fully appreciated that modern quantitative genetics is now fully merged with population genetics and is a growing part of genomics. Indeed, despite concerns of being outdated and in need of major revision (e.g., Nelson et al. 2013), the field is extremely robust and quite healthy. Modern quantitative genetics is the glue that connects many disciplines, especially given its ability to model uncertainty while fully accounting for known genetic and genomic features.

This introductory chapter starts with a historical overview of considerations of the evolution of quantitative traits. We then briefly comment on the theoretical foundations of evolutionary biology as they relate to qualitative traits (addressing some common misconceptions). We conclude with an overview and road map of this volume.

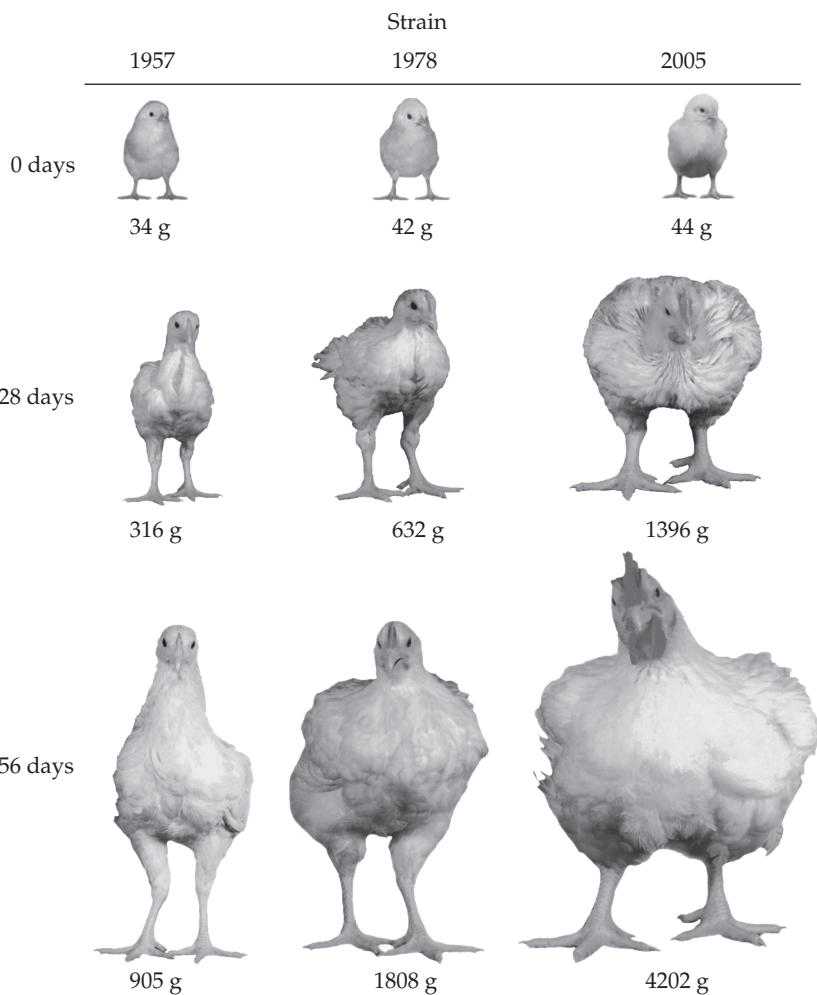

Figure 1.1 A striking example of the power of artificial selection is seen in lines of broilers, chickens selected for meat production. The figure compares the performance of a representative base line from 1957, an improved line from 1978, and a recent line from 2005, all raised in the same environment. Besides these extremely impressive differences in growth, there are equally important improvements in feed-to-protein conversion efficiency. (After Zuidhof et al. 2014.)

A BRIEF HISTORY OF THE STUDY OF THE EVOLUTION OF QUANTITATIVE TRAITS

The Fusion of Population and Quantitative Genetics

Although the histories of population and quantitative genetics are highly intertwined, they have experienced long periods of apparent separation. Their initially separate trajectories trace back to the bitter debate between the **biometricians** and the **Mendelians** following the rediscovery of Mendel in the early 1900s (Provine 1971, 2000; Tabery 2004). Motivated by Mendel's work on the inheritance of major genetic factors, the Mendelians believed that evolution was saltational: moving only by major leaps via the appearance of new mutations. The biometricians (supporters of Darwin and the founders of modern statistics) introduced concepts such as regressions and correlations to quantify continuous variation, and they thought that evolution occurred in very small steps by exploiting this variation. This initial schism between inheritance (Mendel) and evolution (Darwin) was largely driven by antagonistic personalities in the different camps (Provine 1971; although see Hogben 1974 for a

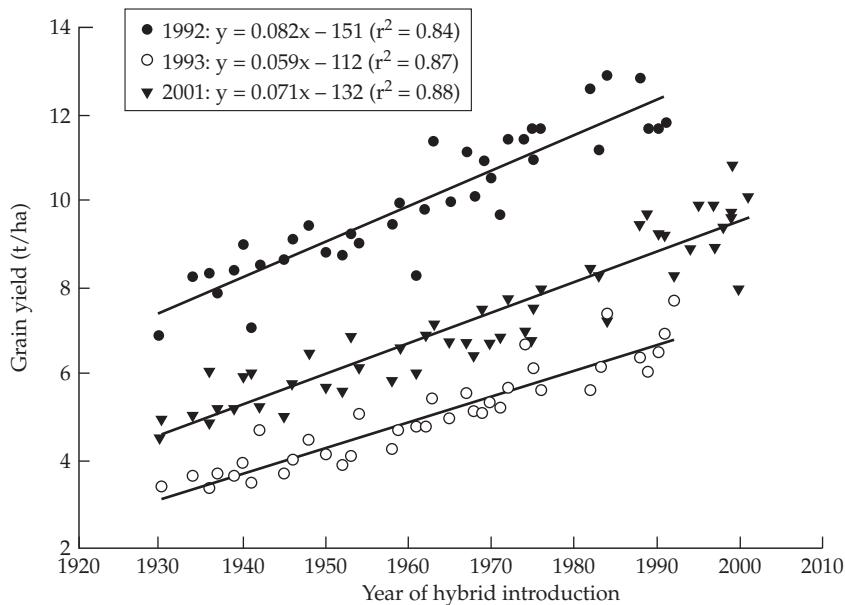

Figure 1.2 Yield (measured in tons per hectare) in maize hybrid lines as a function of year of release. Using remnant seed, all lines were grown in the same set of years, with 1992 being highly favorable, 1993 cool and extremely wet, and 2001 hot and dry. Note that the response is parallel over the three different environments (years), suggesting little genotype \times environment interaction. Such “common-garden” experiments are the cleanest way to separate an observed gain into genetic versus environmental components (Chapters 19 and 20 present alternative mixed-model approaches that can also accomplish this goal). This separation is critical, as a yield improvement over time could simply reflect improved agronomic practices, rather than genetic gain. In maize, hybrid improvement accounts for between 50 and 70% of the total improvement in yield, with the remainder due to improved farming practices (Duvick 2001). (After Duvick 2005.)

different perspective), and significantly delayed the modern synthesis—the fusion of Darwin’s evolution by natural selection with Mendelian inheritance. Vestiges of this difference between the gene-based focus of the Mendelians and the continuous-trait focus of the biometrists still persist today.

The first population-genetics paper, which predated the rediscovery of Mendel (and hence was published well before any considerations of the actual dynamics of genes), was concerned with a quantitative-genetics question. Fleeming Jenkin, Regius Professor of Engineering at the University of Edinburgh, was asked to write a review of Darwin’s *Origin of Species*. Jenkin was a polyglot, and, among other things, invented the cable car and was an actor and an artist. Jenkin (1867) pointed out that, under blending inheritance, half of any variation is removed in each generation. Thus, any change achieved via natural selection would quickly be diluted away by the assumed nature of inheritance (also see Bulmer 2004). Phrased in terms of modern statistics, and recalling that the variance of a product of a constant (a) times a random variable (x) is $\sigma^2(ax) = a^2\sigma^2(x)$, his argument was that

$$\sigma^2(z_o) = \sigma^2\left(\frac{z_f + z_m}{2}\right) = \frac{\sigma^2(z_f)}{2^2} + \frac{\sigma^2(z_m)}{2^2} = \frac{\sigma^2(z)}{2}$$

where z_f and z_m are the (assumed to be uncorrelated) paternal and maternal trait values, z_o is the offspring value, and we assume that the trait variance is the same in both sexes, so that $\sigma^2(z_f) = \sigma^2(z_m) = \sigma^2(z)$. Mendelian genetics provides the solution to this quandary of reduced variation following reproduction, as the segregation variance (variation generated

by the transmission of alternative alleles in the gametes of heterozygous parents) completely restores the genetic variance in each generation (Chapter 16).

Given the nature of Jenkin's argument, it is fitting that the term *variance* was first introduced in the foundational paper of the field of quantitative genetics (Fisher 1918). Fisher's brilliant (yet technically difficult) paper formed the conceptual bridge between Mendelian inheritance with discrete genes and evolution acting on continuous traits (ideas hinted at earlier by Yule 1902, 1906). Despite its enormous importance, Fisher wrote this paper as a high school teacher in 1916, and it was initially rejected by the Royal Society of London. As Crow (1972) succinctly stated, "It was apparently too mathematical for the Mendelists and too Mendelian for the biometricals." It was eventually published by the Royal Society of Edinburgh with the help of Leonard Darwin, Charles's son.

Fisher's theory of the expected resemblance between relatives was built by considering the sharing of alleles at underlying trait loci, and hence had a population-genetics core. Operationally, however, Fisher showed that summary statistics (the additive-genetic and other variance components) largely describe the resemblance between relatives. This was the undercurrent for much of the passive separation of population genetics from quantitative genetics. Although the latter was built around the dynamics of the underlying genes, it focuses on individual-level (breeding values) or population-level (additive variances) summary statistics of these underlying genetic features. This perceived lack of detailed genetics is both the strength and the weakness of quantitative genetics. Simply by having phenotypic measures of a trait on a set of known relatives, a number of short-term predictions (such as the response to selection and the expected resemblance between different sets of relatives) can be made in the absence of any other genetic information.

Immediately following Fisher's paper, major contributions started to appear from the two other founders of population genetics, Sewall Wright and J. B. S. Haldane, who also helped solidify the foundation of quantitative genetics initially laid out by Fisher. Despite this trinity all making deep contributions to the founding of both fields, one source of the passive separation of quantitative from population genetics was the multilocus nature of the former and the initial focus of the latter on single-locus models (Chapters 2 and 5).

No explicit considerations of multiple-locus models of selection were made until the late 1950s (Kimura 1956; Lewontin and Kojima 1960; Chapter 5). The complexity of the dynamics under even two-locus selection models seemed to prevent an easy generalization to the types of genetic architectures thought to be typical of quantitative traits, namely, a large number of loci. However, as detailed in Chapter 5, most of the complications in multilocus systems arise because of selection-generated gametic-phase (linkage) disequilibrium (abbreviated LD). If LD is assumed to be fairly weak (in other words, recombination is strong relative to selection on a given locus), single-locus results (for additive loci) can be used in models predicting selection responses (Chapters 5, 24–28). An important extension of this simplifying assumption was advanced by Bulmer (1971b, 1974a), who showed that the cumulative effects of even small amounts of selection-generated LD have a significant impact on the genetic variance when a large number of loci underlie a trait under selection. Fortunately, the expected LD-generated change in the additive variance is largely predictable (at least over a few generations) given the value of the **genic variance**, σ_a^2 (the additive variance in the absence of LD; Chapters 16 and 24).

Given the assumption of weak selection (on any given locus, but not necessarily on the trait as a whole) and loose linkage, much of the theory of short-term selection response in quantitative traits is built around the **infinitesimal model**, a simplification wherein a large number of loci, each of small effect and usually additive, are assumed to underlie a trait (Chapter 24). In this setting, selection-induced allele-frequency changes at the underlying loci are assumed to be small for several generations, allowing response (both in terms of the mean and any LD-induced changes in the variance) to be largely predictable from information on the resemblances between relatives in the base (i.e., unselected) population. This setting, which is based on parent-offspring regressions, is the foundation for much of modern breeding theory (Chapters 5, 6, 13–23).

Starting in the late 1980s, more realistic, yet partly tractable, models of multilocus selection beyond the infinitesimal model started to appear (Barton and Turelli 1987; Keightley and Hill 1987; Turelli 1988; Turelli and Barton 1990; Bürger 1991a; Chevalet 1994; Chapter 24). To date, the issues with any multiple-locus model are twofold. First, the dynamics can be very complex, making generalizations difficult (but see Chapters 6 and 24). Second, and more critically, predicting the long-term behavior of such multiple-locus genetic systems requires, not just manageable theory, but also a detailed knowledge of the underlying genetic architecture of a trait (number of genes, allelic frequencies, and effect sizes) that is largely unavailable at the present, and likely to remain so into the rather far future (but see Visscher 2016 for a different perspective).

Finally, the foundations for the field of molecular population genetics were laid by Kimura (1955a, 1955b, 1957), and started with Kimura and Crow's (1964) infinite-alleles model (the first attempt to fully model mutation at the DNA-sequence level; Chapter 2). Although this field initially appeared to be very tangential to quantitative genetics, even here there was a strong initial connection with quantitative-genetics theory, as Kimura (1965a) used a modification of the infinite-alleles model to examine the expected distribution of allelic effects at a locus underlying a trait under stabilizing selection (Example 28.4).

Realizing that stochastic forces are extremely important in molecular evolution, Kimura marshaled the power of diffusion approximations (Appendix 1) to examine the interactions of evolutionary forces in finite populations, culminating with his **neutral theory of molecular evolution** (Kimura 1968b, 1983). Again, as with other fields that at first were perceived as only tangential, there were early applications of this molecularly driven theory to quantitative genetics. Robertson (1960a) realized that Kimura's (1957) results on the fixation probability of an allele under drift and selection were directly applicable to breeding. This led to his remarkably simple expression for the expected limit to the selection response: the expected total long-term response (ignoring new mutations) is bounded above by $2N_e R(1)$, where N_e is the effective population size (Chapter 3) and $R(1)$ is the expected response to selection in the first generation (Chapters 13 and 26).

A watershed event in molecular population genetics was Kingman's (1982a, 1982b) introduction of the powerful concept of the **coalescent** (treating a sample of alleles from a population as a genealogy, which eventually coalesces to a common ancestral sequence at some point in the past; Chapter 2). This approach allowed for the development of statistical tests on the nature of forces shaping sequence evolution (Chapters 4 and 8–10). The very slow trickle of molecular data on which to apply this theory in those early days has now become a veritable tsunami of whole-genome sequences at the population level. It is this very flood of population-genomics data that is now driving the fusion of molecular and quantitative genetics. Much of the theoretical foundations for this fusion derive from results originally developed for, and envisioned as being restricted to, molecular population genetics.

The Ongoing Fusion of Molecular and Quantitative Genetics

In large part, the interaction between so-called classical genetics and quantitative genetics that played out during the rise of molecular genetics parallels much of the debate between the early Mendelians and biometricalians, but with less rancor. During the rise of molecular genetics in the 1950s (nicely reviewed by Judson 1979 and Mukherjee 2016), the notion of a gene grew from a fairly nebulous concept into a rather concrete, well understood, object. This resulted in any statistical description of inheritance from quantitative genetics (variances of traits instead of following genes) becoming far less appealing. Indeed, to many geneticists, quantitative genetics appeared as an anachronism, a crutch that biologists no longer needed. As massive advances were made in the dissection of specific, individual genes with discrete, and highly reproducible, phenotypes, the result was a diminished interest in continuous traits. Indeed, Fisher's notion of an infinitesimal model—a large number of loci, each with very small effects—was anathema to this molecular way of thinking.

By the early 1980s, one of the byproducts of this revolution was access to an ever-growing number of molecular-based markers. Their availability opened up the potential for

quantitative trait locus (QTL) mapping, which involves the isolation of small chromosomal regions that influence a trait of interest by applying linkage analysis to line-cross derivatives (LW Chapters 14 and 15). Such studies routinely found relatively small (\sim 10s of megabases) chromosomal segments that appeared to account for nontrivial fractions of the trait variation (5% or more; e.g., LW Figure 15.13). At odds with infinitesimal-like model thinking, this finding reinforced the view of many molecular geneticists on the importance of single genes.

The apparent presence of such major genes suggested that population-genetic models working with these genes (once they have been isolated) could largely supplant standard quantitative-genetics approaches. However, the actual isolation of such candidate genes proved extremely elusive. Eventually, this led to the realization that the large estimated effects of such genes were very often the result of significantly upward estimation bias and the presence of tightly linked clusters of QTLs that fractionate upon finer mapping (Chapter 24).

By the early 2000s, as molecular-marker technology continued to advance, the ability to quickly and cheaply score tens of thousands of markers allowed for association mapping (LW Chapter 16). The foundation of this approach rests on the use of linkage disequilibrium in random samples of unrelated individuals from a large population to fine-map genes (an idea deeply rooted in coalescent theory). As detailed in Chapter 24, one generalization from these studies was that only a very tiny fraction of the variance (typically far less than 1%) of a typical trait can be ascribed to any particular genomic region (with resolution now on the kilobase scale). The use of such dense marker coverage showed that the response to artificial selection is usually the result of changes over a large number of sites (Chapter 25), and their availability has facilitated tests of selection in any given region within a genome (Chapters 9 and 10).

The culmination of these association studies, involving up to millions of scored single-nucleotide polymorphisms (SNPs) on tens of thousands of individuals, was the crisis of apparently “missing heritability” (Manolio et al. 2009). The concern among many human geneticists was that, for all of their hard work on highly heritable traits such as height, detected SNP markers could only account for \sim 10% of the heritability found by standard biometrical analysis (i.e., resemblance between relatives). The result was a near-hysteria on the part of some, as they felt that because the molecular results *must* be correct, something fundamental was being overlooked in quantitative genetics. In reality this disconnect was simply a manifestation of the narrow focus that arose from being trained for decades in a single-gene culture. As pithily remarked by Sheldon (2014),

There is something simultaneously remarkable and encouraging about the fact that a centuries-old method requiring no more than a ruler, a pencil and (I suppose) a slide rule outperformed, by an order of magnitude, the fruits of the genomic revolution.

As detailed in Example 24.1, such a pattern of “missing heritability” is exactly what is expected when each underlying locus only explains a small fraction of trait variation (namely, a large number of underlying loci in partial linkage disequilibrium with the scored markers).

Thus, we have come full circle, with the genomic (i.e., association) data providing strong support for an infinitesimal-like model for the genetic architecture of many traits. However, the subtle distinction from the standard infinitesimal model is that while any particular site accounts for only a very small fraction of the *variance* of a trait, rare segregating alleles having large individual *effects* can be found (Figure 28.8). A quantitative-genetic framework is thus required when using association data for genomic prediction (the framework for genomic selection and genomic-based individualized medicine). A quick glance at any of the front-line journals in genomics highlights this growing merger with quantitative genetics, as many functional-genomic features—such as expression levels of RNAs, proteins, and metabolites—are now routinely examined in a quantitative-genetics framework.

A final example highlighting the connectedness between genomics and quantitative genetics concerns the **Hill-Robertson effect**. In contemplating the consequences of linkage for applied breeding, Hill and Robertson (1966) noticed that the presence of linkage reduced

the chances of the joint fixation of linked beneficial alleles (Chapters 3, 7 and 8). While their work was regarded as entirely theoretical at the time (they never had any expectations of having the marker density required to test it), their idea that selection reduces the effective population size at linked sites is now a key organizing principle in the evolutionary analysis of genomic sequence data (Chapters 3 and 8).

The Common Thread Between Breeding and Evolution in Natural Populations

The connection between trait change through artificial selection in domesticated organisms and trait evolution in natural populations was one of the pillars of evidence offered by Darwin in support of his theory of evolution by natural selection. It is thus not surprising that the subfields of breed improvement (which is simply applied evolution) and evolutionary biology have historically had considerable interactions (Hill and Kirkpatrick 2010; Hill 2014; Gianola and Rosa 2015). Both fields are concerned with predicting an expected change in a trait (or vector of traits) given a specific pattern of selection. Evolutionary biologists face the additional, and daunting, challenge of trying to estimate the nature and target (or targets) of selection (i.e., assigning fitnesses to specific trait combinations; Chapters 20, 29, and 30). We consider this last topic separately, after first examining the common connections between the work of breeders and evolutionary biologists.

The introduction of the full power of quantitative genetics into breeding is in large part due to Jay Lush, and his extremely influential book, *Animal Breeding Plans* (Lush 1937). In particular, he proposed the classical breeder's equation, $R = h^2S$, for predicting the response to a single generation of selection. Lush was heavily influenced by Sewall Wright, as in 1931 he commuted weekly from Iowa State to the University of Chicago to attend Wright's statistical genetics course. He was also influenced by R. A. Fisher, who lectured at Iowa State during the summers of 1931 through 1936. The extension from the univariate breeder's equation to the response to selection on multiple traits, in the form of selection on a weighted index of trait values, was influenced by both Lush and Fisher. Smith (1936), who acknowledges Fisher's help, and Lush's colleague Hazel (1945) both examined the expected selection response and optimal weights of such an index of trait values. Lush (1947) applied the Smith-Hazel results to obtain the optimal weighting of within- and among-family information for artificial selection programs. Smith and Hazel's work also introduced the very powerful concept of genetic correlations.

The breeder's equation is the cornerstone for much of the predicted response to selection in natural populations, and its multivariate extension, which is due to Lande (1976), builds heavily on the ideas of Smith and Hazel, as well as Pearson (1903). Hence, ideas that were initially developed for evolution (Wright's interests) were translated into animal breeding by Lush, and then subsequently found their way back into the evolutionary literature for modeling the expected response in natural populations (Chapter 20; Slakkin 1970; Roughgarden 1972; Lande 1976).

An alternative to the breeder's equation for predicting selection response was proposed by Alan Robertson (1966a) in a very opaque paper on the culling process in cattle. He proposed that the selection response in a trait could be expressed as the covariance between the breeding value of that trait and relative fitness, $R = \sigma(A_z, w)$. As this expression was based on an extension of **Fisher's fundamental theorem of natural selection** (which states that the rate of response in fitness is simply the additive variance in fitness; Chapter 6), it is often called the **secondary theorem** (Orr 2009 suggested that Robertson's theorem is actually more fundamental, and that Fisher's theorem follows as a special case). Price (1970) independently suggested a completely general covariance-based expression for the response to *any* system of selection (Equation 6.8). While both the Robertson and Price results are widely used in evolutionary biology (Chapters 20 and 22; Frank 1995), they have only recently made their way back into breeding, most notably in the analysis of associative effects (Chapter 23; Bijma et al. 2007a).

Until very recently, most selective breeding in outbred populations was based on **best linear unbiased predictor (BLUP)** selection (Chapters 18 and 20), an approach introduced

by Charles Henderson (1975). In keeping with the focus on breeding values seen in Robertson's secondary theorem, Henderson noted that one can significantly improve the estimate of individual breeding value by considering *all* of the known relatives in a sample. This is accomplished using linear mixed models (Chapters 19 and 20; LW Chapters 26 and 27) to return BLUPs of individual breeding values. The individuals with the highest BLUPs are then chosen as the parents for the next generation, with the expected selection response simply being the average breeding values of the selected parents. As this same approach yields a **restricted maximum likelihood** estimator (or REML estimate) of the additive-genetic variance, evolutionary biologists realized that mixed models could be used to estimate trait heritabilities in natural populations using a set of known relatives (Shaw 1987; Cheverud and Dittus 1992; Kruuk 2004). As detailed in Chapter 20, there was some initial overreach in the early 2000s in an attempt by evolutionary biologists to use BLUPs to assess direct targets of selection, but the BLUP framework still remains a powerful tool for evolutionary analysis.

The most recent chapter in the development of breeding methods is the use of dense marker information. Initially motivated by the apparent ubiquity of QTLs of major effects, breeders flirted with **marker-assisted selection (MAS)** schemes, wherein a few well-chosen markers were used to augment phenotypic information when selecting individuals (Lande and Thompson 1990). However, in response to a renewed appreciation for the infinitesimal model, molecular-based breeding has moved to **genomic selection** (Meuwissen et al. 2001), wherein mixed models are used to assign weights to tens of thousands of SNP-tagged segments that span the genome. The simplest variant of this approach recovers BLUP selection (Chapters 13 and 19), but now with the A matrix of all pairwise relationships between individuals in the sample being replaced by a marker-based estimate of the fraction of shared markers (**G-BLUP**, for genomic-BLUP). With the increasing availability of dense SNP markers (and now whole-genome sequences) for even nonmodel organisms, marker-based estimations of relationships are now widely used for REML estimates of additive variances, and also (to a lesser extent) for association mapping, in natural populations (Chapter 20).

Detecting Selection in Natural Populations

Given the biometrician focus on evolution acting on continuous variation, early attempts to measure natural selection in the wild predated Fisher's (1918) treatment of complex trait genetics. Although this focus on detecting selection on metric traits was entirely concerned with the phenotypic level, it marked the beginning of evolutionary quantitative genetics. Two early such attempts were particularly noteworthy. The first was due to Weldon (1895, 1899), who examined morphological features in adult and juvenile crabs (*Carcinus maenas*) in Plymouth Sound and in the Bay of Naples, generating data that enticed Karl Pearson (1903) to start a serious consideration of the statistics of selection. The second was the classic study by Herman Bumpus (1899). During a severe ice storm in February 1898, Bumpus collected 136 immobilized house sparrows (*Passer domesticus*) from several locations around Providence (in the US state of Rhode Island). Of these, only 72 survived. For all 136 individuals, Bumpus recorded sex and male maturity state (adult vs. juvenile) and presented meticulous measurements of their body weight and eight skeletal features. As reviewed in Chapter 30, Bumpus's results continue to be examined today, illustrating the power of carefully collected, and widely disseminated, datasets.

While numerous studies during the early to mid-1900s focused on the fitness consequences of discrete traits, such as various color morphs (reviewed by Endler 1986; Reznick and Travis 1998), the explosion of studies on fitness surface estimation (obtaining an expression for $W(z)$, the expected fitness of an individual with trait value z) began with the method proposed by Lande and Arnold (1983), which built on Pearson (1903). As detailed in Chapters 29 and 30, Lande and Arnold proposed fitting a quadratic regression of fitness as a function of the phenotypes of candidate traits. Although purely phenotypic in nature, this approach has deep connections, not only with Pearson's work, but also with the index-

selection results of Smith (1936) and Hazel (1943). While most estimates of the nature of selection on a particular trait (or combinations of traits) focus on morphological characters, nothing about this approach prevents it from being applied to *any* quantitative trait. Hence, measures of physiological features (such as the levels of target hormones) or genomic-level characters (such as levels of RNAs, proteins, and metabolites) all hold as appropriate traits. The only challenge (which is far from trivial) is their measurement in a meaningful way in natural populations where individual fitnesses have been assessed.

Both Lande-Arnold fitness estimation, and the subsequent methods it spawned, require data on individual fitness, which is often difficult to collect (Chapters 29 and 30). A related question of deep evolutionary interest is whether an observed pattern of trait divergence (either between populations or over time within a single population) is due to selection. Such questions are typically framed using the null hypothesis of whether this observed pattern is consistent with drift alone. The roots of many of the current approaches for testing patterns of trait divergence trace back to Lande (1976), in which he explored whether an observed amount of phenotypic divergence in a specific trait in the fossil record of a species exceeded that expected by drift alone. Unlike methods that estimate whether a particular trait is *currently* under selection, Lande's (1976) approach does not require estimates of individual fitness, but does require models for the expected change in the trait over time under drift. Chapter 12 examines a number of such approaches for constructing null models, be it for a fossil sequence, the trait divergence between extant populations, or genomic data. Given the reckless abandon with which some biologists suggest adaptive scenarios, null models are unquestionably required to judge the significance of a particular pattern of trait divergence. This is especially true for functional-genomic features, such as the levels of mRNA expression among sibling species (Chapter 12).

A final approach for detecting selection, which follows as one of the fruits of the genomic revolution, involves tests for selection on specific genomic locations (Chapters 8–10). These tests have the advantage of being trait-independent (no specific candidate traits are assumed). Further, contemporaneous fitness data are not needed, and indeed such genomic signatures of selection can be a consequence of a past history (perhaps long ago) of selection that may not be presently ongoing. The downside of these purely marker-based approaches is that it may be rather difficult to associate a genomic region with a change in a specific trait, leaving the target of selection unclear.

THE THEORETICAL FOUNDATIONS OF EVOLUTIONARY BIOLOGY

Lewin's maxim that “there is nothing more practical than a good theory” (Lewin 1943; McCain 2015) is highly apropos for evolution. The basic idea of evolution is so inherently simple—organisms change over time from preexisting ones—that it appears to be the ultimate play-at-home game. Despite the care with which most biological studies are presented, often the evolutionary comments are wildly speculative, with little apparent grounding in modern theory. Even worse are the sporadic, and usually rather forceful, comments that routinely appear in the (nonevolutionary) literature that suggest something is woefully wrong, and/or missing, in the current theory. We conclude our introductory remarks by offering some commentary on these issues.

The Completeness of Evolutionary Theory

Without a theoretical framework, science is simply a fact-establishing enterprise. The emergence of facts from consistent observations is progress, but theory provides a mechanistic explanation of the material basis of facts. A theoretical framework also provides the basis for making predictions in areas where observations have not previously been made, not simply based on statistical extrapolation but rather on arguments from first principles. Mathematical theory is particularly desirable, as it allows the development of logical arguments from well-defined assumptions, whereas verbal theorizing can easily go awry in the analysis of

complex systems. Fortunately, evolutionary biology has a well-established framework of principles from which to draw.

As noted above, starting with Fisher's seminal 1918 paper, which both founded the field of quantitative genetics and established a number of principles upon which modern statistics relies, the field of population genetics has experienced a rich history. Indeed, the field of theoretical population genetics, which is at least as well-grounded as any other area of quantitative biology (including biophysics), forms the formal foundation for all of evolutionary theory.

The earliest period of theoretical development (1918–1950) substantially preceded any knowledge of the molecular basis of genes. Starting in the 1950s, dramatic new findings in the field of molecular genetics emerged, including the discovery of DNA as the ultimate genetic material, the mechanisms of recombination, the basic structure of genes and their component parts, the central roles of transcription and translation (and downstream modifications), the existence of mobile genetic elements, and various nuances related to epigenetic inheritance. Yet none of these discoveries led to any alteration in the basic structure of evolutionary theory. Such robustness in the face of revolutionary changes in our understanding of genetics at the molecular level speaks volumes about the generality of our current theoretical framework. Important specific applications may remain to be developed, but the theoretical foundations of evolutionary biology are remarkably accepting of new observations.

Nonetheless, periodic claims are made that the field of evolutionary biology is in a phase of upheaval, with the harbingers of such messages seldom offering the much-needed solution to the (in their view) previously unappreciated problem. Without exception, these episodes have gone badly. Perhaps the most notable of these excursions was Goldschmidt's (1940) argument that large changes in evolution are products of macromutations with co-ordinated developmental effects (a flashback to the Mendelians), and Lysenko's rejection of natural selection in favor of the inheritance of acquired characteristics, which led to a decades-long demise of genetics in the Soviet Union.

One of the more recent alarmist exercises involves a tiny but vocal community clamoring for an “extended evolutionary synthesis” (EES), and claiming that “The number of biologists calling for change in how evolution is conceptualized is growing rapidly,” and that there is currently a “struggle for the very soul of the discipline” (Pigliucci and Müller 2010; Shapiro 2011; Laland et al. 2014, 2015). It is interesting that the list of individuals engaged in this struggle appears not to extend beyond the authors themselves, and the level of discourse is reminiscent of the distant “bean-bag genetics” diatribe of Mayr (1959, 1963), which was promptly disemboweled by Haldane (1964). No glaring errors in contemporary evolutionary theory have been pointed out by the EESers, no evidence of familiarity with current theory has been provided, and no novel predictions have been offered (Welch 2017). There is only a warning that once qualified theoreticians come on board, the revolution will begin.

One of the more dramatic claims is that the discovery of various epigenetic effects amounts to a game-changer in evolutionary biology, imposing the need to revamp our general understanding of inheritance and its evolutionary implications (Jablonka and Lamb 2005; Caporale 2006; Shapiro 2011). Highlighted phenomena include base modifications on DNA, histone modifications on nucleosomes, and mechanisms of gene regulation by small RNAs, all of which can, in principle, have transgenerational effects without direct changes at the level of genomic DNA. Advocates of epigenetic inheritance have generally argued that such phenomena respond in beneficial ways to environmental induction, which then allows for an acceleration in the rate of adaptive phenotypic evolution. This echo of Lysenkoism, in effect, resurrects the concept of the inheritance of acquired characteristics.

The logic underlying the entire subject of epigenetic contributions to evolution has been masterfully dismantled by Charlesworth et al. (2017), and here just two points are made. First, to appreciate the implausibility of a long-term contribution of nongenetic effects to phenotypic evolution, one need only recall the repeated failure of inbred (totally homozy-

gous) lines to respond to persistent selection, with many such experiments dating back to the beginning of the twentieth century (Lynch and Walsh 1998). The absence of genetic variation does not imply an absence of environmental or epigenetic sources of phenotypic variation, yet there is no permanent response to selection within populations unless there is variation at the DNA level.

Second, with respect to the claim that evolutionary theory is incapable of addressing the matter of epigenetic inheritance, one need only turn to models for the inheritance of environmental maternal effects developed well before the discovery of the molecular basis of any epigenetic effects. Existing theory readily demonstrates that variance in maternal effects can indeed contribute to the response to selection, but unless such effects reside at the DNA level, the response is bounded, owing to the fact that transgenerational effects are progressively diluted out (Chapters 15 and 22). The response to selection on environmental (epigenetic) maternal effects is also transient, and it decays away if the selective pressure is eliminated. Finally, if epigenetic effects are sufficiently stochastic, they will reduce, rather than enhance, the response to selection, owing to the reduction in the correspondence between genotype and phenotype.

A persistent claim to novelty by the EESers is the idea that the environmental induction of a trait in a novel situation can enhance the exposure of the trait to selection, thereby magnifying the response to selection. This, however, is by no means a new insight. Rather, such effects are central to the concept of genotype \times environment interaction, the theory of which dates back decades. Indeed, breeders have long exploited this concept to determine the optimum environmental setting in which to select for particular phenotypes. Thus, the idea that evolutionary theory needs to be remodeled to account for phenotypic plasticity is also without merit, and simply reflects a basic lack of familiarity of the existing evolutionary quantitative-genetics literature. Hopefully, the material presented in the following pages will provide some aid in this regard.

Another argument raised against the adequacy of evolutionary theory involves the idea that the field is incapable of dealing with the possibility that evolution “is guided along specific routes opened up by the processes of development” (Laland et al. 2014). This claim again belies a lack of awareness of long-existing evolutionary theory. Although models concerned with the role of mutation in phenotypic evolution commonly assume a symmetrical distribution of mutational effects, it is relatively easy to modify any quantitative-genetic model to allow for biased mutational effects. Indeed, the classical house-of-cards model has a structure in which mutation bias is intrinsic—here there is a fixed set of possible allelic effects, so there is always a directional bias to mutation unless the mean genotypic value is positioned at exactly the intermediate location along the axis of possibilities. As for the role of developmental bias in evolution, one need only consider the substantial theory devoted to multivariate evolution that is explicitly focused on pleiotropy and the ways in which this influences the evolutionary trajectories of complex traits (e.g., Jones et al. 2003, 2007, 2012).

Most remarkable is the EESer claim that the key flaw of contemporary evolutionary theory is the assumption that change in allele frequencies is a necessary component of the response to selection, their counterview being that “the direction of evolution does not depend on selection alone, and need not start with mutation” (Laland et al. 2014). Whereas it has long been appreciated that evolution can, and sometimes does, occur in the absence of selection (for example, by random genetic drift of neutral traits), we await an explanation as to how any sustained form of evolution (aside from cultural evolution) can occur in the absence of genetic variation. Technically speaking, evolution can occur in the absence of allele-frequency change, but only via changes in the form of allelic associations across loci (e.g., via LD, which necessarily implies *genotype*-frequency change), and this does not appear to be what the dissenters have in mind.

Finally, we note that unlike the laws of physics and the features of chemical elements, biology is subject to historical contingencies, and for virtually every set of general observations, one can find some kind of exception. Aficionados of such exceptions are sometimes tempted to claim that their observations are sufficient to dismantle the previous theoretical

framework for broadscale patterns. However, more often than not, a deeper look almost always reveals explanations for exceptions that are fully compatible with the rules of life. The discovery of mitochondrial DNA and nuclear epigenetic effects did not alter our basic understanding of maternal effects, and the discovery of transposable elements did not alter our appreciation of the mutational process. Such observations simply provided a deeper molecular explanation of modes of production of phenotypic variation. Because evolution is a stochastic process, no theoretical framework can ever be expected to predict the exact trajectories of evolution at the molecular, cellular, or developmental levels. As Haldane (1964) pointed out, if population genetics could make such specific predictions, it would not be a branch of biology—it would be the entirety of biology.

Far from providing a weak and/or incomplete caricature of evolving genetic systems, population- and quantitative-genetic theory has provided powerful, general, and sometimes unexpected mechanistic explanations for trait variation and phenotypic evolution. We note several of these in Table 1.1, and emphasize that few of these issues would have ever been revealed and/or resolved with simple verbal arguments. Indeed, as noted above, it was Fisher's (1918) paper that rescued the previously verbalized theory of evolution from the high seas of obfuscation. Having resisted quantitative thinking derived from first principles in genetics, developmental biology, from which many of the pleas for novel theory emanate, remains in many respects in a pre-population-genetics mode of confusion.

Although our specific railing on the EES ideology may be offensive to some or seem like pandering to trivia to others, the implication that a century's worth of theoreticians have been woefully misled is a gross misrepresentation of the facts. Repeated peddling of this view by individuals with no intention of confronting the facts belies reality. As outlined in Table 1.1 and expanded upon in the following chapters, the structure of evolutionary theory that has been developed over the past century has, to this point, found no boundaries in terms of applications, has not been challenged by novel findings in the molecular era, and continues to make predictions that are bolstered by empirical observations. While conflict and cooperation are the engines that keep science running, conflict engineered under false pretenses and incessantly repeated with no evidence is generally motivated by nonscientific goals.

Nonadaptive Hypotheses and our Understanding of Evolution

Darwin's and Wallace's grand views of selection as a natural force for the emergence of adaptive change marked a key moment in the history of biology. So convincing were they, and their popular-science writing disciples such as Dawkins, that most people (including most biologists) view all aspects of biology to be necessary products of natural selection. As it channels the entire field away from a landscape of unbiased study, this dogmatic adherence to the unbounded power of natural selection constitutes one of the most significant problems in evolutionary science.

Whereas natural selection is one of the most pervasive forces in the biological world, it is not all-powerful. As is evident throughout the following pages, the genetic paths open to exploitation by selection are strongly influenced by another pervasive force—the noise in the evolutionary process imposed by random genetic drift which is caused by both the fact that there are finite numbers of individuals within populations and the physical linkage of different nucleotide sites on chromosomes. If the power of selection is weak relative to that of drift, as is often the case at the molecular level, evolution will proceed in an effectively neutral manner. Biased mutation pressure can also play a role here if it is sufficiently strong relative to selection, steering evolution in the direction of mutation bias.

Even if selection were to be pervasive, in order to understand the degree to which natural selection molds the features of populations, it is essential to know what to expect in the absence of selection. It is for this reason that neutral models have been repeatedly exploited in population- and quantitative-genetic analyses. Under such models, random genetic drift, mutation, and recombination are the sole evolutionary forces, with the resultant formulations then providing null models for testing for natural selection. As noted above, such

Table 1.1 A few key areas in evolutionary biology where the mathematical/statistical theory of population and quantitative genetics has enhanced our understanding of the mechanistic basis of trait variation and provided novel predictions. This list is by no means complete, and many of the references are simply exemplars, rather than a full literature citation.

models have been particularly useful in attempts to understand long-term phenotypic changes recorded in the fossil record, where seemingly dramatic changes that have elicited selection arguments are found to be less than impressive when evaluated in the proper context of drift and mutation (Lande 1976; Lynch 1990; Chapter 12). Neutral models are particularly easy to develop for DNA-level features, as mutation can be explicitly defined in terms of the possible nucleotide substitutions. Although neutral models can become more challenging in the case of more complex traits, where the baseline features of mutations can be more difficult to define, this is not a justification for ignoring the matter.

Some investigators (Pigliucci and Kaplan 2000; Hahn 2008) have suggested that so much evidence for selection has emerged that we should abandon the use of neutral theory, with Hahn going so far as to argue that “the implications of our continued use of neutral models are dire,” and “can positively mislead researchers and skew our understanding of nature.” No one argues that selection is unimportant, but the proposition of a selection theory as a null model for hypothesis testing has no logical basis. When properly constructed, neutral models make very explicit predictions, and without such null expectations, arguments for the role of natural selection in evolution are reduced to qualitative hand-waving. Formal rejection of a neutral model, along with measurement of the deviations between observations and expectations, yields a deeper and more defensible understanding of evolutionary processes.

The second problem with invoking the need for a “selection theory” as the null model is that one can concoct a selection argument for essentially any observed pattern, leaving no room for falsifying the null hypothesis of the universal power of selection. If one form of selection does not adequately fit the data, then one can try another, and failing that, still another, but without ever abandoning the pan-selection view. Fluctuating selection (wherein the direction of selection wanders around a mean of zero) can even yield a population-genetic history that closely mimics the expectation under random genetic drift alone, with no discrimination between models being possible without a knowledge of effective population sizes.

A third problem with criticisms of neutral theory is the reliance on incorrect assumptions to reach questionable conclusions. For example, Lewontin (1974) long ago suggested that the fact that standing variation in natural populations is only weakly associated with effective population size (N_e) suggests a violation of the neutral theory, as standing levels of variation at silent sites in diploid populations should scale with $4N_e u$, where u is the mutation rate per nucleotide site (Chapter 4). Although this argument continues to be made (Hahn 2008), it ignores the fact that mutation rates evolve to be inversely correlated with N_e , which naturally leads to weak dependence of standing variation on N_e (Lynch et al. 2016). In this particular case, the discrepancy between data and the neutral theory is greatly diminished once the appropriate null model is constructed.

The call for a selection theory of evolution, like the call for an extended evolutionary synthesis, has not resulted in any theoretical upheaval. No offering of what a novel theory of selection might be has been presented, and none is likely to emerge for the very simple reason that we already have such a theory. From the very beginning, population- and quantitative-genetic theory has fully embraced selection as a central force in evolution. Indeed, the numerous accomplishments of selection theory are summarized, explained, and celebrated in the remainder of this book.

OVERVIEW AND PATHWAYS THROUGH THIS VOLUME

Given the scope (and length) of this volume, we conclude our introduction by providing a brief roadmap and overview of the material presented in the following chapters. We envision the users of this book to be a very diverse community: animal, crop, and tree breeders; evolutionary biologists, human geneticists, and population and statistical geneticists. Given this eclectic audience, our challenge has been to present both the necessary material a user

Table 1.2 Suggested topic-specific pathways through this book.

Topic	Suggested Chapters
Basic population genetics	2–5, 7–10, 27, Appendix 1
Applied breeding	3, 6, 13–19, 21–23, 25–26, Appendix 5
Evolutionary quantitative genetics	6, 13–20, 22, 27–30, Appendices 5, 6
Population genetics of selection response	5–10, 24–28, Appendix 1
Detection of selection with genomic data	2–5, 7–12, 27, Appendices 1–4

might be searching for, while also highlighting connections with other areas that may not initially have been considered relevant.

We assume that the reader has some basic knowledge of the foundations of the genetics of complex traits, which is covered in our first volume (Lynch and Walsh 1998). Given that we extensively refer back to this volume, for brevity it is denoted throughout the current volume by LW. While LW focused on the genetics of complex traits, the current volume examines the forces behind the evolution of such traits: drift, mutation, recombination, and selection. Our treatment of the field will conclude in our final (third) volume, which largely deals with multivariate traits, plus a few specialized, but important, topics (such as genotype \times environment interactions, inbred-line development, and breeding for heterosis). Table 1.2 offers some suggested pathways through this volume, and our overview below is organized by the major sections of this book.

Evolution at One and Two Loci

The next nine chapters develop the population-genetic theory that underpins most analyses of the evolution of quantitative traits, serving as the foundation for the remainder of this volume. Chapter 2 begins this excursion by examining drift and mutation-drift interaction, including important concepts such as the infinite-sites and infinite-alleles models of sequence evolution and the extremely powerful tool of the coalescent for treating drift.

Chapter 3 introduces the concept the genetic effective size of a population. One of the major extensions of this powerful idea over the last few decades was the realization that different regions of the genome likely experience *different* effective population sizes. This is the Hill-Robertson effect: selection acting on a particular locus reduces, perhaps quite dramatically, the effective population size experienced by linked sites. An unresolved debate is whether the majority of this interfering selection simply involves the removal of new deleterious mutations (background selection) or the fixation (or at least increase in frequency) of newly-favorable alleles (hitchhiking and selective sweeps).

Chapter 4 examines the relative strengths of the nonadaptive forces of evolution: mutation, drift, and recombination. All three of these forces can vary substantially among phylogenetic lineages and therefore can substantially influence modes of evolution. Genomics has painted a much fuller picture of these processes than was present even a decade ago, and we review results from numerous whole-genome sequencing studies.

Chapter 5 covers the theory of one and two-locus selection, concluding with a derivation from population-genetic principals of Lush's classic breeder's equation, $R = h^2S$ (which is the foundation for much of current selection-response theory). We also bridge population and quantitative genetics by showing how selection on a trait translates into the nature and amount of selection on underlying loci.

Chapter 6 is essentially the gene-free counterpart of Chapter 5, as it examines general theories of selection response, such as Price's equation, Fisher's fundamental theorem, and both versions of Robertson's secondary theorem. Price's equation is a general expression for any type of selection response, expressed in terms of variances and covariances, which we use to examine the robustness of the breeder's equation.

Chapter 7 focuses on the interactions of drift and mutation with selection, highlighting

some of the less intuitive, and sometimes counterintuitive, features that can arise when these forces interact. Together with Chapter 5, the machinery developed in this chapter is used extensively in Chapters 24–28 to build the population-genetic theory of the selection response of a quantitative trait.

Chapters 8–10 apply the concepts developed in these early chapters in the search for signals of both recent and past selection in genomic data. Chapter 8 develops the theory of selective sweeps, namely the nature of genomic signatures generated by relatively recent selection events. Chapter 9 relates these results to the myriad of tests of very recent (or ongoing) selection using a sample from a population (polymorphism-based tests). Chapter 10 examines approaches using divergence data (differences between two, or more, distantly related populations or species) to search for repeated episodes of selection over a genomic region. Genomic-based searches for selection are an extremely fashionable area of evolutionary and human genetics, and, when handled appropriately, offer important tools for breeders searching for genetic footprints from domestication events. Chapters 9 and 10 are rather detailed, as numerous tests have appeared in the literature, and our goal is to provide the reader with an overview of all relevant approaches. Both of these chapters also stress the important point that all such methods have critical, indeed often fatal, flaws raising caveats to consider when applying these approaches to genomic scans for selection.

Drift and Quantitative Traits

Paralleling our development of population-genetics theory (where we first considered the roles of drift and mutation before examining the impact of selection), before we turn to selection acting on traits, Chapters 11 and 12 examine trait evolution under drift and mutation alone. Chapter 11 examines the impact of drift and mutation on the additive-genetic variance within a population. In order to fully address this issue, it also develops the rather intricate covariances between relatives that arise under general schemes of inbreeding.

Chapter 12 examines the among-population divergence in trait means under drift and mutation. While this topic may seem rather esoteric to some, especially to those with functional-genomics data, this theory is actually very relevant. Modern omics data (such as expression levels of RNAs, proteins, or metabolites) are very much quantitative traits, influenced by (potentially) numerous genes and the environment. Chapter 12 develops a number of tests for whether an observed pattern of change (be it between a set of natural populations, a temporal sequence of morphological phenotypes in the fossil record, the pattern of allele-frequency change over a set of QTL or GWAS-linked markers, or differences in gene-expression levels between species) is consistent with drift. Such drift-based models provide critical null models for tests of selection-driven divergence.

Short-term Response on a Single Character

The remainder of this volume examines the role of selection in changing the distribution of trait values for a quantitative character. We start by considering the short-term changes in a single trait. By short-term, we mean the first few generations, where selection-induced changes in allele frequencies at underlying loci are sufficiently small to be ignored.

Chapter 13 further explores Lush's classical breeder's equation, $R = h^2 S$, for the expected single-generation change in the mean of a quantitative trait. We examine extensions of this result to a number of settings, including selection schemes based on other estimates of an individual's breeding value beyond just their own phenotypic value (e.g., also using the phenotypic values of relatives). We also introduce the multivariate breeder's equation (which is extensively covered in Volume 3).

Chapter 14 considers truncation selection and the response in threshold traits, wherein a binary (presence/absence) trait results from the transformation of some underlying continuous variable (the liability). We also briefly introduce logistic regression and log-linear models, two approaches for the statistical modeling of discrete quantitative-genetic traits.

Chapter 15 extends of the breeder's equation to scenarios where the selection response in the mean has a transient component that changes over time. This can occur when additive

× additive epistasis underlies a trait, for dominance in a tetraploid species, or when there are environmental effects that are partly shared between parent and offspring. The last scenario serves as a brief introduction to maternal effects, which are more extensively covered in Chapter 22 (and especially in Volume 3). The key concept of Chapter 15 is that such transient components of response decay away under random mating when selection is stopped, leaving a reduced permanent response in the mean given by an appropriate interpretation of the breeder's equation.

Chapters 13–15 are entirely concerned with predictable changes in the mean, while Chapters 16 and 17 examine the impact of short-term selection on the variance. Chapter 16 examines Bulmer's theory (and its extensions) on the role of gametic-phase disequilibrium (or linkage disequilibrium [LD] for brevity, even though results also apply to unlinked loci) in changing the additive-genetic variance. The key concept is that the additive variance can be decomposed as $\sigma_A^2 = \sigma_a^2 + d$. The genic variance, σ_a^2 , is entirely a function of the allele frequencies and represents the additive variance in the absence of LD. The disequilibrium contribution, d , is generated by LD, and eventually decays to zero (via recombination) under random mating when selection is relaxed. We use Bulmer's result to examine both the change in σ_A^2 under directional selection and the change in σ_A^2 when selection is largely focused on the population variance (e.g., stabilizing or disruptive selection).

Chapter 17 examines the short-term change in another variance component, the environmental variance, σ_E^2 . A relatively recent appreciation is that σ_E^2 can vary over genotypes, and, as such, can potentially respond to selection. We examine different parameterizations for modeling σ_E^2 in terms of heritable components (i.e., breeding values for environmental variances), and the expected selection response under directional, as well as stabilizing and disruptive selection.

Chapters 18 and 19 cover the analysis of selection experiments, including the very important case of assessing the selection response (e.g., progress) in a breeding program. Chapter 18 reviews least-squares models of analysis, while Chapter 19 examines more recent approaches based on mixed-models (i.e., BLUP) and Bayesian methods (Appendices 2 and 3).

Chapter 20 examines the expected selection response in natural populations. Here, a significant confounding factor is the inability to precisely know the target of selection. We examine both BLUP-based approaches and those based on Robertson's secondary theorem (introduced in Chapter 6), the latter focusing on the nature of selection acting directly on the breeding value of a trait. A key finding is that numerous traits measured in natural populations show at least moderate heritabilities and apparently experience strong selection (so that $h^2 S$ is fairly large), yet show little to no response. We examine a variety of reasons for the apparent failure of the breeder's equation in these settings.

Selection in Structured Populations

Chapters 21–23 conclude our treatment of short-term response on a single trait, considering situations other than mass selection (wherein individuals are selected based on their phenotypic value alone) under random mating. Chapter 21 examines family-based selection schemes, wherein information from families—such as family means over a set of environments or deviations within a given family—are used in selection decisions.

Chapter 22 introduces the important, and much underappreciated, topic of associative effects. Here, individuals interact, and the phenotype of a focal individual is a function of both its own genetic and environmental values, as well as the values of the interacting individuals. This generates a selection response on both a direct and a social (or associative) component, and can lead to situations wherein selection to improve a trait actually results in a reduction in the mean. For example, when one selects the best individuals for egg production in a cage, often these individuals are the most aggressive (and hence able to garner the most resources). While they may have superior genes that directly influence egg production, they also have genes that reduce production in other cage members. A cage full of such birds can easily show a significant *reduction* in egg production. Associative effects

also allow us to model maternal effects (as a special case), and place the concepts of kin and group selection into a single, unified, framework that involves components that can be estimated in standard breeding designs.

Chapter 23 concludes our discussion of structured populations by considering the impact of inbreeding on selection. This theory forms the basis for much of modern plant breeding. We also review some of the theory on the evolution of selfing rates in monoecious species.

Population-genetic Models of Trait Response

Chapters 13–23 consider short-term response, wherein either allele-frequency change is sufficiently small to be ignored, or is modified in very predictable ways, largely independent of the selection scheme (such as the decline in σ_A^2 under drift). Building on the results from Chapters 5 and 7, Chapters 24–28 examine the theory of long-term selection response in the face of significant allele-frequency change. Long-term response is far less predictable than short-term response. Indeed, it is entirely *unpredictable* from knowledge of just the base population genetic variances alone.

Chapter 24 examines the classical infinitesimal model, wherein a large number of loci, all of small effect, underlie a trait. We then consider departures from this basic model, including the continuum-of-alleles model, and the impact of LD and allele-frequency change in driving the distribution of breeding values away from a normal (Gaussian) distribution. Parts of this chapter are fairly technical.

Chapter 25 examines the deterministic theory of long-term response, as well as models with a major gene and background polygenes. In addition to theory (largely based on results from Chapter 5), we also examine the empirical data on long-term selection, and review the common features seen in many experiments.

Chapter 26 examines the impact of adding drift and mutation to the deterministic results from Chapter 25. In particular, we develop Robertson's classical result that the expected long-term selection response (in the absence of mutation) is usually bounded above by the product of $2N_e$ (twice the effective population size) and the response in the first generation. This key result implies that a higher short-term response (which results in a reduced N_e) comes at the expense of a reduced long-term response.

Chapter 27 examines a much longer-term view of selection response by considering adaptive walks, namely the sequence of successive fixations during adaptation over evolutionary time scales. One exciting aspect of this work is that some of the theory (which is rather technical and detailed in places) can be tested in microbial systems, and we review some of these empirical results, comparing them with their theoretical expectations.

Chapter 28, perhaps the most technical chapter in this volume, examines the extensive population-genetics modeling that has been performed on possible explanations for the maintenance of quantitative-genetic variation. Here, we are in the rather embarrassing position of having a wealth of highly detailed models, none of which can account for the data given our current understanding of strengths of selection in natural populations and details of the underlying genetics (number of loci and average mutation rates).

Measuring Selection on Traits

We conclude with the estimation of individual fitnesses in natural populations and the search for specific traits, or trait-combinations, currently under selection. In many ways, these last two chapters are the complement of Chapters 9 and 10. The tests from these previous chapters are trait-independent and require only sequence information, while the methods in Chapters 29 and 30 require estimates of the fitnesses of individuals (which are far from trivial to obtain), as well as the phenotypic values of candidate traits. The search for traits under selection in natural populations is a major focus of much of evolutionary and ecological genetics.

Chapter 29 focuses on the measurement of fitness, and how to partition these estimates across specific episodes of selection. A key concept is the opportunity for selection, I , the

variance in relative fitness. This sets an upper limit on the maximum amount of change in any particular trait over a single generation of selection. We also examine measures of sexual selection, differences in the ability to attract mates. We then turn to estimation of, and various descriptive statistics for, the fitness surface, $W(z)$. This surface describes the expected fitness of an individual whose phenotypic value is z . Most of the methods for estimating fitness-trait associations assume some simple distribution, such as a normal, binomial, or Poisson for fitness (total number of offspring left by an individual). In reality, fitness distributions are expected to be very complex, in part because we expect them to have a large point mass at zero, representing the fraction of individuals leaving no offspring. We conclude by introducing the important Aster model approach, which allows for far more realistic distributions of fitnesses to be constructed.

Chapter 30 extends the univariate analysis of fitness-trait associations to multivariate settings and examines the resulting geometry of multivariate fitness surfaces. We also review the empirical data on the strength of selection in natural populations, introduce path-analytic models for the analysis of selection, and discuss the estimation of selection that occurs on levels above the individual (such as on groups or populations).

Appendices

Our six appendices introduce and review important mathematical and statistical tools used throughout this volume. Appendix 1 reviews diffusions, a class of approximations from probability theory widely used in population genetics to handle complex models with random features, notably the interaction of drift and selection.

Appendices 2 and 3 introduce, respectively, Bayesian methods and the Markov Chain Monte Carlo (MCMC) approaches used to obtain their resulting posterior distributions. Bayesian methods are widely applied in genetics, in large part because of their ability to fully account for all the potential sources of uncertainty when estimating model parameters. The resulting models are analytically rather complex, but with the development of computer resampling methods (MCMC approaches), they can be analyzed in rather straightforward ways. Bayesian methods are ideal for handling the high-dimensional datasets generated by genomics, in which massive numbers of features are measured on a much more modest number of actual samples (e.g., 30,000 measures of gene expression on, say, 100 individuals).

Appendix 4 examines several aspects of multiple comparisons, moving beyond simple Bonferroni corrections to the concept and application of the **false-discovery rate**. The latter is a powerful alternative to the more classical stringent control of experiment-wide type I error, as in genomic studies, we *expect* numerous tests to reject the null, and our concern is more about the quantification of those we accept (**discoveries**) rather than trying to control against *any* false positives (the Bonferroni setting). It also examines another powerful multiple comparison setting, **meta-analysis**, the comparison of results over a large number of studies, showing how to place this into a mixed-model framework.

Appendix 5 presents useful results from matrix algebra, and in particular, the geometry of a matrix, such as eigenstructure and matrix decompositions. While these methods are used throughout the book, they are especially important when describing the curvature of a multivariate fitness surface (Chapter 30).

Appendix 6 concludes with a few brief results on the calculus of matrix and vector derivatives.

Volume 3

The advanced reader might have noticed that a number of important topics are not covered in this volume. As mentioned at the start of this chapter, our treatment of selection response on quantitative traits concludes in Volume 3, which covers important topics in applied breeding such as the development and selection of pure lines and selection programs for hybrid breeding. The bulk of Volume 3, however, is multivariate, examining multivariate selection response in detail. We consider both the change in the mean vector and in the G

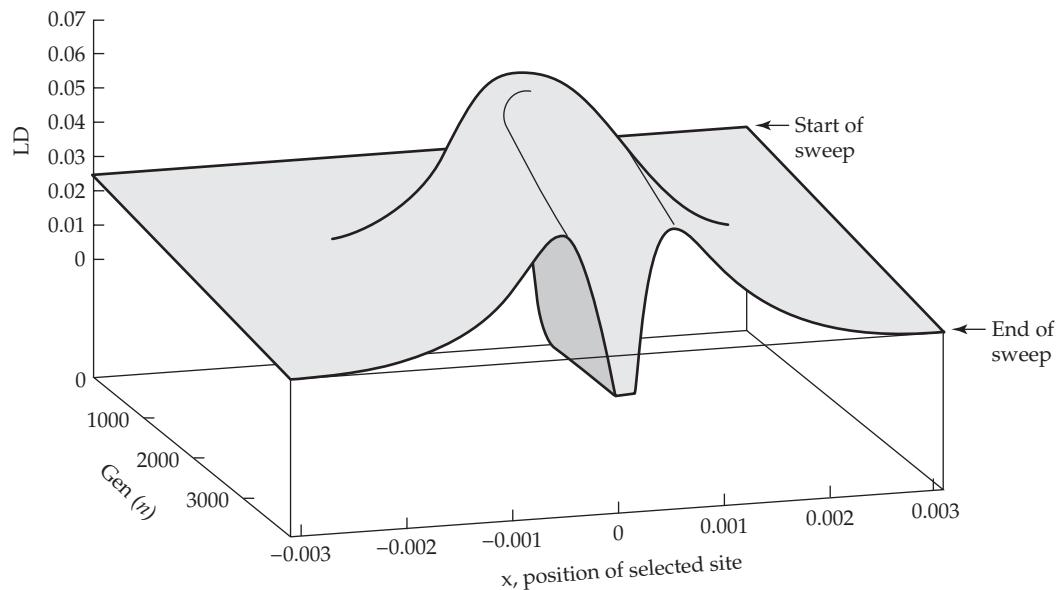

matrix of the additive-genetic variances and covariances for the vector of traits of interest and examine methods for comparing the stability of \mathbf{G} over populations. We conclude with a variety of applications of multivariate methods, such as the theory of index selection, BLUP and genomic selection, dealing with genotype \times environment interactions, and selection on longitudinal traits (those whose phenotypes change over time, such as a growth curve or milk yield). The latter are often called function-valued traits, and can they be modeled by random-regressions which is an extension of BLUP methodology.

Notation

Finally, we need to briefly comment on the bane of almost every theoretical treatment: notation. One of our greatest challenges in trying to forge a cross-disciplinary synthesis spanning the full breadth of quantitative genetics was dealing with the considerable amount of overlapping notational symbols found in the literature. For example, θ is widely used for very different quantities in different subfields of quantitative and population genetics. While we could have created new notation for the various quantities with overlapping symbols, this would have introduced an additional level of complexity. Hence, we have tried (as much as possible) to follow the common usage in the relevant literature for a given field at the expense of some notational overlap. Hopefully, any slight ambiguity introduced by the recycling of some of the notational symbols across different chapters can be distinguished from the context of the presentation.

II

Evolution at One and Two Loci

2

Neutral Evolution in One- and Two-Locus Systems

Variations neither useful nor injurious would not be affected by natural selection, and would be left either a fluctuating element, as perhaps we see in certain polymorphic species, or would ultimately become fixed, owing to the nature of the organism and the nature of the conditions.

Charles Darwin (Chapter 4, 1859)

Although most of the research in evolutionary biology is focused on issues related to natural selection, the rigor of all such analyses depends critically on our understanding of expected patterns of evolution in the absence of selection. The simple reasoning here is that if we are to have much confidence in any adaptive argument, it ought to be possible to firmly reject a simpler, neutral hypothesis. Thus, prior to exploring various population-genetic models for adaptive evolution, we first embark on a broad overview of neutral models of evolution. The theory underlying such models brings us into immediate contact with the issue of **genetic drift**, a commonly misunderstood factor in evolutionary biology, but which is nothing more than the random fluctuations in allele frequencies that necessarily result from sampling finite numbers of gametes in each generation. The magnitude of such allele-frequency fluctuations increases with decreasing population size, and combined with the input of new alleles by mutation, the incessant stochasticity of the process ensures that populations will evolve even in the absence of selection (Kimura 1983).

Consider, for example, a single heterozygous Bb parent that produces two progeny. There is a 50% probability that one offspring will inherit the B allele and the other the b allele, in which case no net change in allele frequency has been transmitted from parent to offspring. However, there is also a 50% probability that both offspring will inherit the same allele. In extremely large populations, these random changes resulting from gamete sampling tend to average out, leaving the allele frequency in the offspring population very close to that in the parental generation. However, over sufficiently long time scales, the cumulative effects of even small single-generation changes in allele frequencies can become quite pronounced. As we will show, if the time scale of interest (t , in generations) is much less than the average number of reproductive adults in the population (N), random fluctuations in allele frequencies can usually be ignored. This justifies the assumption of an effectively infinite population size as a good first approximation in many applications of population and quantitative genetics. However, for situations in which t is on the order of N or larger, evolution can no longer be viewed as a strictly deterministic process. Rather, any observed evolutionary change must be viewed as one realization of many possible outcomes.

In the following pages, it will be shown that even though finite population size induces stochastic evolutionary change, genetic drift has several *predictable effects*. First, even if mating is completely random, there will still be some long-term trend toward matings among relatives. Because all members of a population must ultimately descend from a narrow ancestral base, the smaller the population size, the greater this tendency will be. Thus, in a tiny **dioecious** (separate-sex) population with a stable adult number of two, all matings must be between full sibs, even though the reproductive pair itself may be a random draw from a larger progeny pool in the preceding generation. It follows that the genetic consequences of finite population size must be similar to those of inbreeding—the average homozygosity at a locus is expected to increase with smaller N , although as noted below, this can be offset in part by replenishment from mutationally derived variation. Second, gamete sampling causes allele frequencies to gradually drift toward zero or one, with the probability of ultimate fixation of any particular allele in the absence of selection being equal to its initial frequency. Third, subdivision of a population into isolated demes

results in allele-frequency divergence among demes. The greater the degree of isolation of the subgroups, the more pronounced this differentiation will be.

This and the following two chapters provide a formal basis for these ideas. We first consider matters of one- and two-locus evolution in the context of a population with an idealized mating system and no influence from selective forces. As we will show in subsequent chapters, such models are often of great utility even when selection is operating, provided that the forces of selection are weaker than those associated with random genetic drift. In addition, such theory provides the underlying logic for the development of molecular-marker methods for estimating the power of mutation, recombination, and random genetic drift. These methods, the subject of Chapter 4, are the primary ways we have of describing the past population-genetic environment. Chapter 3 provides a critical link between Chapters 2 and 4 by demonstrating how results derived under the assumption of an ideal random mating population can be extended to a variety of alternative reproductive systems and population structures. In subsequent chapters, the one- and two-locus results introduced here will be used to develop neutral models for formal tests of adaptive evolution within a genomic region of interest (Chapters 8–10) and for the evolution of quantitative traits (Chapter 12).

THE WRIGHT-FISHER MODEL

Because the number of possible types of population structure is literally infinite (involving, for example, various degrees of local inbreeding, geographic subdivision, and age-specific mortality and fecundity), and temporal variation in population size is also common, it is impossible for us to consider the dynamics of neutral alleles in a fully general sense. Instead, we will focus initially on single finite populations of constant size within which mating is random. Even this simple structure admits to many possible variants, depending, for example, on whether there are separate sexes, whether there is variation in family size, and whether generations overlap. These additional layers of complexity will be taken up in Chapter 3, where it will become clear that, with an appropriate redefinition of the concept of population size, most of the results in the current chapter often still hold.

Perhaps the most frequent description of drift is the **Wright-Fisher model**, whose roots trace to Fisher (1922) and Wright (1931). We assume here a diploid population with a fixed number (N) of **monoecious** (hermaphroditic) adults, random mating (including the possibility of self-fertilization), and discrete generations, and we follow the number ($0 \leq i \leq 2N$) of copies of a given allele. The gamete pool produced by the adults is assumed to be effectively infinite, such that the $2N$ gametes that actually contribute to the next generation can be viewed as being sampled with replacement.

Consider a locus with two alleles, B and b , with neither having a selective advantage with respect to the other. If there are i copies of allele B in generation t , the probability P_{ij} that the number in generation $t+1$ is equal to j follows the binomial distribution. Assuming the Wright-Fisher model, each of the $2N$ sampled gametes has probability $i/(2N)$ of being B and probability $[1 - (i/2N)]$ of being b , yielding

$$P_{ij} = \binom{2N}{j} \left(\frac{i}{2N}\right)^j \left[1 - \left(\frac{i}{2N}\right)\right]^{2N-j} \quad (2.1)$$

where the first term in large parentheses is the binomial coefficient. This expression holds for all possible values of $i, j = 0, 1, \dots, 2N$. Note that throughout we will be referring to a diploid population of size N , which requires $2N$ gametes for replacement; this same expression applies to a haploid population of size N if the 2 is deleted.

Letting \mathbf{P} be the $(2N + 1) \times (2N + 1)$ matrix of all the P_{ij} , the probability distribution of the number of copies of allele B in a population can then be expressed succinctly as

$$\mathbf{x}(t+1) = \mathbf{x}(t) \mathbf{P} \quad (2.2a)$$

where the elements of the row vector $\mathbf{x}(t)$ are the probabilities that the allele is present in $i = 0, 1, \dots, 2N$ copies in generation t . Note that P_{ij} , which refers to the element in row i and

column j in matrix \mathbf{P} , is the probability that a population makes a transition from i copies of B to j copies, conditional on starting at i . If the transition matrix \mathbf{P} remains constant from generation to generation, as it does under the assumptions given previously, Equation 2.2a generalizes to

$$\mathbf{x}(t) = \mathbf{x}(0) \mathbf{P}^t \quad (2.2b)$$

This is an example of a **Markov chain** (considered in more detail in Appendix 3).

When considering a single population starting with an allele frequency of $i/2N$, all of the entries in the initial vector $\mathbf{x}(0)$ are equal to zero, except $x_i(0) = 1.0$ (corresponding to i copies being present). Equation 2.2b then yields the evolution of the probability distribution of allelic copy number over time. That is, the elements of $\mathbf{x}(t)$ denote the frequencies of hypothetical replicate populations at time t that are expected to have exactly i copies of the focal allele. The first ($i = 0$) and final ($i = 2N$) elements of $\mathbf{x}(t)$ are of special interest, as they are **absorbing states**—once an allele becomes **lost** ($i = 0$) or **fixed** ($i = 2N$) in a population, it remains at that state indefinitely (barring reintroduction via mutation or migration). As t increases in Equation 2.2b, all of the interior elements of $\mathbf{x}(t)$ eventually converge on zero, and the sum $x_0(t) + x_{2N}(t)$ converges to one. The ultimate probability of fixation of allele B is given by $x_{2N}(\infty)$, whereas the ultimate probability of loss of allele B (or equivalently, of fixation of allele b) is $x_0(\infty)$.

From the elements of $\mathbf{x}(t)$, it is straightforward to compute the expected allelic copy number, the variance in copy number among replicate populations, the probability of fixation by generation t , etc. This **transition-matrix** approach is exact, but many useful approximations have been developed for it (e.g., Gale 1990; Ewens 2004). Some of these approaches will be discussed later, with a powerful alternative method, the **diffusion approximation**, being covered extensively in Appendix 1. In a diffusion, the focus shifts from copy number to allele frequency.

It should be noted that the Wright-Fisher model, in which all individuals synchronously turn over, is just one of many possible conceptual frameworks for approximating a randomly mating population. For example, Moran (1962) developed a treatment whereby a single random individual is chosen to reproduce at each point in time, with a single random individual then being chosen to die. Because allele frequencies can change by only single steps during each time interval under this scenario, the **Moran model** turns out to be more analytically tractable than the Wright-Fisher model, although it is restricted to haploid populations.

Example 2.1. Consider an initially heterozygous individual Bb in a self-fertilizing line maintained by single-progeny descent. With $N = 1$, the only three possible allele-frequency states in the population are zero, one, or two B alleles. Denoting the initial state of the population by $\mathbf{x}(0) = [0, 1, 0]$, the probability that the population is in states 0, 1, or 2 at some future generation t is given by Equation 2.2b with

$$\mathbf{P} = \begin{pmatrix} 1 & 0 & 0 \\ 0.25 & 0.50 & 0.25 \\ 0 & 0 & 1 \end{pmatrix}$$

Although the numerical values for the elements of \mathbf{P} can be obtained directly from Equation 2.1, for this simple example they can also be arrived at intuitively. For example, the elements in the first row of \mathbf{P} denote the probabilities that the population will be in states $j = 0, 1, 2$ in generation $t + 1$ given that it is in state 0 in generation t . The only nonzero element in this row is $P_{00} = 1$. It is nonzero because the $i = 0$ state is absorbing, i.e., once the population enters this state, it remains there indefinitely.

The probability of being in any particular allele-frequency category in generation t , which follows from Equation 2.2b, is a function of \mathbf{P}^t , so for example,

$$\mathbf{P}^2 = \begin{pmatrix} 1 & 0 & 0 \\ 0.375 & 0.250 & 0.375 \\ 0 & 0 & 1 \end{pmatrix}, \quad \mathbf{P}^5 = \begin{pmatrix} 1 & 0 & 0 \\ 0.48438 & 0.03125 & 0.48438 \\ 0 & 0 & 1 \end{pmatrix}$$

and so on. With the initial vector $\mathbf{x}(0) = (0, 1, 0)$, only the middle row of \mathbf{P}^t is relevant, giving the following table for the progression of the elements of $\mathbf{x}(t)$ over time:

t	BB $x_0(t)$	Bb $x_1(t)$	bb $x_2(t)$
0	0.00000	1.00000	0.00000
1	0.25000	0.50000	0.25000
2	0.37500	0.25000	0.37500
3	0.43750	0.12500	0.43750
4	0.46875	0.06250	0.46875
5	0.48438	0.03125	0.48438
...
10	0.49951	0.00098	0.49951
...
15	0.49998	0.00003	0.49998
...
∞	0.50000	0.00000	0.50000

The first and last elements of $\mathbf{x}(t)$, respectively, denote the probabilities that the line will have become fixed for the B or the b allele by time t . Thus, for this particular case, the line eventually becomes completely monomorphic for either the B or the b allele with equal probability. This meets our intuitive expectations for a neutral locus—in the absence of any directional forces, the two probabilities of fixation are equal to the initial frequencies of the respective alleles.

LOSS OF HETEROZYGOSITY BY RANDOM GENETIC DRIFT

The **sampling variance of an allele frequency** provides one way to succinctly define the stochastic effects of random genetic drift. Consider a large pool of gametes, a fraction p of which carry the B allele, and let $2N$ gametes be randomly drawn to produce a new generation of N individuals. Defining the expected frequencies of genotypes BB , Bb , and bb in the progeny generation by the Hardy-Weinberg proportions p^2 , $2p(1-p)$, and $(1-p)^2$, the expected number of B alleles contained in a random offspring is simply $(2 \cdot p^2) + [1 \cdot 2p(1-p)] + [0 \cdot (1-p)^2] = 2p$. The expected square of the number of B alleles carried per individual is $(2^2 \cdot p^2) + [1^2 \cdot 2p(1-p)] + [0^2 \cdot (1-p)^2] = 2p(1+p)$. Thus, the variance (the mean squared value minus the square of the mean) of the number of B alleles carried by an individual is $2p(1+p) - (2p)^2 = 2p(1-p)$, whereas the variance of the total number of B alleles carried in the offspring generation is N times this, $2Np(1-p)$. Because the frequency of allele B is the number of copies divided by $2N$, the sampling variance of the frequency (a second-order moment) is $2Np(1-p)/(2N)^2 = p(1-p)/(2N)$, which is directly proportional to the heterozygosity (the fraction of Bb individuals in the population) and inversely proportional to the population size. The expression $p(1-p)/(2N)$ defines the dispersion in allele frequency resulting from a single generation of gamete sampling, conditional on allele frequency p in the parental population.

In the absence of any counteracting evolutionary forces, the dispersive effects of genetic drift will continue in each generation, leading to a progressive erosion of population-level heterozygosity until all loci have eventually become fixed for just a single allele. To evaluate the long-term impact of finite population size on the expected heterozygosity of a locus, we make use of the properties of the **inbreeding coefficient**, f , which denotes the probability that two alleles at a locus in an individual are **identical by descent (IBD)** (LW Chapter 7).

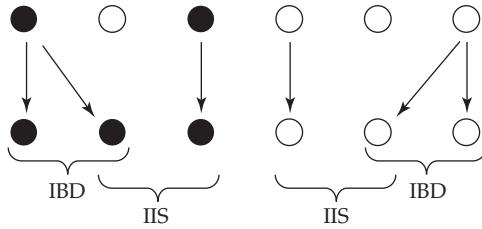

Figure 2.1 Distinction between alleles that are identical in state (IIS) and identical by descent (IBD). The simple example is a case in which the population consists of just three individuals, so that the total number of gametes transmitted randomly per generation is $2N = 6$. A polymorphism exists in the time-zero population (black and white alleles), so not all alleles are initially IIS. After one generation of sampling, two pairs of alleles are IBD because the two copies are direct copies of a parental allele.

Because all gene copies at a locus must ultimately trace back to a single, remote common ancestor, it is essential to start with an appropriate reference generation, which we here take to be the current generation, and then simply query forward in time as to the probability that any random pair of genes traces back to a specific copy of one of the $2N$ genes present at the locus in the reference generation. Under this framework, a pair of genes that are **identical in state (IIS; also known as alike in state, AIS)** need not be IBD, but barring mutation, genes that are IBD must also be IIS (Figure 2.1).

There is always a small chance that uniting gametes will derive from related individuals, even in a randomly mating population. For example, in a monoecious population containing only two individuals, there are only four genes residing at each locus, so the probability that one gamete will randomly unite with another containing a direct descendant of the same parental gene is $1/4$. With four individuals, there are eight gene copies, and this probability becomes $1/8$. Thus, under the idealized Wright-Fisher model with population size N , the probability that two direct copies of any parental gene will randomly unite in an offspring is $1/(2N)$. Barring a rare mutation, all such offspring are homozygotes.

Although the quantity $1/(2N)$ may be thought of as the new inbreeding that is incurred in each generation, this does not fully describe the buildup of homozygosity in a population. For even if uniting gametes do not carry genes that are direct copies of a parental gene, they may still be identical by descent through inbreeding in a previous generation. Under random mating, the probability of the latter event is simply the inbreeding coefficient of the parental generation. Thus, because the probability of drawing genes that are not direct copies of the same parental gene is $[1 - (1/(2N))]$, the expected inbreeding coefficient in generation t is

$$f_t = \frac{1}{2N} + \left(1 - \frac{1}{2N}\right) f_{t-1} \quad (2.3)$$

Subtracting both sides from one yields the recursion formula

$$(1 - f_t) = \left(1 - \frac{1}{2N}\right) (1 - f_{t-1}) \quad (2.4a)$$

which generalizes to

$$(1 - f_t) = \left(1 - \frac{1}{2N}\right)^t (1 - f_0) \quad (2.4b)$$

and finally to

$$(1 - f_t) = \left(1 - \frac{1}{2N}\right)^t \quad (2.4c)$$

if we assume a noninbred base population ($f_0 = 0$). Again, we see the central role that population size plays in the dynamics of genetic variation. As $t \rightarrow \infty$, the fraction of the population that is not inbred, $1 - f_t$, approaches zero at a rate that is inversely proportional to N .

To see the connection between the inbreeding coefficient and the expected heterozygosity in a population, consider a diallelic locus with base-population heterozygosity $2p(1-p)$. In the descendant population with inbreeding coefficient f , individuals can only be heterozygotes if they carry alleles that are not identical by descent, the probability of which is $(1-f)$. If two alleles are not identical by descent, they must have been acquired independently, so the probability that a genotype containing a pair of such alleles is a heterozygote is $2p(1-p)$. Thus, the expected heterozygosity of a population with inbreeding coefficient f and initial allele frequency p is $2p(1-p)(1-f)$. This shows that the fractional reduction in heterozygosity relative to the base population is equal to f . Because this argument applies regardless of the initial heterozygosity (and regardless of the number of segregating alleles), Equation 2.4c may be rewritten to describe the expected population heterozygosity at time t ,

$$H_t = H_0 \left(1 - \frac{1}{2N}\right)^t \quad (2.5)$$

This **rate of decay of heterozygosity** of $1/(2N)$ was first obtained by Wright (1931). It may be a source of encouragement to the nonmathematically inclined that the brilliant Fisher (1922), using a rather different approach, obtained the wrong answer.

The time course for the loss of heterozygosity can be clarified by using an exponential approximation to Equation 2.5. Because $(1-x)^t \simeq e^{-xt}$ for $|x| \ll 1$, for N greater than 10 or so,

$$H_t \simeq H_0 e^{-t/(2N)} \quad (2.6a)$$

Rearrangement then leads to the expected time to reach a certain reduction in heterozygosity,

$$t = -2N \ln(H_t/H_0) \quad (2.6b)$$

which shows that the heterozygosity is reduced to half of its initial value in $\sim 1.4N$ generations and to 5% of H_0 in $\sim 6N$ generations. Thus, a population twice the size of another requires twice the number of generations to reach the same expected state.

With a temporally varying population size, Equation 2.6a becomes

$$H_t = H_0 \prod_{i=1}^t \left(1 - \frac{1}{2N_i}\right) \simeq H_0 \exp \left[- \sum_{i=1}^t 1/(2N_i) \right] \quad (2.7)$$

where the \prod sign denotes a product of terms, and N_i is the population size in generation i . This expression illustrates an important point. Because each of the generation-specific terms, $[1 - (1/2N_i)]$, is necessarily less than one, Equation 2.7 shows that an expansion of population size can reduce the rate of erosion of heterozygosity, but does not eliminate it.

One significant limitation of the preceding expressions is that they only provide information on the behavior of the *expected* heterozygosity in a population. In reality, fluctuations in allelic copy number resulting from random genetic drift ensure that variation in heterozygosity will arise among loci that start in the same state. In a finite population of size N , the heterozygosity of a diallelic locus can take on $N + 1$ discrete values: $0, 2(1/2N)[1 - (1/2N)], \dots, 2(N/2N)[1 - (N/2N)]$. Using the transition-matrix approach (Equations 2.2a and 2.2b), one can obtain the exact probability distribution of heterozygosity for a locus starting with allele frequency $i/2N$, using the fact that $x_j(t) + x_{2N-j}(t)$ is the probability that the population has heterozygosity $2(j/2N)[1 - (j/2N)]$.

An alternative approach was developed by Kimura (1955b), who used diffusion theory (Appendix 1) to obtain an analytical expression for the probability density of allele frequency

at time t , given the starting value p_0 ,

$$\varphi(p_t|p_0) = p_0(1-p_0) \sum_{i=1}^{\infty} i(2i+1)(i+1) \cdot F(1-i, i+2, 2, p_0) \cdot F(1-i, i+2, 2, p_t) \cdot e^{-i(i+1)t/(4N)} \quad (2.8)$$

where $F(1-i, i+2, 2, p_0)$ and $F(1-i, i+2, 2, p_t)$ are specific variants of the hypergeometric function (Equation 15.1.1 in Abramowitz and Stegun 1972). When we use this expression, $[\varphi(p_t|p_0) + \varphi(1-p_t|p_0)]$ is the probability of heterozygosity $2p_t(1-p_t)$ at time t . We will make more use of Equation 2.8 in the next sections, illustrating in particular its implications for the dispersion of allele frequencies among isolated populations. The utility of the diffusion approximation is that it yields to numerous closed-form mathematical approximations, some of which we note below.

PROBABILITIES AND TIMES TO FIXATION OR LOSS

Because Equation 2.8 denotes the probability density of allele frequency p given that the population is still polymorphic,

$$\Omega(p_0, t) = \int_{1/(2N)}^{1-1/(2N)} \varphi(p_t|p_0) dp_t \quad (2.9a)$$

is the probability that both alleles are still present in generation t . The probability that an allele with initial frequency p_0 has been fixed by generation t is

$$p_f(p_0, t) = p_0 + p_0(1-p_0) \sum_{i=1}^{\infty} (2i+1)(-1)^i \cdot F(1-i, i+2, 2, p_0) \cdot e^{-i(i+1)t/4N} \quad (2.9b)$$

whereas the probability of loss of the allele, $p_l(p_0, t)$, is given by Equation 2.9b with $(1-p_0)$ exchanged for p_0 (Kimura 1955b). Summing up,

$$\Omega(p_0, t) + p_f(p_0, t) + p_l(p_0, t) = 1 \quad (2.10)$$

As can be seen from the negative exponential terms in the previous expressions, as $t \rightarrow \infty$, $\Omega(p_0, t) \rightarrow 0$, $p_f(p_0, t) \rightarrow p_0$, and $p_l(p_0, t) \rightarrow (1-p_0)$. Thus, under neutrality, the probability that a particular allele will become fixed is simply equal to its initial frequency, p_0 . It follows that, in averaging over a very large number of replicate populations, the expected allele frequency will remain constant at p_0 , with a fraction p_0 of all replicates ultimately reaching allele frequency 1, and the remaining fraction $1-p_0$ having allele frequency 0.

An issue of special interest is the mean time until an allele is absorbed into either state $p = 0$ or $p = 1$. Using diffusion approximations (Appendix 1), Kimura and Ohta (1969a) obtained expressions for both quantities, and Kimura (1970) presented a description of the entire probability distributions for absorption times. The following example uses a somewhat simpler approach to arrive at results identical to those of Kimura and Ohta (1969a), and provides yet another illustration of how the effects of random genetic drift scale with population size.

Example 2.2. Ewens (2004) used the following line of reasoning to derive the expected time to absorption of a neutral allele under the Wright-Fisher model. Letting δp denote the change in allele frequency in one unit of time, the mean time to absorption for an allele with frequency p may be rewritten as

$$\bar{t}_a(p) = E[\bar{t}_a(p + \delta p)] + 1$$

where E denotes an expected value. In words, this expression states that the mean absorption time starting at frequency p is equal to the mean absorption time one time unit later when the allele frequency is $p + \delta p$, plus one. Approximating $\bar{t}_a(p + \delta p)$ by the first three terms in its Taylor series (see LW Equation A1.2) and then taking expectations (only the δp are random terms; the rest are fixed constants), gives

$$\begin{aligned} E[\bar{t}_a(p + \delta p)] &\simeq E\left[\bar{t}_a(p) + \delta p \frac{\partial \bar{t}_a(p)}{\partial p} + \frac{(\delta p)^2}{2} \frac{\partial^2 \bar{t}_a(p)}{\partial p^2}\right] \\ &= \bar{t}_a(p) + E[\delta p] \frac{\partial \bar{t}_a(p)}{\partial p} + \frac{E[(\delta p)^2]}{2} \frac{\partial^2 \bar{t}_a(p)}{\partial p^2} \end{aligned}$$

Hence, we have

$$\bar{t}_a(p) \simeq \bar{t}_a(p) + E[\delta p] \frac{\partial \bar{t}_a(p)}{\partial p} + \frac{E[(\delta p)^2]}{2} \frac{\partial^2 \bar{t}_a(p)}{\partial p^2} + 1$$

Under neutrality, the expected change in allele frequency is $E(\delta p) = 0$, and as derived previously, the expected variance in allele-frequency change is $E[(\delta p)^2] = p(1 - p)/(2N)$. Substituting into our approximation and rearranging gives

$$\bar{t}_a(p) - \bar{t}_a(p) - 1 \simeq \frac{p(1 - p)}{2 \cdot 2N} \frac{\partial^2 \bar{t}_a(p)}{\partial p^2}$$

which implies the differential equation

$$\frac{\partial^2 \bar{t}_a(p)}{\partial p^2} \simeq -\frac{4N}{p(1 - p)}$$

Performing the double integration with respect to p leads to the solution

$$\bar{t}_a(p_0) \simeq -4N[p_0 \ln(p_0) + (1 - p_0) \ln(1 - p_0)] \quad (2.11a)$$

which is the mean time until an allele with initial frequency p_0 is either lost or fixed in a population.

A similar approach can be used to estimate the mean time to fixation for the subset of alleles that specifically become fixed, $\bar{t}_f(p_0)$. The essential modification here is that in estimating $\bar{t}_f(p_0)$, $E(\delta p)$ is no longer equal to zero, because in order for an allele to become fixed, at least one copy must be produced in each generation. That is, in the case of conditional fixation, of the $2N$ genes drawn in each generation, one is definitely a B allele, whereas the remaining $2N - 1$ genes can be viewed as random, leading to $E(\delta p) = \{(1/2N) + [1 - (1/2N)]p\} - p = (1 - p)/(2N)$. Similarly, because the states of only $2N - 1$ genes are random, $E[(\delta p)^2] = \{(1 \cdot 0) + [(2N - 1)p(1 - p)]\}/(2N)^2$. Unless N is very small, the approximation $E[(\delta p)^2] = p(1 - p)/(2N)$ still holds quite well, and following the procedures utilized previously, we then have

$$\left(\frac{2}{p}\right) \frac{\partial \bar{t}_f(p)}{\partial p} + \frac{\partial^2 \bar{t}_f(p)}{\partial p^2} \simeq -\frac{4N}{p(1 - p)}$$

The solution of this second-order differential equation requires several steps, which we omit, the final result being

$$\bar{t}_f(p_0) \simeq -\frac{4N(1 - p_0) \ln(1 - p_0)}{p_0} \quad (2.11b)$$

The mean time to loss of an allele conditional upon loss is identical to the previous expression, but with $(1 - p_0)$ interchanged with p_0 ,

$$\bar{t}_l(p_0) \simeq -\frac{4Np_0 \ln(p_0)}{1 - p_0} \quad (2.11c)$$

These expressions show that the conditional time to fixation asymptotically approaches $4N$ generations for rare alleles, with the more general fate of such alleles being loss from the population in $\ll 4N$ generations (Figure 2.2).

Finally, because the probability of ultimate fixation of a neutral allele is equal to its initial frequency (p_0) and the probability of ultimate loss is $(1 - p_0)$, it follows that

$$\bar{t}_a(p_0) = p_0 \bar{t}_f(p_0) + (1 - p_0) \bar{t}_l(p_0) \quad (2.11d)$$

Example A1.8 (in Appendix 1) uses diffusion theory to obtain results identical to those just presented.

THE AGE OF A NEUTRAL ALLELE

A classic result from standard theory relates the age of a neutral allele to its frequency (Kimura and Ohta 1973; Maruyama 1974; Watterson 1976; Slatkin and Rannala 1997, 2000). In particular, the expected age t (in generations) of an allele with current frequency p is

$$E(t) = -\frac{4Np \ln(p)}{1 - p} \quad (2.12)$$

assuming a constant population size during the allele's sojourn through the population (Kimura and Ohta 1973). As shown in Figure 2.3, alleles at higher frequency are expected to be older. Most notably, as $p \rightarrow 1$, $E(t) \rightarrow 4N$ generations, which is consistent with the result in the previous example showing that the mean time to fixation of a rare (e.g., new mutant) neutral allele is $4N$ generations. This result is more than just an esoteric finding, as one class of tests for selection evaluates whether an allele, given its frequency, is too young to be compatible with neutrality (Chapter 9).

Equation 2.12 is not, however, the whole story, as a very old allele can sometimes be at low frequency, having transiently drifted up to a high frequency before drifting back toward zero frequency by chance. Thus, we expect the confidence interval for allele-age estimates to be highly asymmetric about the mean. Slatkin and Rannala (2000) provide an approximation for the cumulative probability for the age of an allele, given a frequency of p in a random sample of n alleles,

$$\Pr(t \leq \tau) = (1 - p)^{-1 + [n/(1+nN\tau)]} \quad (2.13)$$

One final caveat is in order with respect to Equation 2.12. Unless the sample size is very large, the estimated frequency of a rare allele can be quite misleading. Consider, for example, a singleton with a sample frequency of $1/n$. Application of Equation 2.12 would imply an estimated age of $4N \ln(n)/[n(1 - 1/n)]$ generations. If ten diploid individuals were sampled, the minimum allele frequency would be 0.05, so the estimated age of a singleton would be $\sim 0.84N$ generations. As very rare alleles, with true frequencies $\ll 1/n$ will either be recorded as singletons or not at all in a sample of size n , it is clear that Equation 2.12 yields upwardly biased estimates of the ages of rare alleles unless the sample size is large enough that the estimate of frequency p is highly accurate.

Example 2.3. The mutation CCR5- δ 32 destroys the human CCR5 receptor, which is used by the HIV virus to enter the cell, leading to significant resistance against HIV infection. This deletion occurs at frequencies up to 14% in Eurasians, but is absent in Africans, Native Americans, and East Asians. Assuming a frequency of $p = 0.10$ and an effective population size $N = 5000$ for Caucasians, Stephens et al. (1998) used Equation 2.12 to estimate the age of this allele (under the assumption of neutrality) to be

$$\hat{t} = -\frac{4 \cdot 5000 \cdot 0.1 \log(0.1)}{0.9} = 5116 \text{ generations}$$

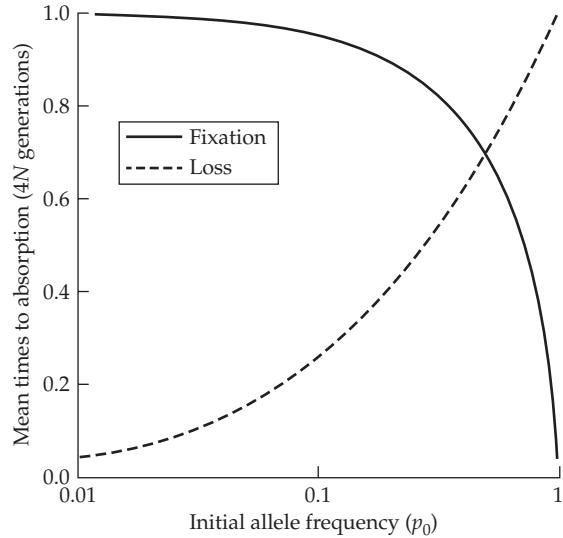

Figure 2.2 Mean times to fixation and loss of neutral alleles with starting frequency p_0 (from Equations 2.11b and 2.11c). The times are scaled in units of $4N$ generations, and thus need to be multiplied by $4N$ to obtain absolute numbers of generations.

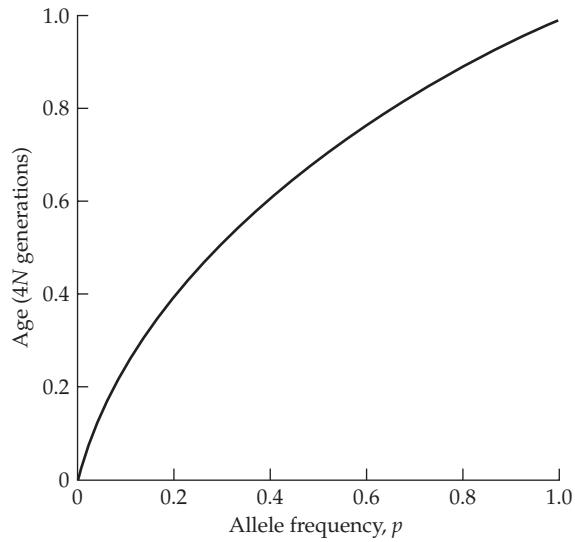

Figure 2.3 Expected age of a neutral allele, given its frequency p (Equation 2.12). Time is scaled in units of $4N$ generations.

However, an independent (and more direct) estimate of the allele's age can be obtained by considering the variation in haplotypes among all sequences carrying this mutation. The $\delta 32$ mutation is in strong linkage disequilibrium with allele 215 at the *AFMB* marker (a highly

variable tandem-repeat locus), to the extent that 84.8% (39 of 46) of sampled $\delta 32$ mutations have the $\delta 32\text{-}215$ haplotype. Clearly, the initial $\delta 32$ mutation at $CCR5$ must have arisen on a chromosome carrying the 215 allele. The recombination fraction between $CCR5$ and $AFMB$ was estimated by Stephens et al. (1998) to be $c = 0.006$. The probability of the $\delta 32\text{-}215$ haplotype remaining intact after t generations (i.e., experiencing no recombinational breakdown) is just $\pi = (1 - c)^t$, which rearranges to

$$t \simeq \ln(\pi)/\ln(1 - c) = 27.4 \text{ generations}$$

Stephens et al. (1998) took these great disparities between age estimates as an indicator that strong selection has promoted the $\delta 32$ mutation much more rapidly than would be likely under a pure drift model. Assuming $\delta 32$ originated as a single mutation, they estimated the selection coefficient to be between 0.2 and 0.4, depending on assumptions about dominance. We will revisit the age of this mutation in Example 9.14.

Example 2.4. Consider a situation in which a random sample of 500 gametes from a population yields 350 copies of a particular allele A , and hence an estimated p of 0.7. Under the joint assumptions of neutrality and constant population size, what is the 95% confidence interval for the estimated age of this allele? From Equation 2.12, the expected age is

$$\hat{t} = -\frac{(4N)0.7\ln(0.7)}{1-0.7} = 1.45N$$

An approximate confidence interval using the approximation given by Equation 2.13 is obtained as follows. To account for N , we first rescale time so that $\tau = 2N$ generations, and after solving for the critical values of τ on this scale, we convert it back to generations. Define τ_α as satisfying $\Pr(t \leq \tau_\alpha) = \alpha$. The 95% confidence interval for allelic age t is given by $(\tau_{0.025}, \tau_{0.975})$. From Equation 2.13, $\tau_{0.025}$ must satisfy

$$(0.3)^{-1+[500/(1+250\tau_{0.025})]} = 0.025$$

the solution of which is $\tau_{0.025} = 0.49$, or $0.49 * (2N) = 0.98N$ generations (Equation 9.38d gives an approximation for τ when n is large). The same procedure can be used to find that $\tau_{0.975} = 3.9N$, showing that the confidence interval about the mean value is very asymmetric.

ALLEL-FREQUENCY DIVERGENCE AMONG POPULATIONS

A natural consequence of allele-frequency drift within populations is the divergence of isolated replicate populations. Suppose a monoecious base population with allele frequency p_0 is suddenly split into several completely isolated subpopulations, each of size N , with random mating within each subpopulation and no selection, migration, or mutation. The variance in allele frequency among subpopulations in generation t is

$$\sigma_p^2(t) = E(p_t^2) - E^2(p_t)$$

Adding and subtracting $E(p_t)$,

$$\begin{aligned}\sigma_p^2(t) &= [E(p_t) - E^2(p_t)] + [E(p_t^2) - E(p_t)] \\ &= E(p_t)[1 - E(p_t)] - E[p_t(1 - p_t)]\end{aligned}$$

Because there are no systematic forces causing the allele frequency to increase or decrease, $E(p_t) = p_0$, so the first quantity on the right is $p_0(1 - p_0)$. The quantity $E[p_t(1 - p_t)]$ is half

the expected heterozygosity in a population in generation t , which was already defined in Equation 2.5. Thus

$$\sigma_p^2(t) = p_0(1 - p_0) \left[1 - \left(1 - \frac{1}{2N} \right)^t \right] \quad (2.14a)$$

which is well approximated by

$$\sigma_p^2(t) \simeq p_0(1 - p_0)(1 - e^{-t/2N}) \quad (2.14b)$$

for $N > 10$. This shows that the among-population variance asymptotically approaches $p_0(1 - p_0)$, which is half the heterozygosity in the base population—over time, the allelic variance within populations (half of the quantity in Equation 2.6a) is transformed into among-population variance, with the total of the two remaining constant. An alternative way to envision this asymptotic result is to note that at fixation the allele frequency has a value of 1.0 with probability p_0 , and otherwise is zero, giving $E(p_0) = 1 \cdot p_0$ and $E(p_0^2) = 1^2 \cdot p_0 = p_0$. Hence, the among-population variance when all alleles are fixed is just $E(p_0^2) - [E(p_0)]^2 = p_0(1 - p_0)$.

Although Equations 2.14a and 2.14b deal with the expected allele-frequency variance, they do not describe the actual form of the distribution of population allele frequencies. However, all of this information is contained in the formulations presented previously on the probability distribution of allele frequencies within populations. For example, the transition-matrix approach (Equations 2.2a and 2.2b) and the diffusion approximation (Equation 2.8) yield the expected temporal dynamics of the distribution of allele frequencies in different replicate populations, all starting from an identical frequency, p_0 (Figure 2.4).

Summing up the calculations to this point, five significant conclusions can be gleaned with respect to neutral alleles. First, with increasing time, the total probability mass for the allele-frequency distribution at a locus declines because only *segregating* alleles are considered, i.e., the proportions of populations that have experienced gene fixation or loss are ignored. Second, regardless of the starting condition, the distribution becomes flatter with increasing time, such that the frequency of a sufficiently old segregating allele is equally likely anywhere over the (0,1) interval. Third, high-frequency alleles are generally expected to be old. Fourth, the distributions in Figure 2.4 can be interpreted in two different ways: as the probability distribution of allele frequencies over a very large number of replicate populations over time, all starting at an identical state, or as the expected distribution of allele frequencies for the subset of loci with identical starting frequencies within a single population. Finally, the expected allele-frequency distribution is a function of t/N generations, as can be seen from the exponential terms in Equation 2.8. As should be clear by now, this scaling of the temporal dynamics of random genetic drift to the reciprocal of population size is a natural consequence of the fact that the variance of allele-frequency change is inversely proportional to N .

BURI'S EXPERIMENT

Because all populations are finite in size, the theory of random genetic drift is of central significance to all areas of population genetics. It may therefore come as a surprise that highly replicated experiments examining the chance dynamics of allele-frequency change are extremely rare. However, the results of one massive experiment nicely affirm the theoretical expectations outlined above, while making one additional important point. Starting with two homozygous lines of *Drosophila melanogaster*, one of which was fixed for allele bw^{75} and the other for allele bw at the brown locus, Buri (1956) established 212 F_1 hybrid populations, with initial frequency 0.5 for both alleles. For the following 19 generations, he randomly mated eight males and eight females within each population and monitored the changes in allele frequencies in each subline. This could be done in the pre-molecular era because the genotype at the brown locus determines eye color: $bw^{75}bw^{75} =$

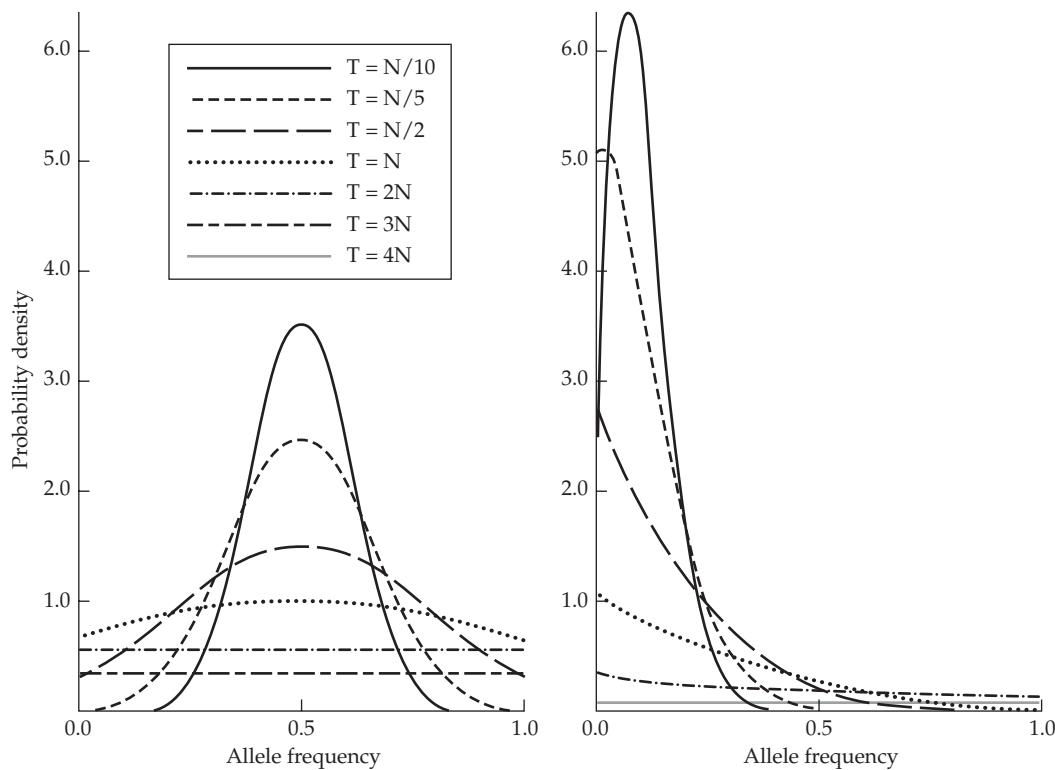

Figure 2.4 Expected probability distributions for the frequencies of segregating neutral alleles in replicate, randomly mating populations of size N after t generations of divergence (fixed alleles are ignored). The initial allele frequency in the base population is 0.5 on the left and 0.1 on the right. The abscissa is the population allele frequency, whereas the ordinate is proportional to the probability of occurrence of that frequency. Note that the time scale is in units of N generations, where N is the population size, so that $t = N$ generations implies 100 generations for a population of size 100 and 10,000 generations for a population of size 10,000. (From Kimura 1955b.)

bright red-orange, $bw^{75}bw$ = deep red-brown, and $bwbw$ = white. (Two separate experiments were performed, one with 107 and the other with 105 populations, but the results are so similar that they have been pooled in the following analysis.)

To evaluate the results in the light of the preceding theory, it is first necessary to demonstrate that the bw^{75} and bw alleles are indeed neutral with respect to each other. This can be done as follows (Figure 2.5, top). In the absence of selection, the expected frequency of the bw^{75} allele averaged over all populations should equal its initial frequency, 0.50, in all generations. Nevertheless, just as the frequency within any population is expected to deviate from 0.50 because of drift, the mean allele frequency in the total aggregate of populations will also vary slightly because the number of populations is finite. The sampling variance of the overall mean frequency is equal to the sum of the expected within- and among-population allele-frequency variances divided by the number of populations, 212. The latter quantity was already defined in Equation 2.14, whereas the former is the expected binomial sampling variance divided by the sample size ($2N$), or $p_0(1 - p_0)[1 - (1/2N)]^t/(2N)$. Figure 2.5 shows that although the frequency of the bw^{75} allele averaged over all populations increased to

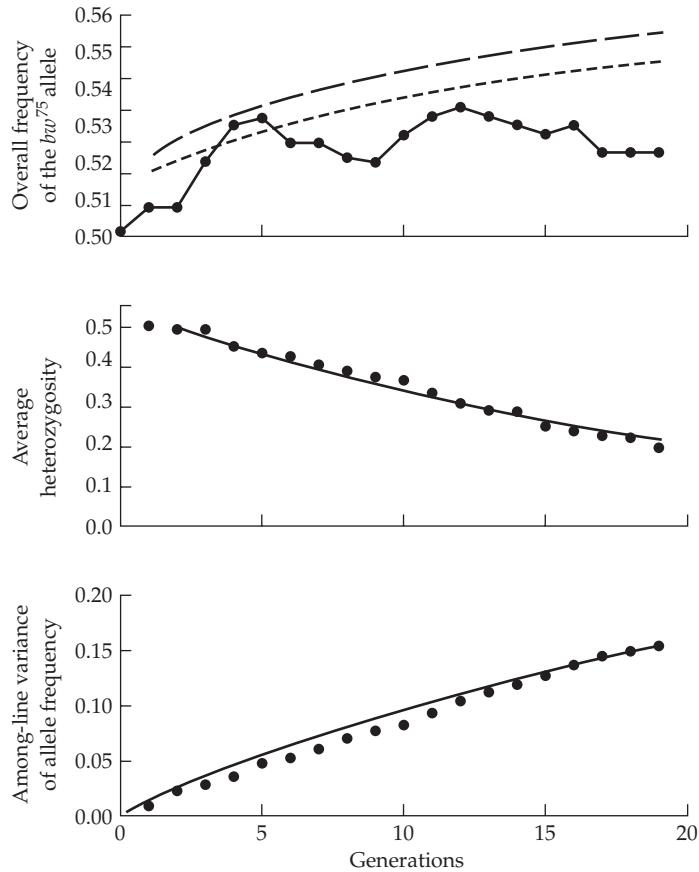

Figure 2.5 Patterns of change in the frequencies of the bw^{75} allele in 212 isolated populations of *Drosophila melanogaster*, each consisting of eight breeding males and eight females. (**Top**) The average allele frequency over the entire pool of populations. The dotted and solid lines, respectively, denote upward deviations of two standard errors from the expected value of $p_0 = 1/2$ under the assumption of effective population sizes of 16 and 10.2 individuals. (**Middle**) Mean observed heterozygosity compared to the expectations assuming an effective population size of 10.2. The expected heterozygosity is 0.5 in generations 1 and 2 because the base population (generation 0) consisted entirely of heterozygotes, and with separate sexes, an additional generation is required for the unification of alleles that are identical by descent. (**Bottom**) Among-line variance of allele frequencies compared with their expectations assuming an effective population size of 10.2. (After Buri 1956.)

0.525, it generally remained within two standard errors of the expectation under pure drift. The overall pattern of change in mean allele frequency is therefore compatible with the expectations for a neutral locus subject to random genetic drift.

The dynamics of the among-population divergence (Figure 2.6) are qualitatively very similar to the expected pattern illustrated in the left panel of Figure 2.4 (corresponding to $p_0 = 0.5$). As the population allele frequencies diverge, the initial bell-shaped distribution does indeed become flatter, eventually acquiring a U-shape as populations that are fixed for the bw^{75} or bw alleles accumulate. Had the experiment been extended further in time, the distribution would have eventually consisted of only two classes, populations fixed for bw^{75} and those fixed for bw , with nearly equal frequencies.

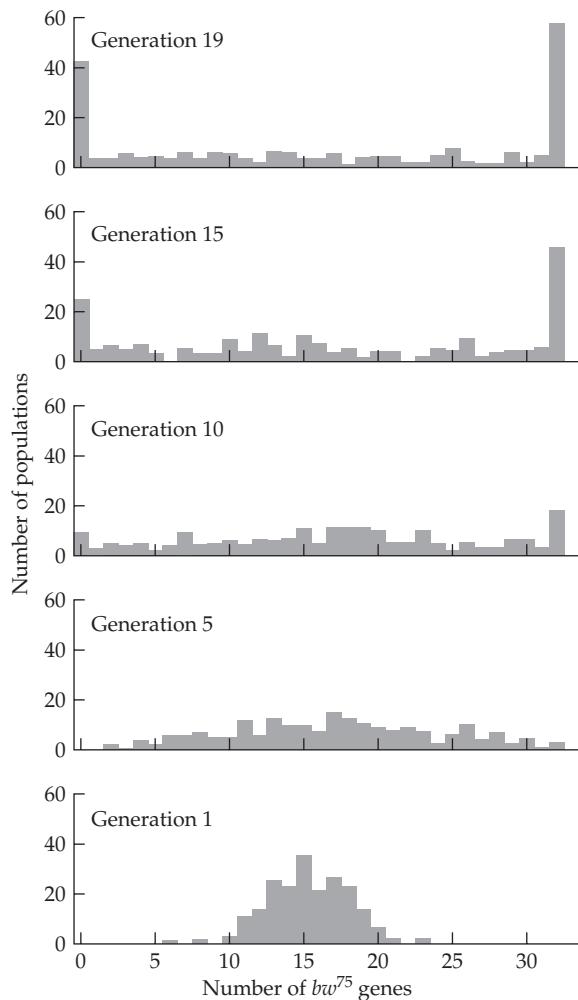

Figure 2.6 Distribution of the number of bw^{75} alleles in 212 populations of *D. melanogaster* each initiated with a frequency of 0.5. Two features are represented in this temporal series: the distribution of frequencies for segregating alleles (1 to 31 copies), the expected form of which is given in Figure 2.4, and the accumulation of fixed alleles (0 or 32 copies). (From Buri 1956).

Despite the qualitative agreement with theoretical expectations, the rate of divergence illustrated in Figure 2.6 is somewhat greater than that expected for randomly mating populations of 16 individuals. However, this does not necessarily invalidate the theory outlined previously, as it is possible that not all 16 potential parents reproduced each generation, and/or that the distribution of family sizes deviated from randomness. Either condition would cause the populations to behave genetically as though they were smaller than its actual size (Chapter 3). With the massive amount of data in Buri's experiment, it is possible to obtain an empirical estimate of this **effective population size** in the following way.

Not including fixed classes, there are 31 possible allele frequencies in Buri's populations (1/32 to 31/32), each of which was observed at various times in one or more of the 212 populations. Focusing on any one allele-frequency class, the single-generation sampling variance conditional on the initial allele frequency for this class (p) can then be calculated

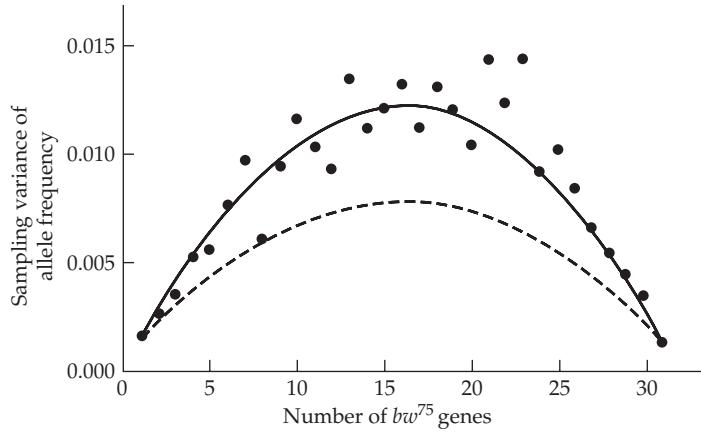

Figure 2.7 Observed sampling variances of allele frequencies for situations in which the donor population contained 1 to 31 bw^{75} genes. The dashed line is the expected pattern, $p(1 - p)/(2N)$, if the actual populations of 8 males and 8 females were randomly mating with equal chances of contributing offspring. The solid line describes the pattern for an average effective population size of 10.2. (From Buri 1956.)

from the allele frequencies observed in the subsequent generation, and compared to the expected value of $p(1 - p)/(2N)$. The 31 points shown in Figure 2.7 provide an empirical description of this function, with an excellent fit being obtained if it is assumed that the average effective population size was $N \simeq 10.2$ rather than the idealized 16. In other words, the sampling variance of allele frequencies is in very close accord with that expected for an average ideal population of 10.2 randomly mating individuals. Once this change in scale from $N = 16$ to $\bar{N} = 10.2$ is taken into account, both the erosion of average heterozygosity within populations and the buildup of among-population variance of allele frequencies are quite consistent with the theory outlined above (Figure 2.5, middle and bottom).

HIGHER-ORDER ALLELE-FREQUENCY MOMENTS

In the previous sections, we evaluated the expected values of various population features under neutrality. However, as just noted, in applying such expressions to empirical studies, it is important to keep in mind that the random sampling of allele frequencies across generations will cause the realized behavior of any particular population or group of populations to deviate from the expected pattern. Thus, there is a practical need for expressions for the variance of various population parameters that result from genetic sampling. This in turn requires an understanding of the behavior of higher-order allele-frequency moments. For example, although the *expected* heterozygosity is a function of $2p(1 - p) = 2(p - p^2)$, as will be shown later, its *variance* depends on p^3 and p^4 .

For a population obeying the features of the idealized Wright-Fisher model, useful expressions can be obtained by noting that the expected value of an allele-frequency moment in generation $t + 1$ can be written as a conditional function of the allele frequency p_t in the previous generation. For example, letting δp denote the change in allele frequency in the previous generation resulting from gamete sampling, the behavior of the first moment (the mean) can be written as

$$E[p_{t+1}|p_t] = E[(p_t + \delta p)|p_t]$$

In the case of neutrality, there are no directional forces, so $E(\delta p) = 0$, and the expected

frequency of an allele remains perpetually at its initial value (p_0),

$$E(p_t) = p_0 \quad (2.15)$$

The second moment is obtained by noting that

$$E[p_{t+1}^2|p_t] = E[(p_t^2 + 2p_t\delta p + \delta p^2)|p_t]$$

Because $E(\delta p) = 0$ and $E(\delta p^2|p_t) = p_t(1 - p_t)/(2N)$ under binomial sampling,

$$E[p_{t+1}^2|p_t] = E\left(p_t^2 + \frac{p_t - p_t^2}{2N}\right)$$

Letting $\lambda_1 = 1 - (1/2N)$, and noting that $E(p_t) = p_0$, this expression can be rearranged to give the recursion equation

$$E[p_{t+1}^2|p_t] - p_0 = [E(p_t^2) - p_0]\lambda_1$$

the general solution of which is

$$E(p_t^2) = p_0 - [p_0(1 - p_0)]\lambda_1^t \quad (2.16a)$$

The general starting expression, which can be extended to all higher-order moments, is

$$\begin{aligned} E[p_{t+1}^k|p_t] &= E[(p_t + \delta p)^k|p_t] \\ &= \sum_{i=0}^k \binom{k}{i} p_t^i E[(\delta p)^{k-i}|p_t] \end{aligned} \quad (2.16b)$$

where the summation gives the terms in the polynomial expansion. For binomial sampling theory, expressions are available for all expected values of powers of δp (e.g., Johnson et al. 2005), so Equation 2.17 can be solved recursively starting with the lower-order moments.

Using expectations for higher-order δp^k terms, expressions for all higher-order moments can be acquired, two of which prove to be particularly useful (Crow and Kimura 1970):

$$E(p_t^3) = p_0 - \frac{3}{2}p_0(1 - p_0)\lambda_1^t - \frac{1}{2}p_0(1 - p_0)(2p_0 - 1)(\lambda_1\lambda_2)^t \quad (2.16c)$$

$$\begin{aligned} E(p_t^4) &= p_0 - \frac{18N - 11}{10N - 6}p_0(1 - p_0)\lambda_1^t - p_0(1 - p_0)(2p_0 - 1)(\lambda_1\lambda_2)^t \\ &\quad + p_0(1 - p_0) \left(p_0(1 - p_0) - \frac{2N - 1}{10 - 6} \right) (\lambda_1\lambda_2\lambda_3)^t \end{aligned} \quad (2.16d)$$

where $\lambda_i = 1 - (i/2N)$. Modifications for these expressions for populations with separate sexes and 1:1 sex ratios are given by Lynch and Hill (1986).

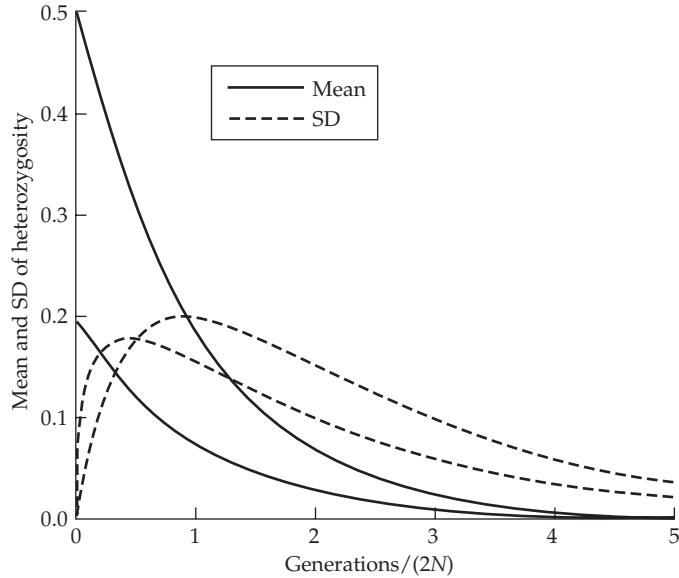

Figure 2.8 Mean heterozygosity and its standard deviation (SD) among replicate populations as a function of time (scaled in units of $2N$ generations). The upper curves assume an initial heterozygosity of $H_0 = 0.5$ and the lower curves of $H_0 = 0.2$. A diallelic locus is assumed, and new variation generated by mutation is ignored. Experimental error resulting from sampling of a finite number of individuals is ignored as well, i.e., we consider only the variance of true population-level heterozygosities resulting from gamete sampling. The expected heterozygosities (solid lines) are obtained with Equation 2.5, whereas the standard deviations (dotted lines) follow from Equation 2.17.

Example 2.5. The preceding expressions can be used to derive the evolutionary (or drift) variance of heterozygosity at a locus under the assumption of Hardy-Weinberg equilibrium, provided there are only two alleles segregating at the locus. Letting $H_t = 2p_t(1 - p_t)$ denote the heterozygosity at generation t , the expected variance of heterozygosity is

$$\begin{aligned}\sigma^2(H_t) &= E\{[2p_t(1 - p_t)]^2\} - \{E[2p_t(1 - p_t)]\}^2 \\ &= E(4p_t^2) - E(8p_t^3) + E(4p_t^4) - [E(2p_t) - p_t^2]^2\end{aligned}$$

A solution is obtained by substituting Equations 2.16a–2.16d for the expectations of allele-frequency moments, with further simplification made possible by using the approximations $\lambda_1 \simeq e^{-t/2N}$, $\lambda_2 \simeq e^{-2t/2N}$, and $\lambda_3 \simeq e^{-3t/2N}$, yielding

$$\sigma^2(H_t) \simeq H_0 \left[\frac{2}{5}e^{-t/2N} + \left(H_0 - \frac{2}{5} \right) e^{-3t/2N} - H_0 e^{-t/2N} \right] \quad (2.17)$$

This quantity can be viewed as either the variance in heterozygosity that develops at a particular neutral locus among replicate populations starting from the same initial allele frequencies or as the variance in heterozygosity among a pool of loci within the same population with identical initial allele frequencies. As with the expected heterozygosity, the temporal dynamics of the evolutionary variance of heterozygosity scale inversely with the size of the population. Moreover, the variation in heterozygosity resulting from genetic drift can be quite high, with the standard deviation always exceeding the expected heterozygosity once $t > 2N$ generations (Figure 2.8). With more than two alleles per locus, the preceding expressions would need to be modified to account for the negative drift sampling covariance between different alleles at the locus.

LINKAGE DISEQUILIBRIUM

In the study of multilocus traits, we are naturally interested in combinations of alleles among loci. If the alleles at two loci are independently distributed, the expected frequency of each gamete type can be predicted from the products of the allele frequencies at the two loci. For example, with two alternative alleles (A and a) at one locus having frequencies p and $1 - p$, and those (B and b) at another locus having frequencies q and $1 - q$, the expected frequencies of gametic types AB , Ab , aB , and ab are pq , $p(1 - q)$, $(1 - p)q$, and $(1 - p)(1 - q)$, respectively, under the assumption of independence. A natural measure of the deviation of the frequency of a gametic type from such expectations is the **coefficient of linkage disequilibrium**

$$D_{AB} = p_{AB} - pq \quad (2.18)$$

where p_{AB} denotes the observed frequency of the AB th gamete.

Here a word on notation is in order. Throughout, we will use italicized letters to designate alleles associated with a particular locus, which will in turn be denoted with an uppercase nonitalicized letter. Thus, Equation 2.18 defines the linkage disequilibrium at loci A and B , using alleles A and B to define the deviation from random expectations.

This definition of D_{AB} has the useful feature of being equivalent to the covariance of the distribution of alleles A and B in the same gametes. To see this, let the random variable x take on a value of one when the allele at the first locus is A and zero otherwise, and likewise let y equal one when the allele at the second locus is B and zero otherwise. Then, $E(xy) = p_{AB} \cdot 1$, $E(x) = \text{freq}(A) \cdot 1 = p$, and $E(y) = \text{freq}(B) \cdot 1 = q$, giving the covariance between allele presence at the two loci as $E(xy) - E(x)E(y) = p_{AB} - pq$.

In the absence of selection, there will be no tendency for the alleles at different loci to be associated positively versus negatively. However, forces such as migration or nonrandom mating may cause some such correlations. Letting D_0 denote an initial level of disequilibrium, c denote the frequency of recombination between loci, and $\lambda_1 = 1 - (1/2N)$, the expected disequilibrium (under random mating) resulting from the joint forces of recombination and gametic sampling is

$$\begin{aligned} E(D_t) &= [(1 - c)\lambda_1]^t D_0 \\ &\simeq D_0 e^{-(2Nc+1)t/(2N)} \end{aligned} \quad (2.19)$$

(Hill and Robertson 1966), showing that disequilibrium declines toward zero in the absence of any replenishing forces.

In contrast, the variance of D can be quite substantial even when its expected value is zero. The problem can be evaluated by use of the following set of recursion equations for fourth-order moments of allele frequencies,

$$\begin{pmatrix} E[p(1 - p)q(1 - q)] \\ E[D(1 - 2p)(1 - 2q)] \\ E(D^2) \end{pmatrix}_{t+1} = \lambda_1 \cdot \begin{pmatrix} \lambda_1 & \lambda_1(1 - c)/(2N) & 2(1 - c)^2/(4N^2) \\ 0 & \lambda_2^2(1 - c) & 4\lambda_2(1 - c)^2/(2N) \\ 1/(2N) & \lambda_1(1 - c)/(2N) & [\lambda_2^2 + (1/4N^2)](1 - c)^2 \end{pmatrix} \cdot \begin{pmatrix} E[p(1 - p)q(1 - q)] \\ E[D(1 - 2p)(1 - 2q)] \\ E(D^2) \end{pmatrix}_t \quad (2.20)$$

where, as previously, $\lambda_i = 1 - [i/(2N)]$ (Hill and Robertson 1968). The evolutionary variance of D associated with drift among replicated populations or among loci starting from the same allele frequencies is

$$\sigma^2(D) = E(D^2) - E^2(D) \quad (2.21)$$

If $D_0 = 0$, then $E(D_t) = 0$, and $\sigma^2(D_t) = E(D_t^2)$. Ohta and Kimura (1969a; their Equations 20–25) obtained a closed-form solution to this expression.

Hill and Robertson (1968) introduced a standardized measure of linkage disequilibrium, often referred to as the squared within-gamete correlation of allele frequencies at two loci

$$r^2 = \frac{D^2}{p(1-p)q(1-q)} \quad (2.22)$$

This is a natural definition in the sense of a correlation coefficient being generally defined as the ratio of a covariance (in this case, D) and the square root of the product of the variances (in this case, $p[1-p]$ and $q[1-q]$ for the allelic variances at each locus). There are, however, conceptual limitations to this measure, as it can only achieve a maximum value of 1.0 if the heterozygosities at both loci are equal. To make matters worse, in many applications of Equation 2.22, investigators have computed the ratio of average values of the numerator and denominator for large numbers of pairs of loci, which is not equivalent to the squared gametic correlation averaged over pairs of loci. This difference in definition can lead to up to 100-fold differences between estimated values of r^2 and the true correlation if allele frequencies are extreme, as is often the case with neutral alleles (Song and Song 2007).

Example 2.6. One common setting generating linkage disequilibrium involves a new allele arising as a single copy on a particular background. Let A denote the derived allele and assume it arose on a B background at a second locus. Initially, all copies of A are associated with B (there are no aB gametes). Because the sum of the AB and aB gamete frequencies is just the frequency q of B , the resulting 2×2 gametic contingency table is

	A	a
B	p	$q-p$
b	0	$1-q$

and the resulting initial values for D and r^2 become

$$D_{AB} = p_{AB}p_{ab} - p_{aB}p_{Ab} = p(1-q) - 0 \cdot (q-p) = p(1-q)$$

$$r^2 = \frac{D^2}{p(1-p)q(1-q)} = \frac{[p(1-q)]^2}{p(1-p)q(1-q)} = \frac{p(1-q)}{(1-p)q}$$

For this example, $r^2 = 1$ only when $p = q$ (Sved 1971), or when there are no aB gametes (A and B always co-occur), in which case the 2×2 gamete contingency table becomes

	A	a		A	a
B	p	0	,	or equivalently	0
b	0	$1-p$		B	q

or equivalently

B	q	0
b	0	$1-q$

For a newly arising mutation, $p = 1/(2N)$, so initially $D_{AB} = (1-q)/(2N)$ and $r^2 \simeq (1-q)/(2Nq)$.

MUTATION-DRIFT EQUILIBRIUM

In the preceding pages, we were largely concerned with the dynamics of gene-frequency change owing to the effects of random genetic drift alone. Under this model, finite population size eventually results in the complete loss of genetic variation (and covariation) within populations, at which point all loci are fixed for ancestral alleles with probabilities equal to their initial frequencies. In reality, however, mutation will always introduce variation at a low rate, which not only offsets some of the loss resulting from drift, but also ensures that neutral loci will continue to diverge among isolated populations. If the time scale of the

problem under consideration is short ($t \ll 2N$) and the initial level of within-population variation is high (relative to the mutational rate of production of new heterozygosity per generation), the contribution from mutation will be negligible, and the preceding expressions will be quite adequate. However, for longer-term evolutionary issues, such as the maintenance of variation in natural populations and interspecific divergence, mutation cannot be ignored.

The incorporation of mutation into a neutral model of evolution is relatively straightforward. For example, suppose there are k possible alleles at a locus, each with a mutation rate u per generation (the **k -exchangeable alleles model**). The dynamics of heterozygosity can then be obtained by recalling from above that the expected frequency of heterozygotes in generation $t + 1$ in the absence of mutation is $[1 - (1/2N)]H_t = \lambda_1 H_t$, whereas the expected frequency of homozygotes is $1 - \lambda_1 H_t$. Following mutation, the heterozygous state will be retained if: (1) neither allele mutated, the probability of which is $(1 - 2u)$, ignoring the very small probability of double mutations to the same state; or (2) one of the alleles mutated to a different state than the other, the probability of which is $[2u(k - 2)/(k - 1)]$, assuming that all allelic types are equally mutationally exchangeable. On the other hand, homozygotes will be mutationally converted to heterozygotes at a rate of $2u$. Thus, the expected dynamics of heterozygosity can be expressed as

$$H_{t+1} = H_t \lambda_1 \left((1 - 2u) + \frac{2u(k - 2)}{k - 1} \right) + 2u(1 - \lambda_1 H_t) \quad (2.23)$$

Setting $H_{t+1} = H_t$, the expected value of heterozygosity under drift-mutation balance is found to be

$$E(H) = \frac{\theta}{1 + [\theta k/(k - 1)]} \quad (2.24a)$$

where $\theta = 4Nu$, a result first given by Kimura (1968a). Note that θ has the pleasing interpretation of being the ratio of the rates of mutational production of heterozygotes from homozygotes ($2u$) and the rate of loss of heterozygosity by drift ($1/2N$). If a large number of alternative alleles ($k \gg 1$) is assumed, as is reasonable when the unit of analysis is an entire gene, Equation 2.24a reduces to

$$E(H) \simeq \frac{\theta}{1 + \theta} \quad (2.24b)$$

which is equivalent to the **infinite-alleles model** of Kimura and Crow (1964). On the other hand, if the unit of analysis is a nucleotide site, then $k = 4$, and

$$E(H) = \frac{\theta}{1 + (4/3)\theta} \quad (2.24c)$$

where u is now the mutation rate per nucleotide site. Equation 2.24a needs to be modified if alleles mutate at different rates or are not equally mutationally accessible (Kimura 1983; Nei and Kumar 2000), but provided $2Nu \ll 1$, as seems to be generally the case (Chapter 4), then $E[H] \simeq \theta$ regardless of the model assumed. As $2Nu \rightarrow \infty$, the infinite-alleles model implies $E(H) \rightarrow 1.0$, whereas the $k = 4$ model implies $E(H) \rightarrow 0.75$. The latter result is a simple consequence of four segregating alleles with equal frequencies (0.25) when the power of drift is overwhelmed by mutation. A number of other mutational models are possible, and a very general treatment is given by Cockerham (1984c), who also considered the transient approach to equilibrium.

As these drift-mutation models play a central role in the neutral theory of molecular evolution (Kimura 1983), substantial attention has been given to additional details that are obscured by the summary statistic of average heterozygosity. For example, θ is the expected average heterozygosity over a large number of loci; this is not likely to be exactly realized at any particular site. Because of the stochastic nature of both mutation and drift, the allele

frequencies at any neutral locus are expected to wander stochastically over time, with some loci being transiently fixed for one particular allele, and others being distributed over the remaining spectrum of allele frequencies. Kimura (1968a) obtained an expression analogous to Equation 2.8 for the complete probability distribution of the frequency of an allele under the symmetric mutation model described above, starting from an arbitrary allele frequency. Although this expression is quite complicated, a highly useful result is that regardless of the starting point, a steady-state distribution of allele frequencies p is eventually attained

$$\phi(p) = \frac{\Gamma(\theta + \beta)}{\Gamma(\theta)\Gamma(\beta)}(1 - p)^{\theta-1}p^{\beta-1} \quad (2.25a)$$

where $\theta = 4Nu$, $\beta = 4Nu/(k - 1)$, with

$$\Gamma(\alpha) = \int_0^\infty x^{\alpha-1}e^{-x}dx \quad (2.25b)$$

being the **gamma function** (Appendix 2). Equation 2.25a may be viewed as either the expected distribution of allele frequencies over all neutral loci within a single population in mutation-drift equilibrium or as the distribution of allele frequencies at a particular locus among replicate populations (or species) with identical N and u . Nei and Li (1976) presented the theory necessary for predicting the approach to the equilibrium state.

The expected value of any function of population allele frequencies (e.g., homozygosity) can be obtained by simply integrating the function over the density distribution $\phi(p)$. It is useful that Equation 2.25a defines a **beta distribution** (Appendix 2), as many of its properties are already well known. For example, the mean of the distribution, which is the expected allele frequency, is

$$E(p) = \frac{\beta}{\theta + \beta} = \frac{1}{k} \quad (2.26a)$$

and the allele-frequency variance among replicates is

$$\sigma^2(p) = \frac{\theta\beta}{(\theta + \beta)^2(\theta + \beta + 1)} = \frac{k - 1}{k^2[2Nuk(k - 1) + 1]} \quad (2.26b)$$

Expressions for the variance of heterozygosity for a population en route to equilibrium were derived by Li and Nei (1975) and Lessard (1981), and at equilibrium

$$\sigma^2(H) = \frac{2\theta[1 + (\theta/\ell)]}{[1 + \theta + (\theta/\ell)]^2[2 + \theta + (\theta/\ell)][3 + \theta + (\theta/\ell)]} \quad (2.27a)$$

where $\ell = k - 1$ (Stewart 1976). Note that as $k \rightarrow \infty$ (the infinite-alleles model),

$$\sigma^2(H) = \frac{2\theta}{(1 + \theta)^2(2 + \theta)(3 + \theta)} \quad (2.27b)$$

which reduces to about $\theta/3$ for $\theta \ll 1$.

Although the preceding results lead to predicted equilibrium allele frequencies, heterozygosities, etc., when viewed in isolation, such results obscure the long-term dynamics of neutral mutations. Given a population of size N , on average $2Nu$ new mutations arise per nucleotide site per generation, each with initial frequency $1/(2N)$. As noted earlier, the probability of fixation of a neutral allele is simply equal to its initial frequency, so that in the long run, at a neutral site, there is an average turnover rate of $2Nu \cdot 1/(2N) = u$ mutations per generation. This simple but powerful result tells us that the long-term rate of nucleotide substitution at a neutral site is equal to the mutation rate, *regardless of the size of the population*, a hallmark of the **neutral theory of molecular evolution** (Kimura 1983). This long-term flux occurs in the face of the maintenance of quasi-steady-state within-population

heterozygosity, which arises as a consequence of the per-generation balance between the loss of variation by fixation and replenishment by recurrent mutation.

Finally, Ohta and Kimura (1971) and Hill (1975) obtained expressions for the expected values of the two-locus moments described in Equation 2.20, under the infinite-alleles model at stochastic drift-mutation equilibrium. Letting $\rho = 4Nc$ and $\theta = 4Nu$, where c is the recombination rate between sites, and u is the mutation rate per site, Hill's expressions reduce to

$$\begin{aligned} E[p(1-p)q(1-q)] &= M(22 + 13\rho + 32\theta + \rho^2 + 6\rho\theta + 8\theta^2) \\ E[D(1-2p)(1-2q)] &= 8M \\ E[D^2] &= M(10 + \rho + 4\theta) \end{aligned} \quad (2.28a)$$

where

$$M = \theta^2 / [(\theta + 1)(18 + 13\rho + 54\theta^2 + \rho^2 + 19\rho\theta + 40\theta^2 + 6\rho\theta^2 + 8\theta)], \quad (2.28b)$$

and the standardized linkage disequilibrium is given by

$$E(r^2) = \frac{10 + \rho + 4\theta}{22 + 13\rho + 32\theta + \rho^2 + 6\rho\theta + 8\theta^2} \quad (2.29a)$$

As will be seen in Chapter 4, for individual nucleotide sites θ is generally substantially smaller than one, whereas for sites separated by hundreds of base pairs or more, ρ is generally greater than one. Under such conditions,

$$E(r^2) \simeq \frac{10 + \rho}{22 + 13\rho + \rho^2} \quad (2.29b)$$

which asymptotically approaches $1/\rho$ for large ρ . Additional theoretical points of interest were developed in Strobeck and Morgan (1978) and Golding and Strobeck (1980). A more daunting problem is obtaining expressions for the evolutionary variances of these statistics. As the components in Equation 2.28a already involve fourth-order moments of allele frequencies within and between loci, their variances are functions of moments up to the eighth order. Hill and Weir (1988) tackled this problem.

Example 2.7. A widely cited expression for $E(r^2)$ originates with Sved (1971; Feldman and Sved 1973), which we will refer to as

$$E(r_{IBD}^2) = \frac{1}{1 + 4Nc} = \frac{1}{1 + \rho}$$

Note that this expression is quite different from Equation 2.29a (as no terms for mutation appear), and also different from the approximation given by Equation 2.29b. To understand this discrepancy, it is useful to reflect on Sved's simple derivation, which focuses on a different measure of correlation than that outlined earlier. Conditional on two random gametes being identical by descent (IBD) from common ancestry at locus A, Sved wished to know the probability Q_{AB} that the alleles at locus B on both gametes are also IBD owing to the absence of recombination between the sites during the entire two pathways back to the common ancestor. With this definition in hand, Sved showed that $Q_{AB} = r_{IBD}^2$.

Let Q_t denote the value of joint IBD in generation t , and consider how this relates to Q_{t-1} , one generation in the past. For a population with size N , at any particular site a random pair of gametes will be direct copies of a gamete in the preceding generation with probability $1/(2N)$, and IBD will exist at both sites provided no recombination has occurred between them, the probability of which is $(1 - c)^2$, where c refers to the recombination rate. Alternatively, the two

sampled gametes will be drawn from different gametes leading to the preceding generation, the probability of which is $1 - 1/(2N)$. In the latter case, joint IBD will still exist if it happened to have been present for the two chromosomal segments in the preceding generation with no recombination again occurring in either. Summing up, the recursion equation for joint IBD is

$$Q_t = \frac{1}{2N}(1-c)^2 + \left(1 - \frac{1}{2N}\right)(1-c)^2 Q_{t-1}$$

Setting $Q_t = Q_{t-1}$ gives the equilibrium solution as

$$\tilde{Q} = \frac{1/(2N)}{1 - [1 - 1/(2N)](1-c)^2} \simeq \frac{1}{1 + 4Nc}$$

Although this is an equilibrium solution like Equations 2.29a and 2.29b, Sved's Q is not equivalent to the measure r^2 in these previous formulae, which are concerned with the long-term average disequilibrium associated with identity in state (IIS). Whereas IIS is a directly observable quantity, IBD is not, and hence there are interpretative problems when applying Sved's expression to empirical data. This is because parallel mutation can cause IIS for alleles that are not IBD, and secondary mutations can eliminate IIS for pairs of alleles that are otherwise IBD. Thus, although Sved's expression is widely used, apparently because of its simplicity, Equations 2.29a and 2.29b appear to be more appropriate for practical applications to observed molecular variation.

THE DETAILED STRUCTURE OF NEUTRAL VARIATION

Although heterozygosity provides a robust measure of genetic variation, as a summary statistic it obscures the details of the underlying structure of this variation, e.g., the number of alleles and their frequencies. Fortunately, at mutation-drift equilibrium, most of these features are just relatively simple functions of θ (Ewens 2004). There are, however, two alternative ways of thinking about molecular variation, each appropriate in a different context, and care must be taken in the interpretation of the mutation rate in each model. In one case, the **infinite-alleles** (or **infinitely many alleles**) model, the unit of observation is the locus (a stretch of DNA), whereas in the **infinite-sites** (or **infinitely many sites**) model, it is the nucleotide site. Results developed here are extensively used in Chapters 8 and 9 in methods for detecting departures from the **equilibrium neutral model**.

The Infinite-alleles Model and the Associated Allele-frequency Spectrum

The infinite-alleles model (briefly introduced earlier) was developed prior to the DNA-sequencing era, but was motivated by emerging knowledge on the structure of DNA sequences. In today's world, different alleles under this model are typically viewed as different sequences (**haplotypes**) over a region of L nucleotide sites, and the general assumption is that L is large enough that each mutation generates a new haplotype (not preexisting in the population), but small enough that recombination can be ignored (so that mutation is the sole generator of novel sequences). Considering the five short sequences in Figure 2.9, under the infinite-alleles framework, there are three different alleles, although there are only two segregating sites. With allele frequencies 0.4 (AAGACC), 0.4 (AAGGCC), and 0.2 (AAGGCA), the allelic heterozygosity of the sample is 0.64. This is, of course, a rather crude perspective, as it ignores the ways in which alleles differ from each other (in this example, two pairs of alleles differ at a single site, whereas one pair differs at two sites).

A	A	G	<u>A</u>	C	C
A	A	G	G	C	C
A	A	G	<u>A</u>	C	C
A	A	G	G	C	C
A	A	G	G	C	<u>A</u>

Figure 2.9 An example of the difference between the infinite-alleles and infinite-sites models. Five sequences (horizontal rows) scored at six nucleotide sites (vertical columns) are sampled from a population. Three of these five sequences are different and are scored as three alleles (or haplotypes) under an infinite-alleles framework (from top to bottom, sequences 1 and 3; 2 and 4; and 5). Conversely, only two of the six sites are segregating (from left to right, columns 4 and 6), giving two polymorphic sites under an infinite-sites framework.

A key parameter for the infinite-alleles model is the per-*locus* population mutation rate, $\theta_L = 4NuL$, which we distinguish from the more commonly used per-*site* measure, $\theta = 4Nu$, where u is the mutation rate per site. As noted previously, under neutrality, provided that the population has been at constant size long enough to be in mutation-drift equilibrium, the expected heterozygosity is given by Equation 2.24b, with $E(H) \approx \theta_L$ for $\theta_L \ll 1$. If the expected heterozygosity is small, a sample will often be **monomorphic**, consisting of only a single allele, or **dimorphic**, consisting of just two alleles. However, at higher levels of heterozygosity, multiple alleles can be expected, and a natural measure of variation is the number of different alleles in a sample. Insight into this quantity under drift-mutation equilibrium is given the probability of having k different alleles in a sample of n genes, which is

$$\Pr(k | \theta_L, n) = \frac{S_n^k \theta_L^k}{S_n(\theta_L)} \quad (2.30a)$$

where

$$S_n(\theta_L) = \theta_L(\theta_L + 1)(\theta_L + 2) \cdots (\theta_L + n - 1) \quad (2.30b)$$

and S_n^k is the coefficient on the θ_L^k term obtained by expanding the polynomial in Equation 2.30b (Ewens 1972). This formula opened up the field of formal statistical tests for whether a pattern of allelic variation is consistent with the equilibrium neutral model. For example, using Equation 2.30a, one can ask if an observed estimate of θ_L (obtained in this case as the allelic heterozygosity) is consistent with the observed number k of different alleles (Chapter 9).

Several useful results follow from Equation 2.30a. First, the probability of a monomorphic sample is

$$\Pr(k = 1) = \frac{(n - 1)!}{(\theta_L + 1)(\theta_L + 2) \cdots (\theta_L + n - 1)} \quad (2.31a)$$

Second, a bit of algebra gives the mean and variance for the number of alleles in a sample as

$$E(k) = 1 + \theta_L \cdot \sum_{j=2}^n \frac{1}{\theta_L + j - 1}, \quad \sigma^2(k) = \theta_L \cdot \sum_{j=1}^{n-1} \frac{j}{(\theta_L + j)^2} \quad (2.31b)$$

An even more complete description of the segregating allelic variation is given by the

allele-frequency spectrum, which describes the joint probability distribution of the *number of alleles* in the sample and their *frequencies*. Given that the numbering of alleles is arbitrary, the convention is to consider the vector (n_1, \dots, n_n) , where n_i denotes the number of alleles that have exactly i copies in the sample. If the sample is monomorphic, then $n_n = 1$, whereas if all n alleles are unique (**singletons**), $n_1 = n$. For the example data set in Figure 2.7, one allele appears as a singleton, whereas the other two alleles both appear as two copies, giving $n_1 = 1$, $n_2 = 2$, and $n_3, n_4, n_5 = 0$. The constraint on the n_i is that

$$\sum_{i=1}^n i \cdot n_i = n \quad (2.32)$$

A very powerful result, due to Ewens (1972) and Karlin and McGregor (1972), is that the joint probability distribution of n_1, \dots, n_n and k is given by the **Ewens sampling formula** (Ewens 1972)

$$\Pr(n_1, n_2, \dots, n_n, k | n) = \frac{n! \theta_L^k}{S_n(\theta_L) (1^{n_1} 2^{n_2} \dots n^{n_n}) n_1! n_2! \dots n_n!} \quad (2.33a)$$

Only nonzero values of n_i are included. The probability that the sample is monomorphic, Equation 2.31a, directly follows by setting $k = 1, n_1 = n$. Equations 2.30a and 2.33a show that the conditional distribution of n_1, \dots, n_n given k is

$$\Pr(n_1, n_2, \dots, n_n | n, k) = \frac{n!}{S_n^k (1^{n_1} 2^{n_2} \dots n^{n_n}) n_1! n_2! \dots n_n!} \quad (2.33b)$$

Note that the righthand side in Equation 2.33a is *independent* of θ_L . This property arises because k is a sufficient statistic for θ_L under the equilibrium neutral model, so that conditioning on k removes any dependence on θ_L . It is this independence that forms the basis of the Ewens-Watterson test of neutrality considered in Chapter 9.

The Infinite-Sites Model and the Associated Site-frequency Spectrum

An alternate framework for summarizing molecular variation is embodied in the **infinite-sites** model, which treats a region as a series of L sites. Each new mutation is again viewed as unique, but now occurring at a novel (not currently segregating) *site*, and as with the infinite-alleles model, recombination within the region is assumed to be insignificant. Because this model allows only a single mutation per site, a particular variant at a polymorphic site is either **ancestral** (original) or **derived** (mutated), and each segregating site is treated as biallelic. With sequence data from one or more outgroups, one can often **polarize** the nucleotides at any particular site, determining which is derived by assuming the outgroup harbors the ancestral state. In the absence of such information, the **minor-allele frequency**, the frequency of the rarest nucleotide, is reported for each site. In the following expressions, we will make use of both measures of the population mutation rate noted above, with $\theta_L = 4NuL = \theta L$.

The infinite-sites model offers a much richer set of information than can be achieved with the infinite-alleles model. One measure is the **number of segregating sites** S , i.e., the number of polymorphic sites in a sample (the loose analog to number of alleles). A second is the **nucleotide diversity** π , the average per-site heterozygosity within the region of interest. Finally, one can consider the **site-frequency spectrum**, the counterpart of the *allele*-frequency spectrum. In this case, instead of counting the number of times each allele appears in the sample, one considers the number of *sites* s_j in the sample with j copies of a nucleotide. The **unfolded frequency spectrum** refers to polarized nucleotides, with s_j being the number of sites with $j \leq n$ copies of the *derived* nucleotide. For a **folded frequency spectrum**, s_j is the number of sites with j copies of the minor nucleotide, with $j \leq n/2$.

For the example data set in Figure 2.9, four of the six sites are monomorphic, whereas site 4 has 3 Gs and 2 As, and site 6 has 4 Cs and an A. For a folded frequency spectrum, this

gives four sites in class 0, one site in class 1, and one site in class 2 (i.e., $s_0 = 4, s_1 = 1, s_2 = 1$). If the nucleotides were polarized, so that (for example) the ancestral states at the six sites were (respectively) A-A-G-G-G-A, the unfolded frequency spectrum would be three in class 0 (sites 1, 2, 3), one in class 2 (site 4), one in class 4 (site 6), and one in class 5 (site 5) (i.e., $s_0 = 3, s_2 = 1, s_4 = 1, s_5 = 1$). Many of the analyses using site-frequency spectrum data condition on only sites that are polymorphic in the sample.

For a very long region ($L \gg 1$) (again assuming neutrality, and mutation-drift equilibrium), the fraction of sites in the entire *population* that have a derived nucleotide at frequency x (for $0 < x < 1$) is given by the (unfolded) **Watterson (1975) distribution**,

$$\phi(x) = \frac{\theta}{x} \quad \text{for } \frac{1}{2N} \leq x \leq 1 - \frac{1}{2N} \quad (2.34a)$$

This tells us that under the neutral model most sites are expected to have a low frequency of derived nucleotides in the population. Reconfiguring Equation 2.34a for unpolarized alleles, so that $0 < x \leq 0.5$ where x is the minor-allele frequency, gives the **folded Watterson distribution**,

$$\phi(x) = \frac{\theta}{x} + \frac{\theta}{1-x} = \frac{\theta}{x(1-x)} \quad \text{for } \frac{1}{2N} \leq x \leq 1/2 \quad (2.34b)$$

The folded and unfolded frequency spectra are very similar over the range where both are defined ($0 < x \leq 0.5$), as high-frequency derived nucleotides are rare under the equilibrium neutral model, due to the fact that most new mutations are lost by drift.

The site-frequency spectrum for a *sample* is not the same as that for the entire population, but it follows from the Watterson distribution. In the case of an unfolded frequency spectrum, for a sample of size n , the number s_i of the L total sites with i derived nucleotides has the expected value

$$E(s_i) = \frac{\theta_L}{i}, \quad \text{for } 1 \leq i \leq n-1 \quad (2.35a)$$

(Fu 1995; Ewens 2004). Because $\theta_L = i E(s_i)$, Equation 2.35a motivates several infinite-site estimators of θ developed in Chapters 4 and 9. By using different regions of the site-frequency spectrum (i.e., different ranges for i) to estimate θ , various assumptions of the standard neutral model (e.g., constant population size, and absence of selection) can be tested (Chapter 9). Similarly, for a folded frequency spectrum, where s_i now denotes the number of sites with minor-nucleotide frequency i/n ,

$$E(s_i) = \frac{\theta_L}{i} + \frac{\theta_L}{n-i} = \frac{\theta_L n}{i(n-i)}, \quad \text{for } 1 \leq i \leq [n/2] \quad (2.35b)$$

where $[n/2]$ denotes the largest integer $\leq n/2$.

Although the expectations given by Equations 2.35a and 2.35b can be used for method-of-moments estimators of θ , likelihood estimators (LW Appendix 4) require the full distribution within a sample, not just the expected value. The probability of seeing exactly k derived nucleotides at a site with allele-frequency x follows from the binomial,

$$\Pr(k | x, n) = \binom{n}{k} x^k (1-x)^{n-k} \quad (2.36a)$$

In addition, the probability that a sample is polymorphic at a site with allele-frequency x is just one minus the probability of a sample monomorphic for either the derived (x^n) or the ancestral $(1-x)^n$ nucleotide,

$$\Pr(1 \leq k \leq n-1) = 1 - x^n - (1-x)^n \quad (2.36b)$$

The probability of seeing k derived nucleotides at a random site in a sample is the average of Equation 2.36a over the possible x values,

$$\Pr(k | n) = \binom{n}{k} \int_{1/(2N)}^{1-1/(2N)} x^k (1-x)^{n-k} \phi(x) dx \quad (2.36c)$$

where $\phi(x)$ is defined by Equation 2.34a. This formula, which forms the null model for several of the likelihood-based tests for a selective sweep (Chapters 8 and 9), is the infinite-sites analog to Ewens' sampling formula for the infinite-alleles model (both of which are functions of n and θ). Ewens' formula (Equation 2.30a) gives the probability that k alleles are seen in a sample of size n , whereas Equation 2.36c gives the probability that a randomly-chosen site is segregating k copies of a derived nucleotide. The latter formula also defines the probability of k copies of a minor nucleotide under the folded spectrum if Equation 2.34b is used for $\phi(x)$.

THE GENEALOGICAL STRUCTURE OF A POPULATION

The preceding analyses showed that a number of summary statistics, such as average levels of heterozygosity and linkage disequilibrium, are defined by the processes of drift, mutation, and recombination in predictable ways, at least for neutral sites. Provided we retain our focus on neutral regions of the genome, it is possible to go quite a bit further, even to the extent of predicting the expected *genealogical* relationships among different sequences sampled within populations. The basic theory, first laid out by Kingman (1982a 1982b) and now called **coalescent theory**, provides an elegant and powerful approach for solving problems in population genetics and molecular evolution. Kingman (2000) reviewed the historical origins of this approach, and detailed overviews can be found in Hudson (1990), Donnelly and Tavaré (1995), Fu and Li (1999), Nordborg (2001), Stephens (2001), Rosenberg and Nordborg (2002), Hein et al. (2005), and Wakeley (2006).

Because all of the genes within a population are direct products of past gametic sampling, they are all ultimately related in a genealogical sense. Thus, if one were to sample two alleles in a current population and then follow them back in time, both copies would eventually be traced to a single copy in an ancestral individual, at which point the two alleles are said to have **coalesced**. A key principle is that the form of the expected gene genealogy for neutral genes, in particular the expected coalescence time, is *completely independent of the mutational process*.

Consider a random sample of n alleles drawn from a current population, assumed to obey all the properties of the idealized Wright-Fisher model, and with no recombination within alleles. Focusing initially on just two of the sampled alleles, we first evaluate the probability that both members of the pair are direct copies of a single allele in the preceding generation. Assuming that each individual produces a large number of gametes, because there are $2N$ gene copies in the population in each generation, this probability is simply $1/(2N)$, whereas $\lambda_1 = 1 - (1/2N)$ is the probability that coalescence occurred at some earlier generation. Conditional on coalescence not having occurred in generation one, the probability of coalescence one further generation in the past is again equal to $1/(2N)$, yielding $\lambda_1(1/2N)$ as the unconditional probability of coalescence two generations back. This simple rule can be generalized to give the probability of coalescence exactly t generations in the past,

$$P_c(t) = \lambda_1^{t-1}(1/2N) \quad (2.37)$$

which defines a **geometric distribution**, with the sum of $P_c(t)$ over the interval $t = 1$ to ∞ being equal to one. One simple related point is that the probability that the **most recent common ancestor (MRCA)** between two sampled alleles occurred within the last t generations is $1 - \lambda_1^t \simeq 1 - e^{-t/2N}$, namely one minus the probability of no common ancestor over the first t generations into the past.

The mean coalescence time for two randomly sampled genes is simply

$$\bar{t}_c(2) = \sum_{t=1}^{\infty} t \cdot P_c(t) = 2N \quad (2.38)$$

Thus, the expected number of generations required for any two random alleles to trace back

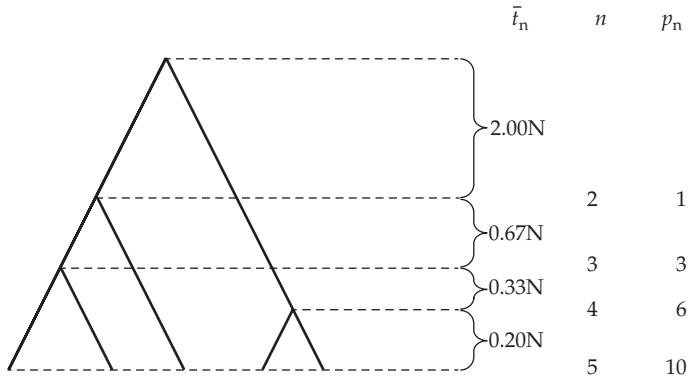

Figure 2.10 Expected coalescence times, \bar{t}_n , for a sample of $n = 5$ neutral genes taken from an idealized Wright-Fisher population of size N . The number of gene pairs in each consecutive step of the coalescent process is denoted by p_n , and the expected times to coalescence at each step are equal to $2N/p_n$ generations. The particular lineages that join during each step are arbitrary. Note that over half of the coalescent time for the total lineage of five samples involves the coalescent event between the final two branches.

to an ancestral copy is simply equal to twice the population size (more precisely, twice the effective population size, as will be defined in Chapter 3).

The logic used to derive this result is easily extended to the entire sample of n gene copies. There are $p_n = n(n - 1)/2$ possible pairs of n copies, each of which will or will not coalesce in the preceding generation with respective probabilities $1/(2N)$ and $[1 - (1/2N)]$. If the sample size is much smaller than the population size, the probability of coalescence for any pair in the sample in the preceding generation is simply the product $p_n/(2N)$. Thus, the probability distribution for the coalescence time of one pair within a set of n sequences is

$$P_c(p_n, t) = [1 - (p_n/2N)]^{t-1} [p_n/(2N)] \quad (2.39)$$

Namely, a geometric random variable with success parameter $(p_n/2N)$. The mean time to coalescence of the first pair is then $2N/p_n$ generations (as opposed to $2N$ generations with a single pair). Because at this point two copies have coalesced into one, the sample size has been reduced by one, and the mean time to coalescence of the next pair is found by resetting p_n to $p_{n-1} = (n - 1)(n - 2)/2$. This procedure can be followed recursively down to the final pair ($p_n = 1$), which again has an expected coalescence time of $2N$ generations (Figure 2.10). The implication of these results is that the expected time for merging n random lineages into $n - 1$ lineages,

$$\bar{t}_n = 2N/p_n = \frac{4N}{n(n - 1)} \quad (2.40)$$

increases with decreasing sample size.

The total expected genealogical depth of a sample, obtained by summing the expectations of each coalescence event, is

$$\bar{t}_c(n) = \sum_{i=2}^n \frac{4N}{i(i - 1)} = 4N \left(1 - \frac{1}{n} \right) \quad (2.41)$$

Thus, under neutrality, the expected time to the most recent common ancestor of all alleles residing at a locus is $\simeq 4N$ generations. This is equivalent to the mean time to fixation of a neutral mutation, as can be verified by substituting $p_0 = 1/(2N)$ into Equation 2.11b.

Notably, the expected distance between the final two nodes in a neutral coalescent tree, $2N$, is at least half the coalescence time for the entire sample. Unfortunately, this fundamental issue is commonly ignored by those who invoke deep splits in a gene genealogy as evidence of an adaptive event.

It is important to note that all of the results in this section were derived without regard to any underlying genetic features of the sampled alleles. However, having determined the expected genealogical features of neutral gene sequences, it is straightforward to incorporate genetic issues, as mutations will arise randomly along the branches of the genealogy in numbers proportional to time. For example, given the average $2N$ generations separating two randomly sampled alleles, the average number of mutations separating such genes is $2 \cdot 2N \cdot u = 4Nu$, the two arising because each copy is $2N$ generations removed from the common ancestor. The actual number of mutations for any realization follows a Poisson distribution, so for this example, the probability that no mutations have arise is e^{-4Nu} .

One of the primary uses of the coalescent derives from its ability to efficiently generate sample distributions of quantities of interest (e.g., the expected pattern of molecular variation among neutral alleles), which provides a formal basis for statistical tests of various evolutionary models (Hudson 2002), including those involving selection (Chapter 9). Although all of the preceding results simply refer to the *expected* coalescent times, each individual coalescence time has considerable evolutionary variance, being equal to the square of its expected value (a feature of geometric distributions). As will be discussed in Chapter 9, a number of useful results have been obtained on the sampling distributions of coalescents, but it is also straightforward to obtain such information by using computer simulations to construct random genealogies. For each simulated sample, one starts with n distinct lineages, picks two at random, and generates a value for t_n by randomly drawing from an exponential distribution with mean value given by Equation 2.40. After these two samples are joined in the coalescent tree, the remaining sample of $n - 1$ distinct lineages is treated in the same way to generate a value of t_{n-1} , and so on, until the last two remaining lineages coalesce to yield t_2 . For each branch of the resultant tree, the number of mutations is then drawn using a Poisson distribution with an expectation equal to the product of the mutation rate and the length of the branch (in generations), e.g., the two branches emanating from the first node have independent numbers of mutations with expectation ut_n . By repeating such **coalescent simulations** several thousands of times, a distribution of interallelic variation under mutation and drift can then be acquired for any mutational model of interest, with the resultant data providing a null model for various tests of selection based on the pattern of variation in an actual sample (Chapter 9).

MUTATION-MIGRATION-DRIFT EQUILIBRIUM

Populations are often structured in space, with distinct **demes** connected by migration to form a **metapopulation**. The joint forces of mutation, migration, and drift structure the genetic variation both within and among demes, and if kept constant eventually lead to equilibrium values. The equilibrium neutral results serve as the framework for tests of abnormally high or low amounts of among-population variation (Chapter 9), corresponding respectively to diversifying and stabilizing selection.

Quantifying Population Structure: F_{ST}

The classic measure of population structure, F_{ST} , was defined by Wright (1943, 1951) as the correlation (identical by descent status) between alleles in different individuals from the same subpopulation. F_{ST} is a measure of the amount of inbreeding introduced by the population structure, relative to what would be expected in one large panmictic population. Effectively, F_{ST} measures the fraction of total genetic variance due to differences between subpopulations (indeed, S stands for subpopulation and T for total population). This directly follows from the standard ANOVA (analysis of variance) identity that the among-group component of variance equals the within-group covariance (LW Chapter 18),

with the latter equal to the correlation among group members times the total variance. In particular, consider the distribution of the allele frequencies for a biallelic locus (with alleles B and b) over a set of populations. If p_0 denotes the average frequency of B over this set, the allelic variance for the total metapopulation is just $p_0(1 - p_0)$. F_{ST} is then defined as the fraction of the total variance attributable to the variance in the frequency of allele B among demes, $\sigma^2(p)$,

$$F_{ST} = \frac{\sigma^2(p)}{p_0(1 - p_0)} \quad (2.42)$$

Wright was somewhat ambiguous in his use of F_{ST} , and some confusion has surrounded various interpretations of its true meaning. These issues were nicely cleaned up by Balding (2003).

Recalling Equation 2.14, which gives the expected variance in the allele frequency between two populations separated from a common ancestor t generations in the past (ignoring mutation and assuming no migration among groups), we have that

$$F_{ST} = \left[1 - \left(1 - \frac{1}{2N_e} \right)^t \right] \simeq \frac{t}{2N_e} \quad \text{for } t \ll N_e \quad (2.43)$$

Under this model, F_{ST} eventually increases to one, as in the absence of mutation, drift eventually removes all variation within groups, with the different demes becoming randomly fixed for alternative alleles.

With recurrent mutation and gene flow among demes, however, neither the within- nor the among-population variation is ever expected to reach absolute zero, and F_{ST} will be in the $(0,1)$ interval, with its magnitude depending on the relative impact of the three contributing forces (mutation, migration, and drift). A variety of methods, including extensions to multiple alleles, have been developed for estimating F_{ST} from samples of alleles from multiple subpopulations under the assumption of the infinite-alleles model (Nei and Chesser 1983; Weir and Cockerham 1984; Weir and Hill 2002; Balding 2003), and others allow for highly mutable alleles with a significant chance of back mutation (Slatkin 1995a; Goodman 1997).

A result of great conceptual utility is that F_{ST} values are closely related to the average coalescence times of alleles within subpopulations, \bar{t}_0 , and of alleles drawn randomly from the entire metapopulation, \bar{t} ,

$$F_{ST} = \frac{\bar{t} - \bar{t}_0}{\bar{t}} = 1 - \frac{\bar{t}_0}{\bar{t}} \quad (2.44)$$

(Slakkin 1991). If \bar{t}_0 is very close to \bar{t} , there is little among-group differentiation, as pairs of alleles within groups have essentially the same amount of time to diverge mutationally as those among groups. Because the coalescent structure of a population simply represents a genealogical sampling process and is independent of the mutations that incidentally arise, Equation 2.44 shows that the equilibrium level of population subdivision is also independent of the mutation process.

Mutation-migration-drift Equilibrium Values of F_{ST}

When migration rates are sufficiently high that essentially all demes exchange at least one individual per generation, the physical structure of the metapopulation has no consequences for population subdivision at the genetic level, i.e., $F_{ST} \simeq 0$. When the forces of mutation, migration, and drift operate simultaneously at moderate levels, some intermediate equilibrium level of among-population differentiation is reached such that the loss of new variants within demes by drift is balanced by the spread of novel variants across demes by mutation. As one might expect, the resultant equilibrium F_{ST} value is a function of the population size within each deme and the pattern of migration over demes, so there are essentially endless numbers of possible patterns of spatial structure and migration. To make some general points, we will consider two commonly envisioned situations (Figure 2.11).

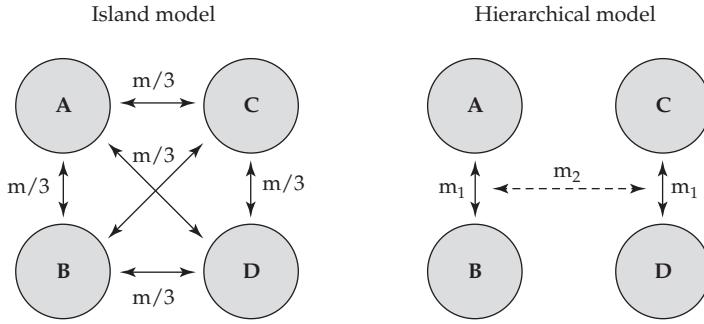

Figure 2.11 (Left) The island model. Most mating occurs within each subpopulation/deme, but some small amount of equally partitioned migration m occurs between them. Hence, a migrant from deme A is equally likely to end up in demes B through D. (Right) A hierarchically-structured population. Here, intragroup migration (between A and B, and between C and D, m_1) occurs at a much higher level than migration between these two groups (m_2).

The simplest structure is Wright's (1951) **island model**, wherein the population consists of d demes, each containing N breeding individuals. Each generation, each deme contributes a fraction m of its genes to a migrant pool, yielding an expected migration rate from any deme to any other of $m/(d - 1)$. A remarkable feature of this model is that the equilibrium amount of genetic variation expected within demes is independent of the level of population subdivision (assuming $m > 0$), a feature known as the **geographic invariance principle** (Maruyama 1971; Nagylaki 1982). Provided there is some potential migratory route between all demes, regardless of the level of migration, the mean coalescence time between random pairs of genes within demes is

$$\bar{t}_0 = 2Nd \quad (2.45a)$$

generations, i.e., twice the sum of the demic population sizes (Li 1976; Strobeck 1987; Hey 1991; Nagylaki 2000). Under this model, the independence of the within-deme variation of the migration rate arises because a lower rate of migration encourages a higher rate of allelic divergence, resulting in a balance between these two opposing factors (frequency and impact of immigrant alleles).

On the other hand, the mean coalescence time for two genes randomly drawn from the *entire* metapopulation is

$$\bar{t} = 2Nd + \frac{(d - 1)^2}{2dm} \quad (2.45b)$$

(Li 1976; Slatkin 1991; Nei and Takahata 1993), which is the sum of the previous term and the additional time required for alleles to coalesce into the same deme. Unlike the amount of variation *within* demes, the differentiation *among* demes clearly depends on m . Substituting Equations 2.45a and 2.45b into Equation 2.44 yields

$$F_{ST} = \frac{1}{1 + 4N \frac{md^2}{(1 - d)^2}} \simeq \frac{1}{1 + 4Nm} \quad \text{for } d \gg 1 \quad (2.46)$$

This again shows that the equilibrium level of population subdivision is completely independent of the mutation rate and largely independent of the number of demes (d), provided the latter is at least moderately large.

This type of framework for interpreting F_{ST} is readily extended to populations with a **hierarchical** structure (Figure 2.11). In the simplest hierarchical model, the metapopulation

is arranged into a series of g groups, each of which is further subdivided into d demes. Within each group, the demes exchange migrants according to the island model with total rate of m_1 (so that $m_1/[d - 1]$ is the rate at which each deme sends migrants to any other particular deme within its group). By definition, there is less frequent exchange of migrants between the different groups, i.e., $m_2 < m_1$. With this type of structure, it is necessary to consider the degree to which the total genetic variation partitions into three components: within demes, among demes within a group, and among groups.

Each of these components can again be expressed in terms of coalescence times. Let \bar{t}_0 be the mean coalescence time for two individuals from the same deme, \bar{t}_1 for two individuals from the same group but different demes, and \bar{t}_2 for two individuals from different groups. As with the island model, the geographic invariance principle gives the mean coalescence time for two individuals from the same deme as $\bar{t}_0 = 2Ngd$, i.e., twice the total population size. In order for two individuals in the same group but different demes to coalesce, they must first trace back to the same deme, which for $m_1 \ll m_2$ requires approximately $t'_1 \simeq g(d - 1)/(2m_1)$ generations (from the second term in Equation 2.45b), and then take an additional \bar{t}_0 generations to coalesce within that deme, giving $\bar{t}_1 = t'_1 + \bar{t}_0$ (Slatkin and Voelml 1991). Finally, for individuals from different groups to coalesce, they first must trace back to the same group, which requires an average of $t'_2 \simeq (g - 1)/(2m_2)$ generations, then trace back to the same deme within a group (t'_1), and finally coalesce within that deme, giving $\bar{t}_2 = t'_2 + t'_1 + \bar{t}_0$.

Using these results, three hierarchical F statistics define the partitioning of the total population variation: F_{DG} among demes within groups, F_{GT} among groups within the total population, and F_{ST} among demes within the total population:

$$\begin{aligned} F_{DG} &= \frac{\bar{t}_1 - \bar{t}_0}{\bar{t}_1} \\ F_{GT} &= \frac{\bar{t}_2 - \bar{t}_1}{\bar{t}_2} \\ F_{ST} &= \frac{\bar{t}_2 - \bar{t}_0}{\bar{t}_2} \end{aligned} \quad (2.47a)$$

(Slatkin and Voelml 1991; Excoffier et al. 2009b). Substituting in the values for the various mean coalescence times noted previously, and assuming d and g moderately large and $m_2 \ll m_1$, results in further simplification,

$$\begin{aligned} F_{DG} &\simeq \frac{1}{1 + 4Nm_1} \\ F_{GT} &\simeq F_{ST} \simeq \frac{1}{1 + 4Ndm_2} \end{aligned} \quad (2.47b)$$

Note that these expressions are equivalent in form to that for the simple island model, in this case with the demic population size (N) determining the variation of demes within groups and group size (Nd) determining that for groups within the total population. Such coalescence approaches are readily extended to much more complex situations (e.g., Nordborg 1997; Nagylaki 1998; Pannell and Charlesworth 2000; Pannell 2003).

3

The Genetic Effective Size of a Population

However, any theory which one finds uncomfortable but for which one cannot say exactly why, deserves serious consideration. Such an uncomfortable feeling signals a challenge to one or more of one's unexamined, and perhaps unjustified, assumptions. Van Valen (1976)

Throughout the preceding chapter, we assumed a population with an idealized set of Wright-Fisher features, including random mating within a homogeneous group of monoeccious, self-compatible individuals with equal expected family sizes, discrete generations, and an absence of density fluctuations. Because almost all populations deviate from this ideal structure in one or more ways, and often substantially so, the relevance of the resultant theory might then seem in doubt. In fact, much of the theory of inbreeding and random genetic drift can be generalized to other types of population structures to a good approximation in a relatively simple manner. To accomplish this task, instead of relying on the total number of adult individuals (N) as a measure of population size, we construct a surrogate index that takes into account the deviations from the ideal model from a genetic perspective. Following the influential work of Wright (1931, 1938a, 1939), such an index has become widely known as N_e , the **effective population size**. With such a reparameterization, essentially all of the results in the preceding chapter hold when N_e is substituted for N . Buri's experiment (Chapter 2) is a case in point—a set of populations with actual size $N = 16$ exhibited allele-frequency dynamics closely approximated by the expectations for an idealized Wright-Fisher population with an effective size of just ten individuals.

Because of its central role in defining levels of variation within populations, the rate of divergence among populations, and the efficiency of natural selection, N_e is one of the most important parameters in population genetics. Although N_e is not as easily measured as the total (census) population size, as will be seen in the following sections, it is, at least in part, defined by observable demographic and mating-system properties of populations (Latter 1959; Lande and Barrowclough 1987; Crow and Denniston 1988). A central goal of this chapter is to illustrate that nearly every violation of the assumptions underlying the Wright-Fisher model leads to a reduction in N_e relative to N , thereby implicating a stronger role for genetic drift in evolution than might be surmised from estimates of total population sizes. We will progressively consider aspects of the mating system (including the possibility of self-fertilization, variation in the sex ratio, and variance in family size), age structure, temporal variation, and spatial structure.

In addition, we will show that the effective size of a population is often strongly influenced by the structural aspects of genomes, independent of population demographic features. The physical linkage of genes on chromosomes ties their mutual fates together, creating stochastic fluctuations of allele frequencies out of chance associations with other loci under selection. Thus, chromosomally regional variation in recombination rates and selection has the effect of creating variation in N_e among different loci in the same population. Tight linkage to a deleterious mutation can result in the loss of an otherwise neutral or beneficial allele from the population, whereas tight linkage to a beneficial mutation can result in hitchhiking to fixation.

This chapter focuses entirely on the concept of N_e from a theoretical perspective, with a goal of providing the reader with a qualitative understanding of the mechanistic determinants of this key population-genetic parameter. Chapter 4 will provide an overview of methods for the estimation of N_e using molecular markers in natural populations, which require no knowledge of a population's demographic features. A more thorough review of a number of the topics that we touch upon can be found in Caballero (1994), and although

we focus on autosomal loci, the general principles are readily extended to sex-linked loci (Caballero 1995; Nagylaki 1995; Wang 1997; Charlesworth 2001).

GENERAL CONSIDERATIONS

An appreciation for the concept of effective population size can be gained by recalling that all members of an ideal monoecious population (consisting of hermaphrodites capable of random self-fertilization) contribute equally to the total gamete pool, with each successful gamete uniting randomly with another gamete derived from the total population of N individuals. Under these conditions, the probability that two uniting gametes are derived from the same parent is simply $P = 1/N$. However, many factors, including self-incompatibility, limited dispersal, differential productivity of gametes, and selection, can cause P to deviate from $1/N$. To account for the joint influence of all of these factors and many others, we define P to be the reciprocal of the effective population size.

Using this definition of $N_e = 1/P$, many of the results in the previous chapter can be generalized, at least to a first-order approximation. Consider, for example, the expected dynamics of the inbreeding coefficient for a diploid, monoecious population. The probability that two uniting gametes are derived from the same parent is now $1/N_e$, in which case there is a 50% chance that they each carry copies of the same gene (i.e., they are identical by descent, one generation removed) and a 50% chance that they carry copies of genes from different parental chromosomes. In the latter case, the uniting genes may still be identical by descent from previous inbreeding with probability f_{t-1} . Finally, there is a $1 - (1/N_e)$ probability that the uniting gametes are derived from different parents, in which case there is again a probability f_{t-1} that they are identical by descent from previous inbreeding. (Here, we are assuming a population without spatial structure, so that the mean degree of inbreeding does not depend on the parental source of alleles.) Summing up the three ways by which identity-by-descent can arise between uniting gametes,

$$\begin{aligned} f_t &= \left(\frac{1}{N_e}\right)\left(\frac{1}{2}\right) + \left(\frac{1}{2}\right)\left(\frac{1}{N_e}\right)f_{t-1} + \left(1 - \frac{1}{N_e}\right)f_{t-1} \\ &= \frac{1}{2N_e} + \left(1 - \frac{1}{2N_e}\right)f_{t-1} \end{aligned} \quad (3.1)$$

This expression is identical in form to Equation 2.3, but with N_e replacing N .

Under the above interpretation, N_e is the size of an ideal population that would exhibit the same amount of inbreeding as the population under consideration. Defined in this way, N_e is the **inbreeding effective size**. There are, however, numerous additional ways to define the effective size of a population. One can, for example, define the **variance effective size** as the N that, when applied to Equation 2.14a, yields the temporal variance in allele-frequency change exhibited by a nonideal population. Crow (1954) emphasized that the inbreeding effective size is most closely related to the number of parents (or the number of grandparents if selfing does not occur) because it is based upon the probability of uniting gametes coming from the same ancestor. In contrast, the variance effective size, which is associated with allele-frequency drift resulting from gamete sampling, is primarily a function of the number of offspring produced. Thus, in an expanding or declining population, the rates of inbreeding and allele-frequency drift can differ in any particular generation (Templeton 2006). However, for populations with stable size, inbreeding and variance effective sizes are generally equivalent, and in the long run this is even true for fluctuating populations because both measures depend on the same sequence of adult population sizes (Caballero 1994; Whitlock and Barton 1997). More discourse on these issues may be found in Crow and Morton (1955), Kimura and Crow (1963b), Crow and Kimura (1970), Crow and Denniston (1988), and Caballero (1994). Unless stated otherwise, the following discussion will assume populations of constant size.

Before proceeding, it bears emphasizing that random genetic drift is a result of two

stochastic processes. First, in sexual species, segregation during meiosis leads to the random transmission of alleles from heterozygous parents, as there is a 50% chance for each alternative allele to be inherited by any given offspring. Second, variation in family size encourages lineages of alleles that happen to be contained within large families to expand at the expense of others. As we will see in the following sections, such variation arises by numerous mechanisms, including simple sampling of gametes, spatial population structure, variation among the sexes, and trapping in various genetic backgrounds by linkage.

MONOECY

To illustrate the mathematical approach to deriving expressions for N_e , we first generalize the concept of a monoecious, self-compatible population to allow for arbitrary gamete production by different individuals. As a reminder, monoecious (a botanical term) individuals are equivalent to hermaphrodites (a zoological term), with both terms referring to the situation in which individuals produce male and female gametes.

Let k_i be the number of gametes that the i th parent contributes to offspring that survive to maturity, μ_k and σ_k^2 be the mean and variance of successful gamete production per individual, and N_{t-1} be the number of reproducing parents. Assuming that mating is random and **isogamous** (so that there is no distinction between male and female gametes), there are $k_i(k_i - 1)$ ways in which the gametes of parent i can unite with each other, and summing over all parents, $\sum_{i=1}^{N_{t-1}} k_i(k_i - 1)$ total ways by which gametes can unite by self-fertilization. Because a total of $N_{t-1}\mu_k$ successful gametes are produced, the expected fraction of zygotes derived from the same parent is

$$P_t = \frac{1}{N_e} = \frac{\sum_{i=1}^{N_{t-1}} k_i(k_i - 1)}{N_{t-1}\mu_k(N_{t-1}\mu_k - 1)} \quad (3.2)$$

where the denominator is the total number of pairs of uniting gametes necessary to produce the next generation. This expression can be simplified greatly by noting that $\sum_{i=1}^{N_{t-1}} k_i(k_i - 1)/N_{t-1} = E(k^2) - \mu_k = \sigma_k^2 + \mu_k(\mu_k - 1)$, and that because all zygotes are derived from two gametes, $N_{t-1}\mu_k = 2N_t$. Substituting into Equation 3.2 and inverting,

$$N_e = \frac{2N_t - 1}{(\sigma_k^2/\mu_k) + \mu_k - 1} \quad (3.3)$$

This shows that for a randomly mating monoecious population with discrete generations, the effective population size is a function of three measurable quantities: the actual population size (N_t) and the mean (μ_k) and variance (σ_k^2) of successful gamete production. All other things being equal, variance in gamete production causes a reduction in N_e , as this inflates the representation of a fraction of the population in the descendant gene pool. Because such variation is expected to be the rule in natural populations occupying environments that are heterogeneous with respect to resource availability, on this basis alone, we can generally expect N_e to be less than the number of reproducing adults.

Equation 3.2 simplifies greatly under a number of conditions. For example, populations that are stable in size have, on average, two successful gametes per parent ($\mu_k = 2$), leading to

$$N_e = \frac{4N - 2}{\sigma_k^2 + 2} \quad (3.4)$$

If we further assume that each parent produces the same number of *potential* gametes (returning us to the ideal random-mating population), an explicit statement can also be made about σ_k^2 . In this case, for any particular draw from the gamete pool, the variance in the number of gametes derived from a particular parent (0 or 1) is $(1/N)[1 - (1/N)]$

(from the properties of a binomial distribution), and because a total of $2N$ gametes are drawn, $\sigma_k^2 = 2[1 - (1/N)]$. Note that this result is very close to the Poisson expectation of $\sigma_k^2 = 2$ with completely random gamete production (because the variance of a Poisson equals the mean), with the slight deviation resulting because we assume a fixed population size. Substitution of the exact expression into Equation 3.4 yields $N_e = N$, showing that the inbreeding effective size of an ideal random-mating population is indeed equal to the number of reproductive adults in the previous generation.

In contrast, in the opposite, and extreme, situation in which all parents produce *exactly* two progeny (such that $\sigma_k^2 = 0$ and $\mu_k = 2$), $N_e = 2N - 1 \simeq 2N$. This shows that the elimination of variance in family size results in the effective population size being twice the actual number of breeding adults, a feature that is often exploited in breeding schemes to minimize the amount of inbreeding.

There are a number of ways in which the breeding systems of a monoecious species can deviate from the assumptions made in the preceding derivations. Consider, for example, species with self-incompatibility, in which case identity-by-descent for pairs of uniting gametes comes through grandparents rather than parents. If we now let k_i be the number of successful gametes for individual i in generation $t - 2$, and again assume random mating, there are $2k_i(k_i - 1)$ ways in which pairs of genes from i can unite through matings in the parental generation $t - 1$ (the 2 arising because we assume that each individual can serve as a mother or father). Because there are $N_{t-2}\mu_k/2$ parents in generation $t - 1$, there are $2(N_{t-2}\mu_k/2)[(N_{t-2}\mu_k/2) - 1]$ ways of drawing different parents, and $4 \cdot 2(N_{t-2}\mu_k/2)[(N_{t-2}\mu_k/2) - 1]$ ways of drawing gene pairs (the 4 because each parent carries two genes). Therefore, the probability that a generation- t individual carries a pair of genes derived from the same grandparent is

$$P_t = \frac{1}{N_e} = \frac{\sum_{i=1}^{N_{t-2}} k_i(k_i - 1)}{N_{t-2}\mu_k(N_{t-2}\mu_k - 2)} \quad (3.5)$$

Employing the same kinds of substitutions used for Equation 3.3,

$$N_e = \frac{2(N_{t-1} - 1)}{(\sigma_k^2/\mu_k) + \mu_k - 1} \quad (3.6)$$

and for constant N (which implies $\mu_k = 2$),

$$N_e = \frac{4(N - 1)}{\sigma_k^2 + 2} \quad (3.7)$$

For populations that are moderately large and stable in size, Equations 3.4 and 3.7 give essentially the same answer, $N_e \simeq 4N/(\sigma_k^2 + 2)$, demonstrating that the prohibition of selfing has a negligible influence on N_e unless the total population size is tiny. The reason for this is that under random mating the increment in inbreeding resulting from self-fertilization is a transient event that can be completely undone in the following generation.

A second potential complication is that in most hermaphroditic species, there is a distinction between male and female gametes (**anisogamy**), so that even with selfing, only a fraction of potential gamete pairs are capable of spawning a successful zygote. When mating is random but selfing is prohibited, the effective population size is the same under isogamy and anisogamy, and Equation 3.6 still applies (Crow and Denniston 1988). However, with selfing permitted,

$$N_e = \frac{N_{t-1}}{(4\sigma_{o,p}/\mu_k^2) + 1} \quad (3.8)$$

where $\sigma_{o,p}$ is the covariance of the numbers of successful male (p , pollen) and female (o , ovule) gametes per parent (Crow and Denniston 1988). If $\sigma_{o,p}$ is positive, as might be

expected in a spatially heterogeneous environment where some individuals acquire more resources than others, the effective population size will be less than the observed size. However, if $\sigma_{o,p}$ is negative, as might be expected when there is a trade-off between male and female function, N_e can exceed N_{t-1} . This results because a negative covariance in male and female gamete production reduces the variance in family size.

Example 3.1. Hedgecock (1994) suggested that marine organisms with high fecundities and broadcast spawning may have effective population sizes that are orders of magnitude smaller than the absolute number of potential breeders. This situation can arise if vagaries in oceanographic conditions are such that only a small fraction of adults produce gametes at points in time and space that allow recruitment to the next generation. Suppose the total adult population size is N , whereas only N_p individuals contribute equally to the breeding pool. Such a situation is sustainable if reproductive adults can individually produce an average of $2N/N_p$ gametes (and many marine species are capable of producing many tens of thousands of gametes). Given such a situation, N_p individuals have expected family sizes of $2N/N_p$, whereas $(N - N_p)$ have zero expected reproductive success, which results in an expected family-size variance among all N individuals of $4[(N/N_p) - 1]$ (Hedrick 2005). Using the logic outlined in the paragraph below Equation 3.4, the additional variance in reproductive success among spawning individuals resulting from random gamete sampling is equal to

$$\left\{ \left(\frac{N_p}{N} \right) \cdot 2N \cdot \left(\frac{1}{N_b} \right) \left[1 - \left(\frac{1}{N_b} \right) \right] \right\} + \left\{ \left[1 - \left(\frac{N_b}{N} \right) \right] \cdot 2N \cdot 0 \right\} = 2 \left[1 - \left(\frac{1}{N_b} \right) \right]$$

Summing these two sources of family-size variance gives $\sigma_k^2 = [(4N - 2)/N_p] - 2$, and substituting into Equation 3.4, we obtain $N_e = N_p$. Thus, provided a species has a high enough gamete production to generate N surviving progeny from a small number of adults, the effective population size can be only a tiny fraction of N .

Example 3.2. Heywood (1986) estimated that σ_k^2/μ_k^2 for seed production is on the order of 1 to 4 in a number of annual plants (including self-compatible species). Unfortunately, the value of σ_k^2 for total gamete production requires additional information on successful pollen production, which is extremely difficult to acquire due to problems in ascertaining paternity. For heuristic purposes, however, let us assume a stable monoecious population. This necessarily implies mean seed and pollen production are both equal to one, and $\mu_k = \mu_o + \mu_p = 2$, as each parent must produce two successful gametes (on average, one male and one female). We will also assume a three-fold higher standard deviation for successful pollen relative to seed production, so that $\sigma_p = 3\sigma_o$, and a perfect correlation between ovule and pollen production. Because the correlation between the number of female and male gametes produced per individual is defined to be $\sigma_{o,p}/(\sigma_o\sigma_p)$, the latter assumption implies $1 = \sigma_{o,p}/[\sigma_o \cdot 3\sigma_o]$. Assuming random mating, and substituting $\sigma_{o,p} = 3\sigma_o^2$ into Equation 3.8, we obtain $N_e = N/[(12\sigma_o^2/\mu_k^2) + 1]$. Thus, for σ_o^2/μ_k^2 in the range of 1 to 4, N_e is between 2% and 8% of the census number (N).

DIOECY

As in the case of monoecy with self-incompatibility, when the sexes are separate, inbreeding always needs to be defined with reference to the grandparent generation, which is the earliest point back to which the two genes of an individual can coalesce. Separate sexes also introduce the possibility of different levels of inbreeding through males and females,

as might be expected, for example, in polygynous species in which most females mate with a relatively small segment of the male population.

If O is the offspring of interest, with M and F being its mother and father, there are two ways by which O may derive two genes from the same grandparent: (1) M and F may share the same mother (with probability $1/N_{ef}$, where $1/N_{ef}$ is the effective number of females); or (2) M and F may share the same father (with probability $1/N_{em}$, where $1/N_{em}$ is the effective number of males). In either case, because each parent transmits to O a gene from the shared ancestor with probability 0.5, the probability that O inherits both genes from the shared grandparent is $1/4$. Thus, the total probability that O inherits two genes from the same grandparent is

$$P = \frac{1}{N_e} = \frac{1}{4N_{em}} + \frac{1}{4N_{ef}} \quad (3.9)$$

What do we mean by the effective numbers of males and females? Assuming random mating (including no prohibition of mating between sibs), the effective number of each sex can be derived by the same method used to obtain Equation 3.3. Skipping the intermediate steps, we simply note that

$$N_{es} = \frac{\mu_{sk} N_{s,t-2} - 1}{(\sigma_{sk}^2 / \mu_{sk}) + \mu_{sk} - 1} \quad (3.10)$$

where s denotes the sex (m or f), and μ_{sk} and σ_{sk}^2 are the mean and variance of gamete production by sex s (Crow and Denniston 1988). Latter (1959) provided a more elaborate expression for N_{es} that explicitly accounts for the variance and covariance of male and female progeny production. Letting ϕ be the sex ratio (proportion of females),

$$N_{em} = \frac{4N_{m,t-2}}{2 + \sigma_{mm}^2 + \frac{2(1-\phi)}{\phi} \sigma_{mm,mf} + \left(\frac{1-\phi}{\phi}\right)^2 \sigma_{mf}^2} \quad (3.11a)$$

$$N_{ef} = \frac{4N_{f,t-2}}{2 + \sigma_{ff}^2 + \frac{2\phi}{1-\phi} \sigma_{fm,ff} + \left(\frac{\phi}{1-\phi}\right)^2 \sigma_{fm}^2} \quad (3.11b)$$

where for male parents, σ_{mm}^2 is the variance of male progeny number, σ_{mf}^2 is the variance of female progeny number, and $\sigma_{mm,mf}$ is the covariance of male and female progeny number, with similar definitions for female parents. There are a variety of situations in which these types of specifications may be useful. For example, if parents produce a fixed number of offspring, the covariances $\sigma_{mm,mf}$ and $\sigma_{fm,ff}$ between numbers of sons and daughters must be negative, whereas these terms can be positive if parents differ in the resources available for overall progeny production.

Further simplification of Equation 3.10 is possible when certain assumptions are met. Consider, for example, the case in which members of the same sex produce equal numbers of potential gametes, such that $\sigma_{sk}^2 = \mu_{sk}$, and the variation in family size is a simple consequence of the random union of gametes. It then follows from the development of the monoecy model that $N_{em} = N_{m,t-1}$ and $N_{ef} = N_{f,t-1}$. Rearranging Equation 3.9, assuming constant population features and dropping the designation of time, and noting that $N_m = (1 - \phi)N$ and $N_f = \phi N$,

$$N_e = \frac{4N_m N_f}{N_m + N_f} = 4\phi(1 - \phi)N \quad (3.12)$$

In this case, N_e attains a maximum of N when the sex ratio is balanced ($\phi = 0.5$), but with skewed sex ratios, N_e is influenced much more strongly by the density of the rarer sex. For example, in a highly polygynous species, as $\phi \rightarrow 1$, $N_e \rightarrow 4(1 - \phi)N \simeq 4N_m$, namely four times the number of males.

In natural populations, where individuals inhabit different environments that influence the availability of resources and mates, it is likely that the variance in progeny production

will exceed the mean (i.e., $\sigma_k^2 > \mu_k$), in which case N_e will be less than that predicted by Equation 3.12. For example, in a summary of data on lifetime reproductive success in female birds, Grant (1990) found that σ_{fk}^2/μ_{fk} ranged from 1.2 to 4.2. Assuming a stable population size ($\mu_{fk} = 2$) and substituting into Equation 3.10, the female effective population sizes for these species are found to be 40% to 90% of the actual number of females. Nonrandom variation in family sizes appears to be the rule even in laboratory populations. For example, caged populations of *Drosophila* typically exhibit effective sizes on the order of 10% of the census size of the adult population (Briscoe et al. 1992). Observations from natural populations of other animals with separate sexes suggest an average N_e/N ratio for single generations on the order of 0.7 (Crow and Morton 1955; Nunney and Elam 1994).

Finally, the results for dioecy can be linked to those for the monoecy model in the following informative way. The mean gamete production for the whole population is $\mu_k = (1 - \phi)\mu_{mk} + \phi\mu_{fk}$, or equivalently, because all individuals have a father and a mother, $\mu_k = 2(1 - \phi)\mu_{mk} = 2\phi\mu_{fk}$. The variance of gamete production across the entire population is $\sigma_k^2 = (1 - \phi)\sigma_{mk}^2 + \phi\sigma_{fk}^2 + \phi(1 - \phi)(\mu_{mk} - \mu_{fk})^2$. Using these expressions, Equation 3.9 is essentially equivalent to Equation 3.7 (Kimura and Crow 1963b), showing that the effective size of an ideal population with separate sexes is the same as that for a monoecious, self-incompatible population with the same population properties μ_k and σ_k^2 .

AGE STRUCTURE

Because the previous formulae were obtained under the assumption of discrete generations, they provide estimates of N_e for explicit generational intervals. Such expressions are reasonable for organisms such as annual plants (ignoring the problem of seed banks; Nunney 2002) or univoltine insects, but for species that reproduce at different ages, as is the case for most vertebrates and perennial plants, the overlapping of generations raises additional complications. Nevertheless, as first pointed out by Hill (1972e, 1979), there is a simple correspondence between the effective sizes of populations with and without age structure.

In the previous formulations, N was the number of potential reproductive individuals entering the population in each generation. For age-structured populations, we must consider instead N_b , the total number of newborns entering the population during each unit of time, as well as the number of time units per generation. The latter quantity, known as the **generation time** (T), is the average age of parents giving birth, which in turn is a function of the age-specific schedules of survival and reproduction. For an ideal monoecious population,

$$T = \frac{\sum_{i=1}^{\tau} i \ell_i b_i}{\sum_{i=1}^{\tau} \ell_i b_i} \quad (3.13)$$

where ℓ_i is the probability of surviving to age i , b_i is the expected number of offspring produced by parents of age i , and τ is the maximum reproductive age. The quantity $\ell_i b_i$ denotes the expected number of births by an individual of age i , discounting for prior mortality. For a dioecious population, T is further complicated by the need to average over males (m) and females (f),

$$T = \frac{T_{mm} + T_{mf} + T_{fm} + T_{ff}}{4} \quad (3.14)$$

where T_{mf} , for example, is the average age of male parents of daughters. The average generation length is the natural time scale for the evolutionary analysis of age-structured populations. Letting $N = N_e T$, with $N_e = 4\phi_b(1 - \phi_b)N_b$ being the effective size of the newborn age class and ϕ_b being the sex ratio of newborns, all of the preceding formulae for discrete generations apply provided the structure and size of the population are stable.

However, we are still left with the rather substantial problem of estimating σ_k^2 , which now depends on variation in longevity as well as variation in fertility.

Felsenstein (1971), Johnson (1977b), and Emigh and Pollak (1979) showed how the variance in offspring production can be expressed in terms of the age-specific parameters ℓ_i and b_i . Again making the assumption that the population is stable in terms of size, sex ratio, and age composition, the effective size of an age-structured population with separate sexes is

$$N_e = \frac{N_{eb}T}{1 + (1 - \phi_b) \sum_{i=1}^{\tau_f} \left(\frac{1}{\ell_{i+1}^f} - \frac{1}{\ell_i^f} \right) \left(\sum_f \right)^2 + \phi_b \sum_{i=1}^{\tau_m} \left(\frac{1}{\ell_{i+1}^m} - \frac{1}{\ell_i^m} \right) \left(\sum_m \right)^2} \quad (3.15)$$

where $(\sum_s)^2 = \left(\sum_{j \geq i+1}^{\tau_s} \ell_j^s b_j^s \right)^2$, τ_s is the maximum age of reproduction for sex s , and $s = m$ or f (Emigh and Pollak 1979). An analogous expression is available for monoecious populations (Felsenstein 1971). While the derivations underlying these expressions rely on the assumption that gametes are drawn randomly from the members within age classes, no assumptions are made with regard to the preference of matings between age classes.

Despite their complicated structure, demographic formulae such as Equation 3.15 are useful for analyzing the sensitivity of a population's effective size to modifications in the life-history schedule. Nevertheless, the Emigh-Pollak equation has some practical difficulties. First, it rests on the assumption of a stable population structure. Such situations are rare in nature because of temporal changes in the environment. Johnson (1977b) and Choy and Weir (1978) derived dynamical equations to resolve these difficulties, and the entire subject was reviewed by Charlesworth (1994a). Second, Equation 3.15 was derived under the assumption that the age-specific mortality and birthrates of individuals are uncorrelated, i.e., that individuals with an elevated likelihood of survivorship do not have elevated or reduced birthrates. This will not be true for populations in which energetic trade-offs exist between different life-history characters. The problem needs further investigation.

Substantial simplification of Equation 3.15 can be achieved under some conditions. For example, if year-to-year survival is age independent, and if the mating system can be described in simple terms, N_e can be defined as a function of a small number of parameters, thus eliminating the need for refined age-specific schedules of survivorship and fecundity. Using this approach, Nunney (1993) concluded that N_e in animals with overlapping generations is typically on the order of $N/2$ to N , although his analysis ignores the important influence of variation in N across generations (as will be seen in a following section).

Example 3.3. While complete age-specific survivorship and reproductive schedules are available for the females of many natural populations, male promiscuity often imposes enormous practical difficulties for ascertaining paternity. Thus, the variance in male reproductive success is generally unknown. However, a long-term study on the behavior and demography of the red deer (*Cervus elaphus*) by Clutton-Brock et al. (1982) allows at least a crude estimate of N_e by use of the Emigh-Pollak equation, as shown in the table below. The study population was roughly constant in density for two decades, and observations on known individuals provide information on the age-specific rates of mortality and reproduction for both sexes. The sex ratio at birth (ϕ_b) averaged 0.43 over several years, so $N_{eb} = 0.98N_b$.

The age-specific survival rates, ℓ_i , in the following table were extracted directly from Clutton-Brock et al. (1982), while the age-specific reproductive schedules, b_i^f and b_i^m , were estimated from behavioral and demographic observations of the authors and adjusted downward to maintain a stable population size. The columns marked (1) and (2) are $\left[(1/\ell_{i+1}^s) - (1/\ell_i^s) \right]$ and $\left(\sum_{j \geq i+1}^{\tau_s} \ell_j^s b_j^s \right)^2$, and column (3) is the product of (1) and (2); all of these are deployed in Equation 3.15.

Age	Females						Males			
	ℓ_i^f	b_i^f	(1)	(2)	(3)	ℓ_i^m	b_i^m	(1)	(2)	(3)

14	0.44	0.40	0.23	0.01	0.00	0.14	0.20	3.97	—	—
15	0.40	0.25	0.20	—	—	0.09	—	—	—	—
16	0.37	0.00	—	—	—	0.05	—	—	—	—
					0.23				12.32	

The summations in the denominator of Equation 3.15 reflect the variation in lifetime reproductive success of females and males. As outlined in the table, these terms are equal to 0.23 and 12.32, respectively, indicating a great inequity between the reproductive properties of the sexes. This results because male red deer appropriate harems, and older males are much more successful at doing so than young ones. The few males that live to an old age may father up to two dozen offspring in their lifetimes, whereas males that die before the age of five (~40% of newborn males) have no reproductive success at all. On the other hand, almost all females reproduce to some degree once they have attained reproductive maturity.

Substituting the sums from the table into Equation 3.15, the effective population size is found to be $0.98N_bT/[1 + (1 - 0.43)(0.23) + 0.43(12.32)] = 0.15N_bT$. Thus, the effective size of this population is ~15% of the number of offspring produced by the population per generation. The mean generation time through females and males is 9.47 and 9.18 years, so $T \simeq 9.32$, and the annual number of offspring produced by the population is $N_b \simeq 270$. Thus, $N_e \simeq 0.15 \times 270 \times 9.32 = 377$.

VARIABLE POPULATION SIZE

Most populations vary in density from generation to generation, often dramatically so, and this raises practical problems in the implementation of the previous theory. As noted in Equation 2.7, with variable population size, the expected loss of heterozygosity over t generations is no longer $[1 - (1/2N_e)]^t$ but rather is now a product of t terms, each incorporating the effective population size of a particular generation such that

$$H_t = H_0 \prod_{i=0}^{t-1} \left(1 - \frac{1}{2N_{e,i}}\right) \quad (3.16)$$

Thus, it is informative to evaluate the size of an ideal population of constant size with the same expected heterozygosity after t generations as a population with variable size over the same period. An approximate answer can be obtained by noting that with a moderately

large $N_{e,i}$, Equation 3.16 simplifies to

$$H_t \simeq H_0 \exp \left(- \sum_{i=0}^{t-1} \frac{1}{2N_{e,i}} \right) \quad (3.17)$$

which may be compared to

$$H_t \simeq H_0 e^{-t/2N_e}$$

for the ideal case of constant effective size. Equating the exponents of these two expressions,

$$N_e^* \simeq \frac{t}{1/N_{e,0} + 1/N_{e,1} + \dots + 1/N_{e,t-1}} \quad (3.18)$$

Thus, the long-term effective size N_e^* is approximately equal to the harmonic mean of the generation-specific effective sizes. An asterisk is placed on N_e to remind the reader that the inbreeding projected by N_e^* strictly pertains to generation t . Other generations may exhibit more or less loss of variation than anticipated depending upon the actual pattern of temporal changes in $N_{e,i}$.

Example 3.4. To see how population bottlenecks have especially pronounced effects on N_e^* , consider a population whose effective size regularly fluctuates between 10 and 100. From Equation 3.18, $N_e^* = 2/(0.1 + 0.01) = 18.2$. Thus, the total loss of heterozygosity from this population every two generations is equivalent to that expected for an ideal random-mating population with a constant effective size of 18, which is much closer to the expectation for a constant population size of 10 than 100. Frankham (1995) and Vucetich et al. (1997) showed that N_e^* is frequently in the range 10% to 20% of N_e for a diversity of natural populations of animals. In the extreme case where the effective population size is effectively infinite for $t - 1$ generations and N_e for one generation, $N_e^* = tN_e$.

PARTIAL INBREEDING

Although most of the previous formulations assumed a random union of gametes, the frequency of mating between relatives often exceeds that expected under random mating. Many plants, for example, produce a significant proportion of offspring by self-fertilization. If the total population size were infinite, a fixed proportion of matings between relatives would simply lead to an equilibrium condition wherein the production of new inbreeding each generation is balanced by the breakdown of old inbreeding through outcrossing (Wright 1951, 1969; Hedrick 1986b; Hedrick and Cockerham 1986). However, such an equilibrium does not exist for finite populations, where allele frequencies are subject to random genetic drift. Here we consider the consequences of partial selfing in monoecious populations and of partial full-sib mating in populations with separate sexes, in both cases assuming an otherwise randomly mating population. Both subjects were evaluated in considerable detail by Caballero and Hill (1992a) and Wang (1996).

Assuming a constant number of adults, for a population in which a proportion β of progeny from each family is a product of self-fertilization,

$$N_e = \frac{2(2 - \beta)N}{\sigma_k^2 + 2(1 - \beta)} \quad (3.19)$$

(Crow and Denniston 1988; Caballero and Hill 1992a; Wang 1996). Further assuming that the numbers of outcrossed and selfed progeny per parent are independent variables, the

variance in gamete transmission (σ_k^2) can be simplified by noting the logic below Equation 3.4: for the outcrossed progeny, there are $2N(1 - \beta)$ random gametes drawn, each with variance $\simeq 1/N$ per focal parent, yielding a variance of $\simeq 2(1 - \beta)$; for the selfed progeny, there are $N(1 - \beta)$ parents to draw from, but because each successful draw leads to two transmitted gametes, the variance per draw is $\simeq 4/N$, yielding a total variance contribution $\simeq 4\beta$; the total variance is then $\sigma_k^2 \simeq 2(1 + \beta)$, and Equation 3.19 reduces to

$$N_e = \frac{(2 - \beta)N}{2} \quad (3.20)$$

If mating is random, so that $\beta = 1/N$, then $N_e = N - 0.5$, a result that can also be obtained directly from Equation 3.3 by letting $\sigma_k^2 \simeq \mu_k \simeq 2$. Under obligate self-fertilization, a mode of reproduction in some plants and hermaphroditic animals, $\beta = 1$ and $N_e = N/2$. Self-fertilization results in a reduction in the effective population size because the nonindependence imposed by inbreeding reduces the effective number of alleles per locus within individuals.

For the case of species with separate sexes, with β being the fraction of offspring derived by full-sib mating, and assuming equal numbers of males and females and Poisson-distributed family sizes,

$$N_e \simeq \frac{(4 - 3\beta)N}{4 - 2\beta} + 1 \quad (3.21)$$

(Wang 1995). Three special cases are of interest here. For a population derived entirely by full-sib mating, $\beta = 1$ and $N_e = N/2$, as in the case of complete selfing. With complete avoidance of sib mating, $\beta = 0$ and $N_e = N + 1$. Finally, with the type of population structure assumed, there are $N/2$ families, so under random mating, the probability of full-sib mating is simply $\beta = 2/N$, which implies $N_e \simeq N + 0.5$.

SPECIAL SYSTEMS OF MATING

It is important to bear in mind that, when applied to matters of genetic variation, the equations for N_e given above are appropriate for predicting the *expected* loss of heterozygosity resulting from inbreeding at the population level. When variation in pedigree structure exists among individuals, as will almost always be the case in nature, the actual degree of inbreeding will generally *vary* among loci within individuals as well as among individuals within the population. Given a cumulative level of inbreeding (loss of heterozygosity) at a locus equal to f , identity by descent will be binomially distributed among individuals with mean f and variance $\sigma_f^2 = f(1 - f)$. With completely linked loci, this is also the total variance in f , as there will be no variation in f among loci. However, for unlinked loci, the realized inbreeding at each locus need not be the same. Weir et al. (1980) found that the coefficient of variation of $(1 - f)$ among individuals is approximately $(3N_e)^{-1/2}$ for randomly mating monoecious populations, $(6N_e)^{-1/2}$ for randomly mating but monogamous, dioecious populations, and $(12N_e)^{-1/2}$ for monoecy with selfing excluded and for dioecy with random mating. These asymptotic values are reached in only a few generations. Thus, provided the population size and number of constituent loci are moderately large, the variation in inbreeding is negligible for most practical purposes (see also Franklin 1977; Cockerham and Weir 1983).

In contrast to the usual situation, one can also envision (and implement) systems of mating involving fixed relationships such that all members of the population have exactly the same average inbreeding coefficient over all loci (Wright 1921b). Consider first the most extreme form of inbreeding—obligate self-fertilization, a mode of reproduction in some plants and hermaphroditic animals. Because under this scheme of mating all individuals are reproductively isolated, a collection of such lines is equivalent to a series of populations, each consisting of a single individual, and after t generations of selfing, the expected fraction of heterozygotes at any locus is reduced to

$$H_t = H_0(1/2)^t \quad (3.22)$$

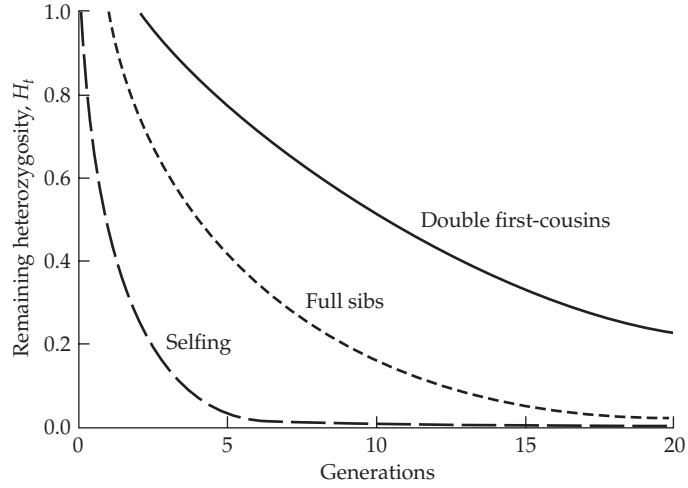

Figure 3.1 Erosion of expected heterozygosity under continuous breeding schemes involving self-fertilization, full-sib mating, and double first-cousin mating.

where H_0 denotes the initial level of variation. After $t = 3$ generations, only 12.5% of the initial heterozygosity remains (Figure 3.1).

The next most intense system of inbreeding involves continuous brother-sister mating. Starting with unrelated parents, it takes a generation of full-sib mating before alleles identical by descent can appear in the same individual. Written in terms of the inbreeding coefficient, such that $H_t = (1 - f_t)H_0$, the exact recursion equation under full-sib mating is

$$f_t = \frac{1}{4}(1 + 2f_{t-1} + f_{t-2}) \quad (3.23a)$$

and in one of the first applications of matrices in population genetics, Haldane (1937a) provided the approximation

$$H_t \simeq H_0(0.81)^t \quad (3.23b)$$

Thus, starting from a non-inbred base population, 12 generations of full-sib mating will result in a loss of 90% of the initial heterozygosity.

Moving on, with a constant population size of four breeding adults, the minimum relationship between individuals is that of double first-cousins (Figure 3.2, left). Starting with four unrelated individuals, it then takes three generations for alleles that are identical by descent (IBD) to appear in the same individual, and thereafter

$$H_t \simeq H_0(0.92)^t \quad (3.24)$$

(Wright 1921b). The number of generations required for the loss of 90% heterozygosity is now 30 (Figure 3.1).

These types of results are of special interest to managers of small, captive populations of endangered species and/or breeding stocks viewed as genetic resources for the future. Here we consider just one of the many practical questions that arise in these areas. Given a limited number of founders and an upper ceiling on the number of individuals that can be maintained, what is the optimal breeding scheme for minimizing the erosion of genetic variation? Wright (1921b) suggested that the best way to minimize the loss of heterozygosity from a small population would be to restrict matings to pairs of individuals with the

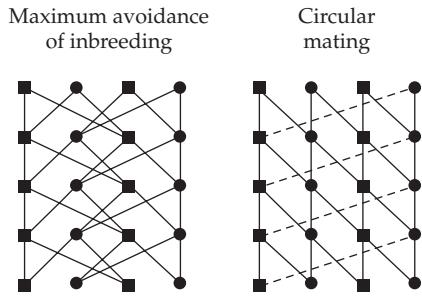

Figure 3.2 Mating schemes under continuous double first-cousin mating (left) and under circular mating with four individuals (right). Genes that are identical by descent do not appear in the same individual for three and four generations, respectively, under these two schemes. Males and females are denoted by separate symbols (squares and circles), and lines connect parents (above) and offspring (below).

least degree of relatedness. Such a breeding scheme, known as **maximum avoidance of inbreeding (MAI)**, is exemplified by all three of the special mating systems just noted—in each case, matings occur between the most distantly related individuals within each line. An added advantage of MAI is that for a population size of $N = 2^m$, m generations will pass before any inbreeding occurs at all. For example, with $N = 64$, $m + 1 = 7$ generations would pass before two copies of a founding gene could appear in the same individual under a maximum avoidance scheme. Once the inbreeding begins, the proportion of heterozygosity lost each generation is very nearly constant, approaching an asymptotic value of $1/(4N - m - 1)$ (Robertson 1964), which, with $N = 4$ and $m = 2$ under double first-cousin mating, equals 0.08, giving the fraction retained as $1 - 0.08 = 0.92$, recovering Equation 3.24.

Note that when N is large, $m \ll N$ and the asymptotic rate of loss of heterozygosity is $\simeq 1/(4N)$ per generation under MAI. Comparing this expression with Equation 2.4c, it can be seen that this mating scheme has the same effect as doubling the size of a random-mating population. This result is not strictly a consequence of the avoidance of inbreeding but, again, is the outcome of all families producing equal numbers of offspring. In fact, even under a random-mating scheme, if family sizes are equilibrated, provided $N \geq 4$, the erosion of heterozygosity is

$$H_t \simeq H_0 \left(1 - \frac{1}{4N}\right)^t \quad (3.25)$$

where t is the number of generations after the onset of inbreeding (Wright 1951). This can be seen by returning to many of the formulae in the earlier sections of this chapter and setting $\sigma_k^2 = 0$. Under the idealized scheme of random mating discussed earlier, variances in allele frequencies arise from variance in the number of progeny left by each individual and from segregational variance resulting from the sampling of alleles within individuals. For randomly mating populations of even moderate size, about half of the total sampling variance of allele frequency arises from each source, so that equilibration of family size reduces the total sampling variance by 50%.

The central point of the preceding discussion is that, for a fixed census size, three factors can potentially be manipulated to reduce the rate of inbreeding: avoidance of matings among relatives; equilibration of family sizes; and a sex ratio as close to one as possible. In some domesticated animals, the latter is a problem because females have only one or two offspring per year. In such cases, Gowen et al. (1959) suggested that when the sex ratio of contributing parents is r females to each male, the loss of genetic variance will be minimized if every male contributes exactly one son and r daughters, and every female leaves one daughter and also contributes a son with probability $1/r$. Wang (1997) improved on this

scheme with the constraint that a female contributing a son does not contribute a daughter and another female from the same male family instead contributes two daughters.

Kimura and Crow (1963a) noted that Wright's intuition that MAI minimizes the long-term loss of genetic variation is actually not quite correct, pointing out that a **circular mating** (CM) scheme (Figure 3.2) ultimately leads to a lower rate of loss of heterozygosity. Under this breeding design, females and males are arranged such that each of them is mated to two "neighbors," with the last individual in the linear array being mated with the first, thereby completing the circle. Nevertheless, although circular mating ultimately reduces the rate of loss of heterozygosity relative to MAI, it is inferior in the early generations of mating, and even with small N , it may take more than 100 generations before its superiority is realized. Thus, because most of the initial genetic variation in a population will generally have been lost by this time, the practical advantages of circular mating are actually quite negligible.

The major limitation of both the MAI and CM schemes is that they only impede the loss of genetic variation—ignoring new mutations, any randomly mating finite population will ultimately become homozygous at every locus. However, Robertson (1964) obtained the more general (and counterintuitive) result that the rate of loss of overall genetic variation from a population actually *declines* as the relatedness between mates increases. In the extreme, genetic diversity can be preserved indefinitely by subdividing a population into several isolated lines. Although the individual lines are all expected to become homozygous eventually, different lines will become fixed for different sets of genes, with the overall level of preservation of genetic diversity being defined by the number of inbred lines. In effect, complete inbreeding gives rise to a condition equivalent to each family having preserved the equivalent of one gamete from the base population. For example, for a locus with initial allele frequency p_0 , assuming a large number of families, the allele frequency in the total collection of lines would remain close to p_0 , so that subsequent random mating of the lines would render the heterozygosity close to its original state, $2p_0(1 - p_0)$. It must be emphasized, however, that these arguments assume that intense inbreeding in small lines has no consequences that might endanger the line's survival. In reality, however, very small lines are likely to die out occasionally just by accident, and extreme inbreeding also often has serious deleterious effects on fitness (LW Chapter 10). The gradual replacement of extinct lines by members of surviving lines will lead to further loss of variation.

POPULATION SUBDIVISION

Although few species exhibit internal isolation as extreme as that just noted, many (probably most) species occupy spatially structured environments. Such structure causes local inbreeding, as mates are more related than random pairs from the entire population. One of the simplest models of population structure is Wright's (1951) island model, introduced in Chapter 2 (Figure 2.11). Here, the metapopulation consists of d demes, each containing a fixed number N of randomly mating individuals with idealized Wright-Fisher properties, and each deme contributes an equal fraction m of its genes to the migrant pool, which is then equally distributed among the remaining demes. Under this model, an equilibrium level of population divergence is eventually reached (Equation 2.46), at which point the increase in divergence resulting from within-deme genetic drift is balanced by the exchange of alleles by migration.

Recalling from Chapter 2 that the mean coalescence time for an ideal, random-mating population is $2N$ generations, Equation 2.45b (giving the mean coalescence time under this population structure) implies an effective size for the overall metapopulation of

$$N_e = Nd + \frac{(d - 1)^2}{4dm} \quad (3.26)$$

In this simplest case, we see that the effective size of a metapopulation exceeds the sum of the demic effective sizes (Nd) by an amount approaching $d/(4m)$ when the number of

demes is large. With low migration rates ($m \ll 1$), this inflation can be substantial. For example, if $m < 1/(4N)$, N_e exceeds twice the total number of breeding adults ($2Nd$). This confirms Robertson's (1964) argument that population subdivision can reduce the overall rate of loss of variation by drift as unique alleles are sequestered within individual demes. However, numerous authors have pointed out that this inflation of N_e in the ideal island model is a special consequence of the absence of variation in deme productivity (analogous to the consequences of constant family sizes within a single population, noted above).

The next simplest type of island model allows for extinction and recolonization of the individual demes. In each generation, a fraction e of the demes goes extinct, but immediate recolonization ensures the maintenance of a fixed number (d) of demes. Tracing back to Slatkin (1977) and Maruyama and Kimura (1980), most attempts to model this process have assumed that the newly colonized deme is immediately restored to size N in a single generation, with recolonization involving k immigrants either derived from a single random deme (the **propagule-pool model**) or from a random pool of migrants from the entire metapopulation (the **migrant-pool model**). This simple modification results in a reduction in N_e for the metapopulation by inducing variation in productivity among the demes surviving in each generation—demes that contribute to a colonization event experience a burst of productivity relative to demes that do not.

Using the logic noted above, approximate expressions for mean coalescence times for metapopulations experiencing extinction and recolonization (Pannell and Charlesworth 1999) yield formulae for the metapopulation N_e . Such expressions are functions of the relative rates of extinction and migration and the size and type of colonizing pool, and we only give two examples for the propagule-pool model. If the extinction rate is smaller than the migration rate ($e \leq m$) and much smaller than the relative size of the colonizing pool ($e \ll k/N$),

$$N_e \simeq Nd \frac{[4m + (1/N)]}{4(e + m)} \quad (3.27a)$$

a result also obtained by Maruyama and Kimura (1980) and Whitlock and Barton (1997). Under these conditions, local extinctions are sufficiently rare that within-deme variation is able to recover substantially by migration between bottleneck events, and although $N_e < Nd$, it approaches the latter value as $e \rightarrow 0$ unless N is tiny. On the other hand, if the extinction rate is relatively high, such that $e \gg m$ and $e \gg k/N$,

$$N_e \simeq \frac{d}{4e} \quad (3.27b)$$

In this case, extinctions are so frequent that local demes (reestablished from a small number of colonists and experiencing little immigration) are almost completely inbred, and the total effective size is independent of the number of individuals per deme and simply defined by deme number and average deme longevity (e^{-1} generations).

A more general expression for the effective size of a metapopulation under the island model was derived by Whitlock and Barton (1997). Assuming large d , so that $d \simeq d - 1$ as a first-order approximation,

$$N_e \simeq \frac{d(1 + 4Nm)}{4m + 2\sigma_K^2(1 + 2m)} \quad (3.28)$$

where σ_K^2 denotes the among-deme variance in the number of gametes contributing to the next generation (the analogue for the variance σ_k^2 in individual contributions). Comparing this expression to Equation 3.26, it can be seen that $\sigma_K^2 > 0$ will always cause a reduction in N_e . In addition, for N_e to be less than the total metapopulation size $2Nd$, σ_K^2 need only be larger than $1/(2N)$. This amount of among-deme variance in gamete production is trivial, as even under ideal conditions in which individual family sizes are Poisson distributed, the variance in total deme productivity will be on the order of $2/N$. This follows from the fact, noted above, that within an ideal random-mating deme, $\sigma_k^2 = 2$, so that at the deme level, $\sigma_K^2 = 2/N$. Thus, it appears that population subdivision will almost always result in

a reduction in N_e , provided the individual demes are not completely isolated, a point first made by Wright (1940; see also Nunney 1999).

SELECTION, RECOMBINATION, AND HITCHHIKING EFFECTS

Up to now, we have assumed that alleles are immune to selective processes, which is, of course, unrealistic in many cases. In fact, selection generally causes a still further reduction in N_e by inflating the among-family variance in offspring production. Evaluating the magnitude of such effects is complicated by the fact that unlike family-size variation induced by environmental heterogeneity, which can be erased in a single generation, genetic variation in fitness is sustained across generations. Such heritable transmission will elevate the genetic representation of some individuals in future generations beyond the expectations under drift alone. This phenomenon was initially mentioned by Morley (1954), who noted in sheep flocks exposed to selection that “the genetically superior individuals will tend to be most inbred.” The processes that we will examine are analogous to those that occur in spatially structured populations with random extinction, except that now specific alleles can become trapped in genetic backgrounds that are destined for elimination or fixation.

Before proceeding, it must be emphasized that because N_e is defined in the context of hypothetically neutral loci that serve as benchmarks for the pure drift process, our concern here is not so much with the specific loci under selection, but with the effects of such selection on the dynamics of neutral-allele frequencies elsewhere in the genome. Because the long-term effects of selection depend on the frequency of recombination between selected loci and their associated neutral markers as well as on the mode of selection, the issues are quite technical. Our goal is simply to provide a heuristic overview of why the effects of selection almost always lead to a substantial reduction in N_e . Chapter 8 examines many of these issues in greater detail.

Effects From Selection at Unlinked Loci

Robertson (1961) first considered the influence of a constant selection regime on the long-term dynamics of a neutral locus assumed to be entirely unlinked to any selected loci. In addition to any baseline variance in gamete production among individuals that might exist for environmental reasons (our previous σ_k^2), in the first generation of selection there will also be an among-family genetic variance in relative fitness, σ_w^2 , associated with the differential contributions of individual families. Here the relative fitness (w_i) of the i th family is simply the expected contribution to the next generation relative to the average in the population, such that the mean relative fitness $\sum_{i=1}^{N/2} w_i/(N/2) = 1$, where we assume a balanced sex ratio and $N/2$ families. For populations with features in accordance with the standard Wright-Fisher model, a single generation of selection will then reduce the effective population size to

$$N_e \simeq \frac{4N}{\sigma_k^2 + 2 + 4\sigma_w^2} \quad (3.29a)$$

which is identical in form to Equation 3.4 except for the additional variance associated with selection in the denominator. Note that because σ_w^2 is the variance in relative fitness among families and the average family size is two, $4\sigma_w^2$ is the genetic variance in actual family size. This expression demonstrates that the random association of neutral alleles with families with different genetic endowments has the same qualitative effect as environmental differences in family sizes (σ_k^2).

Of course, it would be a rare situation in which selection operated only for a single generation, and Robertson (1961) had the additional insight that with subsequent generations of selection, new stochastic associations between selected and unselected loci will arise each generation, while old associations are lost at rate 0.5 with free recombination. This yields a long-term cumulative contribution to the among-family genetic variance in

relative fitness proportional to $[1 + (1/2) + (1/4) + (1/8) + \dots]^2 \sigma_w^2 = 4\sigma_w^2$, which (as above) is then further multiplied by 2^2 to translate relative fitness into the genetic variance in family size. Although this result ignores the fact that the stochastic effects of selection will dissipate over time as favorable alleles at the loci under selection go to fixation, this additional layer of complexity is readily incorporated. Letting L denote the per-generation fractional loss of additive genetic variance at selected loci, the preceding series simply has terms in powers of $(1 - L)/2$ instead of $1/2$, and again after converting the variance in relative fitness to the absolute scale, the long-term effective population size becomes

$$N_e \simeq \frac{4N}{\sigma_k^2 + 2 + 4[2/(1 + L)]^2 \sigma_w^2} \quad (3.29b)$$

(Santiago and Caballero 1995). If we further assume that baseline variation in family sizes unassociated with selection simply reflects random gamete sampling, then from above $\sigma_k^2 \simeq 2$, and under Robertson's assumption of no reduction in variance by selection ($L = 0$), the long-term effective size becomes

$$N_e = \frac{N}{1 + 4\sigma_w^2} \quad (3.29c)$$

Equations 3.29b and 3.29bc are quite general in the sense that they apply to any scheme of selection. However, they are also a bit opaque in that the mechanistic determinants of σ_w^2 and L are not defined and the substantial effects of linkage are omitted. The remainder of this chapter is focused on the removal of these limitations.

Example 3.5. The genetic variance for relative mean-family fitness is a function of the intensity of selection and the heritability of the selected traits. For example, in the case of truncation selection on a single trait (Chapter 14), $\sigma_w^2 = \bar{t}^2 t_{FS}$, where \bar{t} is the standardized selection differential (the change in mean phenotype imposed by selection in units of phenotypic standard deviations, Equation 14.3a), and t_{FS} is the phenotypic correlation among full sibs (Milkman 1978), which is equivalent to half the heritability for an ideal trait with an additive genetic basis (LW Chapter 18). For situations in which the most extreme 1% to 10% of the phenotypic distribution is selected, \bar{t} is in the range of 2.7 to 1.8 (LW Chapter 2), and t_{FS} takes on a maximum value of 0.5 when the heritability of the trait is equal to 1.0. Thus, recalling Equations 3.29a through 3.29c, with very strong truncation selection on a highly heritable trait, σ_w^2 may take on high enough values to reduce N_e several-fold relative to the expectation in the absence of selection, even when the selected loci are unlinked. Chapter 26 examines the reduction in N_e due to truncation selection on a trait in more detail.

Selective Sweeps and Genetic Draft

The effects of linked loci on N_e are substantially greater than those from unlinked loci for the simple reason that chromosomally juxtaposed sites are necessarily mutually influenced by each other's fitness attributes for extended periods. For example, a neutral allele linked to a site under positive selection can **hitchhike** to high frequencies (and even fixation) if the force of selection is strong relative to the recombination rate between the sites (Maynard Smith and Haigh 1974). One direct consequence of this reduction in N_e is a depressed amount of molecular variation at neutral sites in regions of low recombination, an expectation that is in agreement with many empirical observations (Chapter 8). However, as will be emphasized in the next section, the periodic fixation of favorable alleles is just one potential explanation for this kind of observation, an alternative hypothesis being **background selection**, the constant purging of new deleterious mutations (Charlesworth 2012).

A simple way of evaluating the effects of **selective sweeps** of beneficial mutations on variation at completely linked neutral loci was presented by Gillespie (2000). Recall from Chapter 2 that the variance of neutral allele-frequency change from generation to generation in a Wright-Fisher diploid population is equal to $p(1 - p)/(2N)$, where p is the current allele frequency. Now imagine that this locus is completely linked to other genomic sites incurring beneficial mutations that collectively cause rapid fixations at an average rate of δ per generation. Because such mutations arise independently of the allele at the linked neutral locus, such selective sweeps will result in the fixation of neutral alleles with probabilities proportional to their current frequencies, in this case p and $(1 - p)$ at the neutral focal locus. If we assume that selective sweeps cleanse a population of linked variation essentially instantaneously (or at least rapidly relative to the usual rate of genetic drift), then conditional on a sweep occurring, the variance in allele-frequency change will be $p(1 - p)$. Thus, for a neutral locus in an ideal randomly mating population subject to periodic selective sweeps, the total variance in allele-frequency change is the weighted sum of both contributions $\sim p(1 - p)\{[(1 - \delta)/(2N)] + \delta\}$. Because this expression applies to all initial allele frequencies, equating the term in braces to $1/(2N_e)$ yields

$$N_e \simeq \frac{N}{1 + 2N\delta} \quad (3.30a)$$

a result also obtained by Maruyama and Birky (1991) by a different method. Here and below, it is appropriate to view N as the effective size of a population based solely on the demographic considerations noted earlier in this chapter.

When selective sweeps are rare relative to the strength of random genetic drift, such that $\delta \ll 1/(2N)$, $N_e \simeq N$, but as $N \rightarrow \infty$, $N_e \rightarrow 1/\delta$, showing that even populations with enormous numbers of reproductive adults may approach an asymptotic upper limit to N_e defined, not by genetic drift, but by **genetic draft** (Gillespie 2000)—the stochastic result of hitchhiking effects that inevitably arise in linked genomes. That is, when N is very large, the effective size of a population can be more strongly influenced by the physical (i.e., linkage) features of the genome than by demographic factors. In principle, the frequency of selective sweeps may increase with N , as larger populations provide more opportunities for rare beneficial mutations, so strong linkage may even lead to the potential situation in which N_e eventually scales negatively with absolute population size (Lynch 2007).

The preceding result applies to the extreme case of complete linkage. If, instead, a significant amount of recombination occurs between a neutral marker and the selected locus while the latter is proceeding toward fixation, then a selective sweep is not expected to completely remove the variation at the marker locus. As detailed in Chapter 8, the extent to which a neutral locus can free itself of stochastic associations with newly arising beneficial mutations depends on the rate of the sweep (which in turn is a function of the relative power of selection and drift, $s/[1/(2N)] = 2Ns$) as well as on the relative power of recombination and selection (c/s , where c is the rate of recombination between the two loci).

Incorporation of these technical issues by Wiehe and Stephan (1993) led to an expression identical in form to Equation 3.30a, with $2N\delta$ being replaced by a term that is smaller in absolute value. Gillespie (2000) expressed this influence of recombination as

$$N_e \simeq \frac{N}{1 + 2Nf_s\delta} \quad (3.30b)$$

where f_s is the probability that no recombination occurs between the selected site and the marker locus under consideration during the sweep. Following the completion of the sweep, f_s is equivalent to the probability that a random individual will contain two IBD copies of the original neutral allele on the gamete in which the new favorable mutation arose. With free recombination $f_s \simeq 0$, but with complete linkage, $f_s = 1$, returning us to Equation 3.30a. The general form for f_s is

$$f_s \simeq (4Ns)^{-c/s} \quad (3.31)$$

which will be further discussed in Chapter 8.

Background Selection

We now turn to the influence of selection against recurrently appearing deleterious mutations, which cause a still further reduction in N_e as a consequence of induced variation in family size. Contrary to the situation with selective sweeps, which are sporadic and chromosomally restricted in scope, the effects of recurrent deleterious mutations are expected to be persistent across the entire genome for the simple reason that the vast majority of mutations are deleterious (LW Chapter 10). Here we attempt to provide a heuristic understanding of the effects of such background selection by considering separately the effects of unlinked and linked deleterious mutations, relying on a simple model in which interfering loci harbor two alternative allelic types (beneficial and deleterious).

If the beneficial allele at a locus mutates to a defective type at rate u per generation, with the latter causing a fractional reduction in heterozygote fitness equal to s , the equilibrium frequency of the deleterious allele is equal to u/s (provided that s is substantially stronger than the power of drift and mutation) (Chapter 7). The genetic variance in relative fitness associated with this locus then has an expected value close to $2us$. This result can be obtained by noting that the additive genetic variance for a single locus is equal to $2a^2p(1-p)$ (LW Chapter 4), where a is the difference in phenotype between adjacent genotypic classes and p is the allele frequency. In this case, $a = s$, and because u/s is small, $p(1-p) \approx p = u/s$. Summing over all n loci capable of mutating to deleterious alleles, the total genetic variance in fitness among individuals is $2nus = Us$, where $U = 2nu$ is the diploid deleterious mutation rate.

This result can be used to evaluate the overall effect of unlinked background selection by noting that unless the number of chromosomes is very tiny, the vast majority of pairs of genes within genomes will be unlinked (with x chromosomes of equal size, the fraction of linked pairs will be $< 1/x^2$ because genes located on opposite ends of chromosomes are effectively unlinked). Thus, we can make use of Robertson's equation (3.29c), noting that the variance of mean family fitness is $Us/2$ after discounting by averaging over both parents. This shows that in the absence of any linkage, deleterious mutations are expected to cause a relatively small reduction in N_e ,

$$N_e \simeq \frac{N}{1 + 2Us} \simeq Ne^{-2Us} \quad (3.32)$$

with the exponential approximation applying under the assumption that $Us \ll 1$. This assumption is justified by numerous observations suggesting that U is on the order of 0.1 to 1.0 and s is on the order of 0.01 (LW Chapter 12).

Some impression of the impact of linkage follows from the logic used to obtain Equations 3.29b and 3.29c. As noted above, for unlinked loci, the initial stochastic associations of neutral alleles and selected loci last for an average of $\sum_{i=0}^{\infty} (1/2)^i = 2$ generations, giving a total contribution to the variance proportional to 2^2 . Letting the recombination rate between loci be c , this expression generalizes to $\sum_{i=0}^{\infty} (1-c)^i = 1/c$ generations, and hence a contribution of $1/c^2$ to the variance. Thus, a single selected locus is expected to reduce the variation at a linked neutral locus, which in effect causes a local depression in the effective population size to

$$N_e \simeq Ne^{-us/c^2} \quad (3.33)$$

(Barton 1995a). With $c \ll 0.5$, the absolute value of the exponential term can be considerably larger than that for unlinked loci, $4us$. The challenge is to determine the joint effects of the full spectrum of all linked and unlinked loci surrounding the neutral reference locus.

Insight into the overall power of selection on linked deleterious mutations can be gleaned by considering the extreme case of a completely nonrecombining, but otherwise sexual, genome, i.e., allowing only for segregation during gamete production. Assuming a total of n selected loci, for which the mutant alleles have identical and multiplicative effects

on fitness, the average number of deleterious alleles in a gamete is $nu/s = U/(2s)$, where U is again the deleterious mutation rate per diploid genome. Assuming large enough N_e that deleterious mutations do not go to fixation, with this type of genomic architecture (no recombination), only those gametes that are free of deleterious mutations can contribute to the future genetic constitution of the population. Because the number of deleterious mutations per gamete is Poisson distributed in sufficiently large populations with multiplicative selection (Kimura and Maruyama 1966), the frequency of such mutation-free gametes is simply $e^{-U/(2s)}$, leading to the conclusion that with complete linkage, selection against segregating deleterious mutations leads to

$$N_e = Ne^{-U/(2s)} \quad (3.34)$$

(Charlesworth et al. 1993a). This shows that background selection has the potential to cause a dramatic reduction in N_e in a nonrecombining (but segregating) population. For example, with $U = 0.1$ and $s = 0.01$, $e^{-U/(2s)} = 0.0067$. This expression also applies to a nonrecombining chromosomal region if U is redefined to be the deleterious mutation rate for the region under consideration.

Hudson and Kaplan (1994) extended this result to allow for recombination, assuming that the latter operates at uniform rates per physical distance over chromosomal regions. Their results show that

$$N_e \simeq Ne^{-U/(2s+C)} \quad (3.35a)$$

where C denotes the rate of recombination between the ends of the region. Because $1/(2s + C) \gg s$, Equation 3.35a predicts a much smaller N_e than that obtained for freely recombining loci (Equation 3.32), showing that the total contribution from interference from unlinked loci (which is embedded in Equation 3.35a) is relatively minor relative to that from loci in the immediate vicinity of the neutral locus. Moreover, because s is expected to be $\ll 1$, and for an entire chromosome, C is of order 1.0, Equation 3.35a can be roughly approximated as

$$N_e \simeq Ne^{-U/C} \quad (3.35b)$$

where U/C is equivalent to the diploid deleterious mutation rate per unit of recombination (Hudson and Kaplan 1994, 1995). This result, which has been obtained by several different methods (Barton 1995a; Nordborg et al. 1996; Santiago and Caballero 1998), shows that the impact of segregating deleterious mutations on N_e is largely independent of the mutational effect s . As will be seen in Chapter 4, the ratio of mutation and recombination rates can be estimated from molecular polymorphism data, so if the fraction of mutations that are deleterious is known, U/C is also estimable.

Finally, it is worth noting that some conditions exist under which selection may actually promote an increase in N_e , the most obvious involving increases in the coalescence times for linked alleles in a chromosomal region under balancing selection. Pálsson and Pamilo (1999) also found that with very strong linkage and a low efficiency of selection ($2Ns < 1$), repulsion disequilibrium can build up between simultaneously segregating deleterious mutations, leading to a form of associative overdominance (LW Chapter 10) and an elevation of N_e . Although this condition arises in the absence of direct balancing selection on any specific site, it remains unclear whether the special requirements necessary for such an outcome are very common. Santiago and Caballero (2005) also found that in a subdivided population, selective sweeps within demes can sometimes lead to an increase in N_e for the total metapopulation, as the migration of a sweeping chromosomal region drags new variation into a recipient deme, leading to an overall effect akin to balancing selection.

With these exceptions aside, there are two general lessons to be learned from all of the preceding discussion. First, although the individual demographic and genetic effects that influence N_e may appear to be only moderate in nature, their cumulative effects can easily depress N_e below the actual number of reproductive individuals by several orders of magnitude, and second, although population geneticists often develop analytical descriptions of various processes under the assumption of an effectively infinite population size, the

physical linkage of the genome ensures that even populations with extraordinarily large N need not be immune to drift-like processes imposed by hitchhiking effects. These points will be made clearer in Chapter 4 as we explore the direct manifestation of such effects on standing variation in natural populations.

Example 3.6. Because natural populations are subject to both positive and negative selective forces, the total influence of selection on N_e must reflect *both* background selection and selective sweeps. This necessarily raises even more technical issues than were outlined above. Significant progress was made by Kim and Stephan (2000), and here we simply outline the basic result. If background selection operates as an essentially continuous process resulting from the recurrent introduction of deleterious alleles, the depressive effects of both forms of selection, as well as baseline demographic effects, may be treated as largely independent. The reduction in N_e resulting from background selection can then be obtained by use of one of the above expressions, e.g., Equation 3.35b as a first-order approximation for a sexual population (with \bar{N} already taking into consideration demographic effects).

Consider a large monoecious population of constant breeding size and variance in family size $\sigma_k^2 = 4$. Based on demographic considerations alone, from Equation 3.4, $N_e \simeq 2N/3$. Letting $U = 1$ and $C = 1$, Equation 3.35b implies that background deleterious mutations further reduce N_e to $(2N/3)e^{-1} \simeq 0.25N$. The effective population size dictated by these demographic and deleterious-mutation processes further defines the background N'_e within which occasional beneficial mutations arise and sweep to fixation, so that the effective population size resulting from the joint operation of all three effects can be approximated by substituting N'_e for N in Equation 3.30b. Supposing a complete sweep occurs every 10,000 generations (so that $f_s = 1$ and $\delta = 0.0001$), then $N_e = 0.25N/[1 + (0.50N \cdot 0.0001)]$. With $N = 10^4, 10^6$, and 10^8 , this implies $N_e/N \simeq 0.17, 0.0049$, and 0.00005 , respectively.

In general, the joint operation of background selection and selective sweeps will reduce N_e more than either does alone, although it is, at least in principle, possible for background selection to reduce the influence of selective sweeps in regions of very low recombination by depressing N_e , which in turn will reduce the fixation probability of favorable alleles (Chapters 7 and 8). The simultaneous operation of positive selection on multiple loci (which was ignored in the derivation of Equations 3.30a and 3.30b) can also slightly alleviate the overall effects of selection on N_e as simultaneously segregating mutations interfere with each other's fixation, thereby reducing the incidence of complete selective sweeps (Kim and Stephan 2003). These issues are examined in greater detail in Chapter 8.

4

The Nonadaptive Forces of Evolution

I may be wrong but I doubt it. Charles Barkley

Although natural selection plays a major role in the evolution of many traits, three additional factors determine the patterns of genetic variation within and among populations. We refer to these factors—mutation, recombination, and random genetic drift—as the **nonadaptive forces of evolution** because their operation is generally independent of the specific selective factors operating on the extrinsic phenotypes of individuals. Migration (briefly touched upon in Chapters 2 and 3) might be added to this list, although we regard this added complexity as being independent of the internal genetic machinery of a population. As will become clear in the following chapters, the three nonadaptive forces together comprise the **population-genetic environment**, which defines the paths of evolutionary change that are open vs. closed to natural selection.

Knowledge of the magnitude of the nonadaptive forces of evolution should be sufficient to arrive at a full description of the dynamics of allele- and gamete-frequency change within populations in the absence of external forces of selection. Moreover, this logic works in reverse—under certain assumptions, observed patterns of variation in neutral genomic regions can be used to infer the magnitude of the evolutionary forces responsible for such patterning.

The goals of this chapter are, therefore, three-fold. First, we will consider how observations on putatively neutral molecular markers can be used to estimate rates of mutation, recombination, and random genetic drift. Second, we will summarize the existing data resulting from such analyses, providing information that will play a central role in subsequent chapters. As a consequence of the recent emergence of new technologies for high-throughput genomic sequencing, this is a rapidly developing area that will undoubtedly experience additional refinements in the near future. Finally, after showing that the intensities of the nonadaptive forces of evolution vary by orders of magnitude among species in fairly predictable manners, we will summarize existing theory that helps explain such patterns.

Although our ultimate desire is to obtain accurate estimates of the individual forces of mutation, recombination, and drift, as will be seen below, it is often much easier to obtain ratios of these features than to measure them individually. Fortunately, this is not always an undesirable situation, for as we saw in Chapter 2, in the absence of selection, the ratio of the power of mutation (u) and the power of drift ($1/2N_e$) defines the level of heterozygosity in a population, and the ratio of the recombination rate per nucleotide site (c_0) and the power of drift defines the magnitude of linkage disequilibrium. Therefore, before summarizing the approaches for estimating N_e , u , and c_0 separately, we will first consider methods for estimating the composite population parameters $\theta = 4N_e u$ and $\rho = 4N_e c_0$. As will be seen below, accurate estimates of N_e are particularly difficult to achieve directly, especially for large populations. However, by using combined estimates of θ , ρ , u , and/or c_0 , obtaining approximate measures of long-term N_e is sometimes possible.

Throughout this chapter, we will assume that we are dealing with molecular markers known in advance to behave in an effectively neutral fashion. Numerous methods to test this hypothesis will be discussed in Chapters 9 and 10. We will largely focus on measures at the level of individual nucleotide sites, as it is now routine to obtain large quantities of DNA-sequence data, and per-nucleotide site measures are readily extrapolated to larger units of analysis such as genetic loci. Thus, u and c_0 will, respectively, denote the mutation rate per nucleotide site and the recombination rate between adjacent sites.

RELATIVE POWER OF MUTATION AND GENETIC DRIFT

In Chapter 2, it was demonstrated that if the forces of drift and mutation remain constant for a sufficiently long time, the level of heterozygosity at a neutral nucleotide site (with four possible allelic states) will stochastically wander around an expected equilibrium value of $\sim 12N_e u / (3 + 16N_e u)$, where u is the mutation rate per gamete per nucleotide site (assuming all nucleotides mutate at the same rate). As will be seen below, the average heterozygosity per neutral nucleotide site is far below 1.0 in all phylogenetic groups, so the preceding expression is generally closely approximated by $4N_e u$. This particular measure has great practical utility. Because $2u$ is the mutation rate per site per diploid genome, $4N_e u$ is equivalent to the ratio of the power of mutation to the power of random genetic drift, $1/(2N_e)$. For haploid species, the expected nucleotide diversity at a neutral site is $2N_e u$.

Nucleotide Diversity

Suppose a population sample of n random sequences has been obtained for a particular genomic region. In principle, such a stretch of DNA might consist of intronic or intergenic sequence or of the subset of **silent (synonymous)** sites in one or more coding regions. Letting k_{ij} be the number of site-specific differences between observed sequences i and j , and L be the number of sites per sequence, the average fraction of pairwise differences between the sampled sites,

$$\hat{\theta}_\pi = \frac{2}{n(n-1)} \sum_{i=1}^n \sum_{j>i}^n k_{ij}/L \quad (4.1)$$

yields a heterozygosity-based estimate of $\theta = 4N_e u$ (Tajima 1983). This formulation, frequently called the **Tajima estimator**, is often denoted by π in the literature.

If we are to confidently use $\hat{\theta}_\pi$ as an estimator of θ , aside from knowing whether the assumptions of neutrality and equilibrium are valid, it is critical to know the sampling variance of $\hat{\theta}_\pi$. Such variance results from two sources of uncertainty. First, heterozygosity is subject to **evolutionary variance**, which results from the natural fluctuations of nucleotide frequencies generated over time by the stochastic forces of mutation and drift (Chapter 2). Although this source of variation is not easily observed directly, assuming a population in drift-mutation equilibrium, the expected evolutionary variance of the true population value of θ based on L independent (effectively unlinked) sites is $\simeq (\theta/3)[(2\theta/3) + (1/L)]$ (Tajima 1983). This source of variance is intrinsic to the features of the population, independent of the sample taken. Second, **sampling variance** results from the use of a finite number of sampled sequences to estimate θ_π . For an equilibrium population, this variance is $\simeq \{2\theta/[3(n-1)]\}\{[(2n+3)\theta/3n] + (1/L)\}$, where n is the number of sequences sampled per site (Tajima 1983).

Summing over these two sources of variance, for sites in stochastic drift-mutation equilibrium, the expected total variance of heterozygosity-based estimates of θ is

$$\sigma^2(\hat{\theta}_\pi) \simeq \frac{\theta}{3(n-1)} \left(\frac{2(n^2 + n + 3)\theta}{3n} + \frac{n+1}{L} \right) \quad (4.2)$$

(Pluzhnikov and Donnelly 1996). With increasing numbers of sampled alleles per site, i.e., as $n \rightarrow \infty$, the total variance of estimates of θ based on nucleotide diversity approaches a minimum equal to the evolutionary variance. Even in this case, and with an enormous amount of sequence per individual (large L), the sampling coefficient of variation of $\hat{\theta}_\pi$ is $\simeq \sqrt{2/9} \simeq 0.47$. Adding more individuals or sites to a survey will not alter this minimum.

It is worth reemphasizing that Equation 4.2 is an appropriate estimator of the variance of a nucleotide-diversity estimate only if the latter is based on neutral sites in drift-mutation equilibrium (the **standard neutral model**). Even for assuredly neutral sites, this expression will not apply for *nonequilibrium* situations, e.g., populations that have experienced relatively recent expansions or contractions. Under the latter conditions, the variance of

heterozygosity must be evaluated more directly from the spectrum of allele frequencies across all sites and from their higher-order moments. A number of related technical issues are covered and general expressions derived in Nei and Roychoudhury (1974), Nei (1978), Nei and Tajima (1981a, 1983), Nei and Jin (1989), and Lynch and Crease (1990).

Finally, now that high-throughput sequencing has become routine for entire diploid genomes, it is possible to estimate the average nucleotide diversity over millions of putatively neutral sites, yielding per-individual measures with a high degree of precision. Because most pairs of sites are on different chromosomes, a full survey of even a single individual from a random-mating population should provide a very accurate description of the average per-site diversity across the entire population. Moreover, when a survey of two random individuals is possible, the covariance of heterozygosity within sites provides a direct estimate of the evolutionary variance of heterozygosity among sites, which, as noted above, should closely approximate $(\theta/3)[(2\theta/3) + (1/L)]$ under the assumption of drift-mutation equilibrium (Lynch 2008a). These observations are now quite salient, as Pluzhnikov and Donnelly (1996) showed that for a fixed amount of resources for sequencing L_n total bases, the optimal strategy for obtaining minimal-variance estimates of θ is generally to sample no more than two or three individuals, putting the effort instead into sampling more sites, i.e., maximizing L at the expense of n .

Number of Segregating Sites

Although nucleotide diversity is the most transparent means of estimating θ , it is by no means the only, or even the most efficient, approach. Watterson (1975) pointed out an alternative statistical measure of allelic diversity—the total number of segregating sites (S) in the region analyzed over the full set of n sequences. Because a segregating site is any nucleotide position that harbors two or more variants, S clearly increases with the length L of the sequence and the number of individuals assayed. Watterson (1975) showed that under the assumptions of neutrality and drift-mutation equilibrium, an unbiased estimator of the per-site parameter $\theta = 4N_e u$ is

$$\hat{\theta}_S = S/(L a_n) \quad (4.3a)$$

where

$$a_n = \sum_{j=1}^{n-1} 1/j \quad (4.3b)$$

By rearranging, it can be seen that Equation 4.3a relates directly to the expected site-frequency spectrum for a sample under drift-mutation equilibrium with a known value of θ (Equation 2.35a). A central point here is that when the nucleotide sites surveyed are neutral and in drift-mutation equilibrium, like the Tajima estimator (Equation 4.1), the **Watterson estimator** provides a separate estimate of θ . In Chapter 9, we will see that when the assumptions of neutrality and/or equilibrium are violated, the values of $\hat{\theta}_\pi$ and $\hat{\theta}_S$ deviate from each other in ways that yield insight into past population-genetic processes.

The sampling variance for the Watterson estimator, analogous to Equation 4.2 and again under the assumptions of neutrality and equilibrium, is

$$\sigma^2(\hat{\theta}_S) \simeq \frac{\theta}{a_n} \left(\frac{\theta b_n}{a_n} + \frac{1}{L} \right) \quad (4.4a)$$

where

$$b_n = \sum_{j=1}^{n-1} 1/j^2 \quad (4.4b)$$

For sample sizes smaller than ten, the Tajima and Watterson estimators have similar expected sample standard deviations, but with larger n , the latter can be up to two-fold smaller

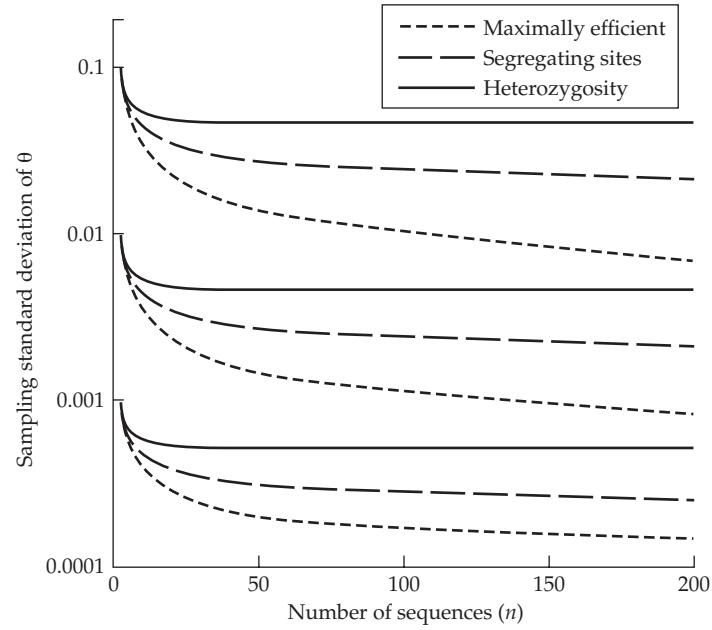

Figure 4.1 Expected sampling standard deviations for estimates of θ from sequences assumed to be neutral, in drift-mutation equilibrium, and experiencing no intragenic recombination. Results are derived from Equations 4.2 (Tajima estimator based on heterozygosity, solid line), 4.4 (Watterson estimator based on segregating sites, long-dashed line), and 4.5 (maximally efficient, short-dashed line), for $\theta = 0.1$, 0.01 , and 0.001 in descending order. The assumed number of sites is $L = 10,000$ in all cases.

than the former, although there is little to be gained with either approach once n exceeds 50 or so (Figure 4.1). It should, however, be emphasized that both Equation 4.2 and Equation 4.4a were derived under the assumptions of sequences experiencing *negligible recombination*. The necessary modifications to allow for intragenic recombination, derived in Pluzhnikov and Donnelly (1996; their Equations 6 and 7), play a role in some methods for estimating the population recombination rate, as described in the following section.

One significant issue that arises with the use of S to estimate θ in the modern era of high-throughput sequencing involves the introduction of upward bias from sequencing errors. With large numbers of sites and individuals, errors will inevitably appear as singletons but nonetheless enter the estimate of S . Such effects can be quite deceptive in population-genetic analyses because rare alleles are expected to be common under the neutral hypothesis. Johnson and Slatkin (2008), Kang and Marjoram (2011), and Keightley and Halligan (2011) suggested methods for eliminating the bias from S when an accurate estimate of the sequencing-error rate is available. An alternative approach relaxes this constraint by estimating the error rate from the data themselves (Lynch 2009).

Alternative Approaches

Felsenstein (1992) pointed out that neither of these approaches is likely to provide the most efficient estimates of θ (i.e., to yield estimates with minimum sampling variance), as they do not utilize all of the information in the sample of sequences. In particular, both approaches ignore the genealogical relationships of sequences (i.e., the coalescent structure of the sample), although under neutrality, the expected contribution to variation from each genealogical branch can be expressed in terms of θ (Equation 2.33b).

To evaluate how much improvement might be achieved by exploiting such information, Fu and Li (1993a) derived a maximum-likelihood estimator of θ for the extreme situation in which one knows with certainty the genealogical relationships of the sequences and the numbers of mutations and generations on each branch of the genealogy. The expected sampling variance of this estimator is

$$\sigma^2(\hat{\theta}_{ML}) = \frac{\theta}{a_n} \left(\frac{\theta a_n}{n-1} + \frac{1}{L} \right) \quad (4.5)$$

A comparison of this expression and Equations 4.2 and 4.4 illustrates that there is substantial room for improvement in the estimation of θ over the traditional heterozygosity and segregating-sites methods, provided the number of sequences exceeds five or so, and assuming a reasonably accurate gene genealogy can be obtained (Figure 4.1).

Gene genealogies cannot be constructed without error. However, by using information on the expected coalescence times of samples of neutral sequences, Fu (1994a, 1994b) developed several generalized least-squares estimators that account for the sampling variances and covariances of mutations on different branch segments. Several of these estimators, which utilize the concepts of the site-frequency spectrum (Fu 1995; Li and Fu 1999; see Chapter 2), asymptotically perform in a near-optimal manner as the sample size increases, again provided the sites are neutral and the population is in drift-mutation equilibrium.

As one or both of the latter two assumptions (neutrality and equilibrium) are likely to be violated to unknown degrees in many natural settings, having an estimator with minimum sensitivity to both problems would be highly useful. In fact, just such an approach can be extrapolated from Watterson's estimator (Equation 4.3). The basis for this strategy follows from the property for neutral alleles that in an equilibrium population, the number S_j of derived single-nucleotide variants found j times in a sample of size n has the expected value $L\theta/j$ (Watterson 1975; Fu 1995). Because the total number of segregating sites, S , has an expected value of $L\theta a_n$, it follows that Watterson's estimator is equivalent to an average of estimates of θ , each weighted by the inverse of the number of observations.

The simplest estimate of θ , based only on singletons ($j = 1$), is then

$$\hat{\theta}_1 = S_1/L \quad (4.6a)$$

which is also equivalent to the number of mutations (per site) on the external branches of a gene genealogy (Fu and Li 1993b). Such an estimator is attractive for two reasons. First, the singletons in a sample are a function of the very recent past, especially when the overall sample size is large, and hence are not expected to be influenced by distant periods of population-size change. Second, because the dynamics of rare alleles are primarily governed by the drift process, singleton frequencies are expected to most closely reflect the pattern expected under neutrality even when such mutations are nonneutral (Messer 2009). The sampling variance of the singleton-based estimator is

$$\sigma^2(\hat{\theta}_1) = \frac{\theta}{n} \left(\frac{n-1}{L} + \frac{\theta[2a_n(n-1)-1]}{n} \right) \quad (4.6b)$$

Considering just the sampling variance of the estimators of θ to this point, as $n \rightarrow \infty$, those for $\hat{\theta}_W$ and $\hat{\theta}_{ML}$ are $\theta/(15.4L)$, whereas that for $\hat{\theta}_\pi$ is $\theta/(3L)$, and that for $\hat{\theta}_1$ is θ/L . Thus, although the singleton-based estimator is likely to have the smallest amount of bias associated with selection, a focus on only a fraction of the segregating sites results in higher sampling variance.

Empirical Observations

Estimates of θ , mostly derived as silent-site heterozygosity from protein-coding genes using Equation 4.1, have been summarized for a wide range of species across the Tree of Life by Lynch (2007) and Leffler et al. (2012), and more specifically on metazoans and land plants

by Romiguier et al. (2014) and Corbett-Detig et al. (2015). Across a diverse assemblage of more than 100 eukaryotic and prokaryotic species, there is an inverse relationship between organism size and θ_π , with estimates for prokaryotes falling in the broad range of 0.007 to 0.388, with an average value of 0.104 (and a large standard deviation of 0.111). The average values for unicellular eukaryotes (mean = 0.057, SD = 0.078) and invertebrates (mean = 0.026, SD = 0.015) are 50% to 75% lower, and estimates for land plants (mean = 0.015, SD = 0.013) and vertebrates (mean = 0.004, SD = 0.003) are still smaller. Because the numbers of independent studies contributing to these estimates are in the range of 15 to 50, the cited means approach a level of reliability (with some caveats given below), but because of sampling error at the gene, individual, and population levels, the standard deviations likely overestimate the true evolutionary variance.

For both of the unicellular groups, silent-site heterozygosity measures are likely to be downwardly biased estimators of $4N_e u$ ($2N_e u$ for haploids), for at least two reasons. First, most recorded studies of microbial species are derived from surveys of pathogens, whose N_e may be abnormally low because of the restricted distributions of their multicellular host species, and second, silent-site variation will underestimate the neutral expectation if such sites experience some form of purifying selection. Such conditions can arise for a variety of reasons: (1) translation-associated selection when certain tRNAs have higher affinities for certain alternative codons (often referred to as **codon bias**); (2) selection on sites involved in splice-junction identification for species with introns; (3) secondary selection against codons that are one mutational step from termination codons; and (4) inhibition of double-strand break repair between highly divergent alleles. The molecular biological underpinnings of some of these factors, as well as their potential population-genetic consequences, are reviewed in Lynch (2007). Because all of these forms of selection are expected to be quite weak, they will be most effective in populations with very large N_e . Thus, although θ_π may underestimate $4N_e u$ ($2N_e u$ for haploids) in some microbial species by as much as ten-fold, the bias may be minor in multicellular eukaryotes. Many uncertainties remain, however, and we return to the topic in Chapter 8.

With these caveats in mind, the existing data make a compelling statement with respect to the relative power of mutation and random genetic drift—in essentially no eukaryotic species is there evidence that the former exceeds the latter (as this would cause $4N_e u > 1$), and in large multicellular land plants and vertebrates, the ratio is almost always on the order of 0.03 or much smaller. Thus, drift appears to be a more powerful force than mutation at the nucleotide level in all species, except perhaps the smallest microbes. As the absolute population sizes of many species (certainly microbes) can exceed $1/u$ by orders of magnitude (see below), these observations clearly support the idea introduced in Chapter 3 (and detailed in Chapter 8) that N_e is usually substantially smaller than the actual number of reproductive individuals in a population, and that this is largely a consequence of selection on linked sites, especially in large populations. Analyses of data on metazoans and land plants by Corbett-Detig et al. (2015) suggest that selection on linked sites typically reduces silent-site heterozygosity below the expected value $4N_e u$ by ~10%, although there are a few cases involving small, wide-ranging species where the downward bias is as great as 70%.

RELATIVE POWER OF RECOMBINATION AND GENETIC DRIFT

As will be seen in subsequent chapters, recombination plays an important role in evolution because the physical scrambling of linked genes increases the ability of natural selection to promote or eliminate mutations on the basis of their individual effects. On the other hand, high rates of recombination can often inhibit the establishment of pairs of mutations with favorable epistatic effects.

Two general approaches provide insight into the level of recombination per physical distance along chromosomes. Genetic maps, generally derived from controlled crosses, are based on observations on the frequency of meiotic crossovers between informative markers

(LW Chapter 14), whereas studies of linkage disequilibrium (LD) in natural populations use the theoretical concepts introduced in Chapter 2 to indirectly infer the relative magnitudes of the historical forces of random genetic drift and recombination. High-density genetic maps have the power to yield accurate estimates of average recombination rates over fairly long physical distances (usually with markers being separated by millions of nucleotide sites, which typically corresponds to >1% recombination per generation). However, because patterns of LD are generally outcomes of many thousands of generations, they have the potential to reveal much more refined (kilobase scale) views of the recombinational landscape. For a mapping cross involving n gametes with a recombination frequency c between marker sites, the expected number of recombinants is nc , so for sufficiently close sites, the typical outcome will be a complete absence of recombinants. On the other hand, if n random chromosomes are sampled from a natural population with a mean coalescence time between random alleles of $\bar{t} = 2N_e$ generations (Chapter 2), the expected number of recombination events is $2\bar{t}nc = 4N_e nc$. Thus, this chapter will focus on the use of LD, rather than directly observed meiotic crossover events, to derive inferences about recombination.

Before proceeding, we again remind the reader that we use c_L to denote the recombination rate between sites separated by a particular distance L , with c_0 denoting the recombination rate between adjacent sites. When referring to population-scaled recombination rates, we will use separate notations of $\rho_L = 4N_e c_L$ and $\rho = 4N_e c_0$. Although it is tempting to assume that $c_L = c_0 L$ and $\rho_L = \rho L$, as will be outlined below, such a linear transformation is not generally valid.

Recall from Chapter 2 that $\rho_L = 4N_e c_L$ is the effective number of recombination events between sites (separated by L base pairs [bp]) per generation at the entire population level, which is also equivalent to the ratio of the power of recombination to the power of drift. Just as the amount of segregating variation at neutral sites provides insight into the population mutation rate $\theta = 4N_e u$, the amount of standing LD is a function of the population recombination rate, ρ_L . Although a wide variety of methods for estimating the latter parameter have been proposed, the challenges to obtaining accurate measures are substantial. The markers employed must not only have at least moderate frequencies (to ensure accurate estimates of gamete frequencies and reasonable likelihoods of observing recombination events), but must also behave neutrally (to ensure the validity of the application of drift-recombination theory). Moreover, most of the proposed estimators rely on the assumption of drift-mutation-recombination equilibrium, while also suffering from very high sampling variance, which demands substantial replication over independent pairs of sites.

Number of Recombinational Events in a Sample of Alleles

The power of using population-level data in the detection of historical recombination rates is limited by the fact that recombination events only leave a trace if they involve pairs of doubly heterozygous chromosomes. Moreover, there is no way to directly determine whether multiple recombinants in a sample are a result of parallel recombination events or intact descendants of the same events. Thus, to obtain unbiased estimates of ρ_L , we require a method for converting the *observed* number of recombinant events in a sample to the *actual* number that likely occurred (R). This is not unlike the challenge in genetic-map production of converting observed into actual numbers of recombination events between markers (LW Chapter 14). We start with a description of methods involving short spans of DNA, e.g., single genes with **phased haplotypes** (such as complete sequences for each of the two alleles within diploid individuals). Chromosomal regions of such small size will often have recombination rates between their boundaries $\ll 0.01$, and hence would have no chance of revealing recombinants in simple mapping crosses.

For a set of sequences with the most extreme distance between polymorphic sites being L nucleotides, assuming a population in drift-mutation-recombination equilibrium, the expected number of recombination events, R , in a sample of n sequences is equal to $\rho_L a_n$, where a_n is given by Equation 4.3b (Hudson and Kaplan 1985). Thus, a potential

estimator for ρ_L is

$$\hat{\rho}_L = \hat{R}/a_n \quad (4.7)$$

where \hat{R} is the estimated number of recombinational events that have occurred between the maximum span of polymorphic sites in the history of the sequences within the sample. Note the similarity of the form of this expression to that relating the number of segregating mutations to θ (Equation 4.3a).

The primary impediment to applying this expression is the estimation of R . One approach, proposed by Hudson and Kaplan (1985), starts with the **four-gamete test**, which asserts that any pair of heterozygous sites exhibiting four gametic haplotypes must reflect the prior action of at least one recombination event, assuming an absence of parallel mutations. Under this view, starting with a fixed gamete of the form AB , a single mutation will create either an aB or Ab gamete, resulting in two gametic types in the population. This is a noninformative situation because recombination between the ancestral (AB) and derived (aB) haplotypes cannot generate a novel haplotype. If, however, prior to fixation of the first mutation, a mutation arises at the remaining homozygous site, there will be three haplotypes (e.g., AB , Ab , and aB), with the fourth type (ab) arising only by subsequent recombination between aB and Ab haplotypes. Judiciously applying this criterion to all pairs of segregating sites in a sample of sequences and ensuring that the same event is not counted more than once, it is possible to estimate R_{\min} , the minimum number of crossover events in the history of the sample (Hudson and Kaplan 1985). More complex approaches attempt to derive information from the complete haplotype structure in a sample (Myers and Griffiths 2003; Liu and Fu 2008).

In principle, with knowledge of the expected fraction of detectable recombination events, d_r , one could extrapolate the observed R_{\min} to an estimate of the actual value R . Assuming conditions of drift-mutation equilibrium, Stephens (1986) found approximate lower and upper bounds to d_r giving rise to observable, nonparental haplotypes,

$$d_{r,\min} = 1 - [2 \ln(1 + \Theta)]/\Theta + [1/(1 + \Theta)] \quad (4.8a)$$

$$d_{r,\max} = 1 - [2(1 - e^{-\Theta})]/\Theta + e^{-\Theta} \quad (4.8b)$$

where $\Theta = 4N_e uL$ is the population mutation rate for the stretch of DNA being surveyed. These two limits are respectively approached as $c \rightarrow 0.0$ (complete linkage) and $c \rightarrow 0.5$ (free recombination). As $\theta = \Theta/L$ is generally on the order of 0.001 to 0.01 for neutral sites, unless the segments being analyzed have lengths in excess of 1000 nucleotides, the majority of recombination events will simply reproduce parental gamete types, and hence not be scored as recombinants (Figure 4.2).

Given an estimate of Θ , Equations 4.8a and 4.8b can be used to approximate the total number of recombination events in the sample as R_{\min}/\bar{d}_r , where \bar{d}_r is the average of $d_{r,\min}$ and $d_{r,\max}$. However, even this approach is not fully adequate because only a subset of the recombinant gametes that are nonparental with respect to markers are also novel with respect to the entire population, i.e., the fraction of uniquely detectable recombination events in the population is even lower than suggested by Equations 4.8a and 4.8b.

An empirical approach to this problem was suggested by Zietkiewicz et al. (2003; see also Lefebvre and Labuda 2008). Letting p_i denote the frequency of the i th haplotype in a sample, an estimator for the fraction of detectable (but not necessarily unique) recombinant alleles is

$$\hat{d}_r = \sum_{i=1}^L \sum_{j>i}^L 2p_i p_j L_{\max,ij}/L \quad (4.9)$$

where $L_{\max,ij}$ is the distance between the maximally separated heterozygous sites in the ij th comparison. Through simulations, one can establish the fraction of potentially informative recombination events that would indeed produce novel haplotypes in the sample, thereby converting \hat{d}_r to \hat{d}'_r , the fraction of recombination events that lead to uniquely observable

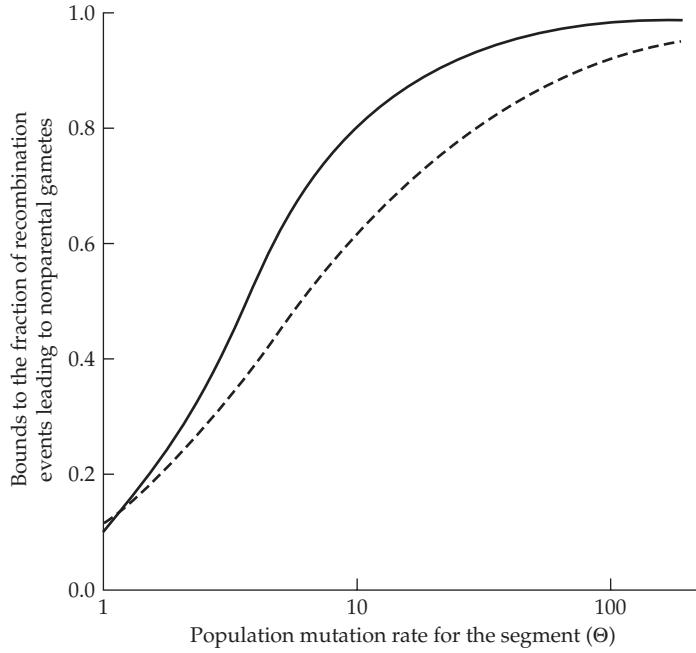

Figure 4.2 Approximate upper and lower bounds on the fraction of recombination events that produce nonparental gametes among two or more neutrally evolving sites (from Equations 4.8a and 4.8b). $\Theta = L\theta$ is the product of the population mutation rate per site (θ) and the length of the segment (L in base pairs).

recombinants. Recalling Equation 4.7, a method-of-moments estimator for the population recombination rate is then

$$\hat{\rho}_L = \hat{R}_{\min} / (\hat{d}'_r a_n) \quad (4.10)$$

Other Approaches for Narrow Genomic Intervals

An alternative method-of-moments approach to estimating ρ_L was suggested by Hudson (1987), who noted that the variance of pairwise measures of neutral sequence divergence is expected to decline with increasing levels of recombination. (With strong linkage disequilibrium, some random pairs of haplotype blocks will be identical over all polymorphic sites, while others will differ at all such sites.) This approach requires an estimate of the average number of nucleotide differences between random sequences of length L , $\Theta_\pi = \theta_\pi L$, as well as the observed variance of pairwise divergence,

$$\hat{\sigma}_k^2 = \frac{2}{n(n-1)} \sum_{i=1}^n \sum_{j>i}^n (k_{ij} - \Theta_\pi)^2 \quad (4.11)$$

where k_{ij} is the number of sites at which sequences i and j differ, and n is the number of chromosomes scored in the sample. Wakeley's (1997) Equation 15 allows one to estimate ρ_L as a function of Θ_π , $\hat{\sigma}_k^2$, and n .

Fuller use of the information in sample data can be achieved by considering the probabilities of various sample counts of the four gametic types at two loci or nucleotide sites (i.e., AB , Ab , aB , and ab) assumed to be biallelic, neutral, and in drift-mutation-recombination equilibrium (Hudson 2001). For any hypothetical combination of the parameters θ , ρ_L , and

sample size n , one may compute the probability of the observed data for each pairwise combination of markers (Golding 1984; Ethier and Griffiths 1990), although obtaining exact probabilities of two-locus sampling configurations is mathematically challenging, and for large sample sizes, approximations must often be obtained by computer simulation (but see Jenkins and Song 2009). Further simplification can be achieved by obtaining probabilities of sampling configurations conditional on two alleles actually segregating at both sites, as this eliminates the dependence on θ (Hudson 2001). One can then combine the likelihood estimates with respect to ρ_L over all nonoverlapping pairs of linked segregating sites to obtain a global estimate of ρ (Hudson 2001). (Usually, this is done by assuming that $\rho = \rho_L/L$, although as noted below there are problems with this approach when the distances between sites are highly variable.) Because the data are not entirely independent, this **composite likelihood approach** is just an approximation to a full ML analysis, and the confidence limits for the resultant estimates can only be achieved by computer simulations. McVean et al. (2002) extended this approach to allow for parallel mutations, which in species with high mutation rates, can lead to the false appearance of recombination under the usual assumptions of the four-gamete test.

The efficiency of all of these methods can be questioned in the sense that they use summary statistics that do not necessarily make full use of all of the information in the sample. Most notably, they do not account for the genealogical relationships among the sampled haplotypes. To this end, several more elaborate ML approaches and their Bayesian extensions go well beyond the method of Hudson (2001) (e.g., Kuhner et al. 2000; Nielsen 2000; Fearnhead and Donnelly 2001). As the number of genealogies consistent with any given set of mutational and recombinational parameters is enormous, exact solutions are not possible with these computationally intensive approximations. Moreover, although one would expect estimates derived in an explicit likelihood framework to perform better than the ad hoc procedures outlined above, it remains unclear whether that is the case for the sample sizes (n and L) that have been typically applied to date, as all existing estimators appear to be biased, have very large sampling variances, and rely on the assumption of an equilibrium population (Wall 2000).

Large-scale Analysis

The methods outlined in the preceding paragraphs were developed largely for analyzing sequences at the level of gene-sized fragments. However, with the sequencing of entire genomes of multiple individuals now becoming routine, genome-wide profiles of LD can be obtained. One limitation of genome-sequencing technologies is that sequence read lengths remain small (often on the order of 100–200 bp), so that unlike the situation when individual alleles are cloned and sequenced, the phases of haplotypes are not certain for double heterozygotes at distant pairs of sites. However, unambiguous haplotypes can still be inferred from information contained within singly heterozygous individuals, with the resultant frequency estimates enabling one to compute the full slate of LD statistics. Moreover, mean read lengths are rapidly expanding, so this will soon be a minor consideration.

One approach to estimating ρ from whole-genome sequencing relies on data from just a single individual (Lynch 2008a). This maximum-likelihood method estimates the correlation Δ of “zygosity” (heterozygosity and homozygosity) of pairs of sites separated by specific distances (L) across the genome to obtain disequilibrium measures that are nearly unbiased with minimal sampling variance. Spatial patterns of heterozygosity arise because recombination causes variation in coalescence times among chromosomal regions. In effect, this leads to clustering of heterozygous sites in long stretches of DNA that by chance have experienced little recombination and have long coalescence times. For any distance L (in nucleotides) between sites, Δ_L is defined as the deviation of the frequency of pairs of nucleotide sites with mixed zygosities from the random expectation

$$\Delta_L = 1 - \frac{H_{1d}}{2\pi(1-\pi)} \quad (4.12)$$

with H_{1d} denoting the fraction of pairs of sites at distance L containing one heterozygote

and one homozygote, and $2\pi(1 - \pi)$ being the expected fraction of such mixed pairs under a random distribution given an average level of heterozygosity π .

For the situation in which the genome-wide patterns of variation are largely driven by mutation, recombination, and genetic drift, and the population is in equilibrium, by using expressions from Ohta and Kimura (1969b) for the two-allele model, it can be shown that

$$E(\Delta_L) \simeq \frac{\theta(1 + 2\theta)(18 + \rho_L)}{2(1 + \theta)A} \quad (4.13a)$$

where

$$A = 9 + 6.5\rho_L + 0.5\rho_L^2 + 19\theta\rho_L + 12\theta^2\rho_L + \theta\rho_L^2 + 54\theta + 80\theta^2 + 32\theta^3 \quad (4.13b)$$

(Lynch et al. 2014), where $\rho_L = 4N_e c_L$ is the scaled population recombination rate for sites separated by distance L (and having recombination rate c_L). Note that as $\rho_L \rightarrow 0$, $E(\Delta_L) \rightarrow \theta(1 + 2\theta)/(1 + 7\theta)$, which is closely approximated by θ when $\theta \ll 1$ (which, as noted above, is generally the case). As $\rho_L \rightarrow \infty$, $E(\Delta_L) \rightarrow \theta(1 + \theta)/\rho_L \simeq \theta/\rho_L$. Thus, given an estimate of θ , with estimates of average Δ_L for neutral sites separated by $L = 1, 2, 3, \dots$ sites, each based on thousands to millions of pairs of sites, the decline in Δ_L with L can be used to infer the distance dependence of ρ_L .

Another potentially powerful method for estimating ρ with population-genomic data takes advantage of the standardized linkage disequilibrium (r^2) introduced in Chapter 2. For neutral sites in drift-mutation equilibrium, Equation 2.29a gives a full expression for r_L^2 in terms of θ and ρ_L . However, provided $\theta \ll 1$ (which is always the case) and $\rho_L \gg \theta$ (which, as shown below, is generally the case for physically distant sites), Equation 2.29a simplifies to

$$r_L^2 \simeq \frac{10 + \rho_L}{(11 + \rho_L)(2 + \rho_L)} \simeq \frac{1}{2 + \rho_L} \quad (4.14)$$

The simplification to the right of this equation (Hill 1975; McVean 2002), which causes no more than 10% bias in estimating ρ_L , is often relied on in the literature (Hayes et al. 2003; Tenesa et al. 2007). We noted in Example 2.7 that another commonly used approximation, $r_L^2 \simeq 1/(1 + \rho_L)$, has a more restricted meaning, which limits its use with molecular data.

As the sampling variance for r_L^2 for single pairs of polymorphic sites is generally very high, the usual strategy is to procure a large number of estimates for different pairs of informative markers separated by a certain window of physical distance, and then to pool these into a single estimate for that distance. Subtracting an expected contribution $1/n$ to r_L^2 resulting from finite sample size (Weir and Hill 1980), and rearranging Equation 4.14, leads to the estimator for sites separated by distance L ,

$$\hat{\rho}_L = \frac{1}{\widehat{r_L^2} - (1/n)} - 2 \quad (4.15)$$

A significant problem, often unappreciated, is that estimates of r_L^2 can be substantially biased if sample sizes are small or allele frequencies are extreme (Song and Song 2007).

Before proceeding, it is useful to review the specific mechanics of recombination between nucleotide sites, as we have not yet clarified how the recombination rate scales with distance L . Although it is often assumed that the recombination rate is simply equal to the crossover rate between sites, this is generally not true for closely spaced sites. Recombination events nearly always involve heteroduplex formations between homologous chromosomes, i.e., the temporary physical annealing of homologous regions of complementary strands (usually no more than a few hundred base pairs). When such heteroduplexes contain heterozygous sites, the nonmatching sites have to be resolved by **gene conversion**. Inclusion of these processes in the interpretation of the recombination rate is essential because although recombination events result in the potential for gene conversion, not all gene conversion events are accompanied by crossovers. Because gene-conversion tracts are relatively short,

when sites are far apart, most recombination events result from crossing over, but when sites are close together, recombination mostly results from the conversion of single sites.

To understand this in a more quantitative way, let c_0 be the total rate of initiation of recombination events per nucleotide site (with or without crossing over), L be the number of sites separating the two focal positions (with $L = 1$ for adjacent sites), and x be the fraction of recombination events accompanied by crossing over. Using Haldane's (1919) mapping function (LW Equation 14.3), which assumes random and independent recombination at all sites, the crossover rate can be represented as $0.5(1 - e^{-2c_0xL})$, which is $\simeq c_0xL$ for $c_0xL \ll 1$, and asymptotically approaches 0.5 for large c_0xL . In the following, we assume distances between sites that are small enough that the crossover rate $\simeq c_0xL$.

As noted by Andolfatto and Nordborg (1998), from the perspective of two sites, a gene conversion event has consequences equivalent to a crossover if the conversion tract encompasses just one of the sites. Under the assumption of an exponential distribution of tract lengths with mean length T (in bp), the total conversion rate per site is $(1 - x)c_0T(1 - e^{-L/T})$ (Langley et al. 2000; Frisse et al. 2001; Lynch et al. 2014). The total recombination rate between sites separated by distance L is then

$$c_L \simeq c_0[xL + (1 - x)T(1 - e^{-L/T})] \quad (4.16a)$$

For $L \ll T$,

$$c_L \simeq c_0L \quad (4.16b)$$

whereas for $L \gg T$,

$$c_L \simeq c_0Lx \quad (4.16c)$$

These results show that the simple division of an estimate of ρ_L by L to obtain an estimate of the per-site parameter $\rho = 4N_e c_0$, a common practice, may yield rather different answers depending on the distance between sites; at large distances ρ specifically measures the population crossover rate between sites.

Empirical Observations

Applying the preceding methods to population samples, many attempts have been made to measure the population recombination rate $\rho = 4N_e c_0$, usually first estimating ρ_L at various distances between sites, and then dividing by L under the assumption that $c_L = c_0L$, i.e., assuming a linear relationship between the recombination rate and physical distance between sites. As noted above, this is a reasonable approximation provided the distance between sites is less than the average length of a conversion tract but will lead to an underestimate of ρ (by a factor of $1/x$) when greater distances are relied upon. Using this procedure, all estimates of the per-site parameter $4N_e c_0$ are smaller than 0.1, with many falling below 0.01 (Table 4.1). Because the fraction of recombination events resulting in crossing over (x) is typically in the range of 0.05 to 0.25 (as reviewed below), these general observations provide strong support for the idea that random genetic drift is generally a much more powerful force than recombination at the level of individual nucleotide sites.

By dividing estimates of $4N_e c_0$ by parallel estimates of $\theta = 4N_e u$, the effective population size cancels out, yielding an estimate of the ratio of recombination and mutation rates at the nucleotide level (c_0/u). All such estimates are smaller than 5.0, and nearly half are smaller than 1.0, implying that the power of recombination between adjacent sites is generally of the same order of magnitude or smaller than the power of mutation (Table 4.1). The average estimate of c_0/u for *Drosophila* is ~ 2.7 , whereas that for humans is ~ 0.8 . Average c_0/u for 14 land plants is 1.1 (SD = 1.2), although this may somewhat underestimate the average for purely outcrossing species because several of the taxa included in the survey (e.g., *Arabidopsis* and *Oryza*) are predominantly self-fertilizing, which reduces the effective amount of recombination (Hagenblad and Nordborg 2002).

It is notable that even though prokaryotes do not engage in meiosis, estimates of c/u for such species are generally of the same order of magnitude as those for eukaryotes (Lynch

Table 4.1 Estimates of the per-site population recombination rate ($\rho = 4N_e c_0$) and the ratio of the per-site recombination and mutation rates (c_0/u , obtained by dividing estimates of ρ by estimates of $\theta = 4N_e u$). All estimates are derived from population surveys of nucleotide variation at silent sites in protein-coding genes.

2007). This suggests that, relative to the background rate of mutation, recombination at the nucleotide level is not exceptionally low in prokaryotes, although the downward bias in estimates of θ for this group (noted above) may lead to inflated estimates of c_0/u .

Applying the single-individual estimator (i.e., the correlation of zygosity) and fitting the generalized recombination function (Equation 4.16a) clarifies a number of features of recombination in mammalian species (Lynch et al. 2014). First, estimates of $4N_e c_0$ in mammals are generally in the range of 0.001 to 0.005, again implying a substantially higher power of genetic drift than of recombination at the single-site level.

Second, the fraction of recombination events resulting in crossovers is generally in the range of $x = 0.05$ to 0.25 . This is consistent with empirical work suggesting $x \simeq 0.30$ in the budding yeast *S. cerevisiae* (Malkova et al. 2004; Mancera et al. 2008), and $x = 0.15$ in the fly *D. melanogaster* (Hilliker et al. 1994). Indirect LD-based analyses have also led to estimates of $x \simeq 0.14$ in humans (Frisse et al. 2001; Padhukasahasram and Rannala 2013), $x = 0.08$ in *D. melanogaster* (Langley et al. 2000; Yin et al. 2009), $x = 0.05$ in the plant *A. thaliana* (Yang et al. 2012), and $x = 0.06$ to 0.16 in wild barley (Morrell et al. 2006). Thus, observations in a variety of organisms consistently point to the fact that the vast majority of recombination events are simple local gene-conversion events unaccompanied by crossovers, raising questions about the frequently used assumption that $c_L = c_0 L$.

Third, based on single-individual LD analysis, the inferred average lengths of conversion tracts in mammals are typically in the range of $T = 10^3$ to 10^4 bp, which is consistent with more direct observations made in other species: $T \simeq 400$ bp in bacteria (Santoyo and Romero 2005); $T = 500$ to 4000 bp in *S. cerevisiae* (Ahn and Livingston 1986; Judd and Petes 1988; McGill et al. 1990); $T = 400$ to 1400 bp in *D. melanogaster* (Hilliker et al. 1994; Preston and Engels 1996; Miller et al. 2012); and $T = 200$ to 3000 bp in mammals (Chen et al. 2007; Paigen et al. 2008; Rukšć et al. 2008). Referring to Equations 4.16b and 4.16c, this suggests

that the assumption of $c_L = cL$ is generally approximately valid provided $L < 500$ bp, whereas for distances > 5000 bp, the recombination rate primarily reflects the crossover rate, i.e., $c_L \simeq c_0 Lx$.

Finally, the results in Lynch et al. (2014) suggest that the level of LD at closely spaced sites (< 200 bp) in vertebrates is generally much higher than can be accounted for by the standard neutral model outlined above, a conclusion that was reached in a number of other studies: *Drosophila* (Andolfatto and Przeworski 2000); humans (Przeworski and Wall 2001); sorghum (Hamblin et al. 2005); and *Arabidopsis* (Kim et al. 2007). There are at least three reasons why unusually high levels of LD may exist at closely spaced sites, all associated with the nonindependence of mutational and/or recombinational events. First, new mutations arise in a significantly clustered manner on spatial scales of ~ 100 bp, possibly as a consequence of an occasional defective polymerase engaging at origins of replication or of the localized deployment of error-prone polymerases in DNA repair (Schriener et al. 2011; Harris and Nielsen 2014). Second, recombination and double-strand-break repair are mutagenic, violating the usual assumption of the independence of these two processes (Hicks et al. 2010; Malkova and Haber 2012; Arbeithuber et al. 2015). Third, nonhomologous gene conversion can introduce excess LD at individual sites (Walsh 1988; Mansai and Innan 2010).

EFFECTIVE POPULATION SIZE

Although the theory outlined in Chapter 3 suggests numerous ways in which the effective size of a population might be estimated from demographic data, such information is often difficult to come by, except in carefully controlled breeding populations. Moreover, estimates of N_e based on demography alone generally do not incorporate the long-term effects of selection on linked chromosomal regions, and certainly not selective sweeps or background selection.

Nevertheless, there are several ways in which inferences about N_e can be made without direct demographic observation. From the standpoint of natural populations, two approaches harbor the most promise—monitoring temporal changes in putatively neutral allele frequencies, and ascertaining genome-wide patterns of LD, in both cases back-calculating the value of N_e that best explains the data (reviewed by Wang 2005).

Temporal Change in Allele Frequencies

Consider a **single nucleotide polymorphism** (usually abbreviated as a **SNP**) sampled on two occasions separated by t generations, with initial frequency p_0 , and recall from Chapter 2 that the expected variance in allele-frequency change after t generations is $p_0(1 - p_0)(1 - e^{-t/(2N_e)}) \simeq p_0(1 - p_0)t/(2N_e)$ for small $t/(2N_e)$. This represents only the true population variance (the evolutionary variance in the preceding parlance), to which the sampling variance associated with errors in *observed* allele-frequency estimates (owing to finite sample size) must be added. Summing these two sources of stochasticity yields an overall estimate of the expected variance of allele-frequency change of $p_0(1 - p_0)[t/(2N_e) + 1/(2n_0) + 1/(2n_1)]$ between two time points, where n_0 and n_1 denote the number of individuals (assumed to be diploid) genotyped in the two generations. Letting \hat{p}_0 and \hat{p}_1 be the estimated allele frequencies in the two generations, an estimate of the observed variance in allele-frequency change across generations can be written as $(\hat{p}_1 - \hat{p}_0)^2$ because $E(\hat{p}_1 - \hat{p}_0) = 0$ under neutrality.

Krimbas and Tsakas (1971) suggested that by equating the observed and expected variance of allele-frequency change and rearranging, the effective population size can be estimated from observations over two consecutive generations ($t = 1$)

$$\widehat{N}_e = \frac{1}{2\widehat{F}_1 - (1/n_0) - (1/n_1)} \quad (4.17a)$$

where

$$\hat{F}_1 = \frac{(\hat{p}_0 - \hat{p}_1)^2}{\hat{p}_0(1 - \hat{p}_0)} \quad (4.17b)$$

is a measure of the standardized variance of allele-frequency change. Provided $t/(2N_e) \ll 1$, the same expression applies when samples are made t generations apart, if t is substituted for one in the numerator of Equation 4.17a. (Note that the definition of F_1 is identical in form to the population-subdivision statistic F_{ST} , presented as Equation 2.42, except that the latter is concerned with spatial rather than temporal variation.)

Despite their intuitive nature, Equations 4.17a and 4.17b yield biased estimates because the contributions of the sampling variance (and in some cases, covariance) of allele frequencies to F_1 are not fully accounted for (Pamilo and Varvio-Aho 1980; Nei and Tajima 1981b; Pollak 1983; Tajima and Nei 1984; Waples 1989a). Additional limitations are that \hat{F}_1 is undefined if $\hat{p}_0 = 0$, and that Equations 4.17a and 4.17b do not immediately allow for the incorporation of multiple alleles. An alternative estimator that deals with these problems is

$$\hat{N}_e = \frac{t - 2}{2\hat{F} - (1/n_0) - (1/n_1)} \quad (4.18a)$$

where \hat{F} is calculated by either

$$\hat{F}_2 = \frac{1}{k} \sum_{i=1}^k \frac{(\hat{p}_{0i} - \hat{p}_{1i})^2}{[(\hat{p}_{0i} + \hat{p}_{1i})/2] - \hat{p}_{0i}\hat{p}_{1i}} \quad (4.18b)$$

(Nei and Tajima 1981b), or

$$\hat{F}_3 = \frac{1}{k} \sum_{i=1}^k \frac{(\hat{p}_{0i} - \hat{p}_{1i})^2}{(\hat{p}_{0i} + \hat{p}_{1i})/2} \quad (4.18c)$$

(Pollak 1983), where k is the number of alleles. The details leading up to these alternative expressions can be found in the primary references, but it is notable that because $(\hat{p}_{0i} + \hat{p}_{1i})/2$ is generally much larger than $\hat{p}_{0i}\hat{p}_{1i}$, both estimators usually lead to very similar results (Waples 1989a). One drawback of Equation 4.18a is that it requires an interval of at least three generations.

More refined measures of F can be obtained by averaging estimates of F_1 , F_2 , or F_3 over multiple loci, and Pollak (1983) derived a generalized estimator that allows for sampling across more than a single time interval. All of these approaches assume that the sampling of individuals at the beginning of an interval has no effect on the allele-frequency variance, which is reasonable when samples constitute a minor fraction of the population or are taken in a nondestructive manner or following reproduction. An additional concern is that the sampling scheme for allele frequencies, which is straightforward in a synchronized population with discrete generations but potentially problematical in species with overlapping generations. In the latter case, the contributions of sampled individuals to the overall allele-frequency estimates need to be weighted by the reproductive values of various age classes (Waples and Yokota 2007), a difficult enterprise with species with poorly understood life histories. Attention to these issues is provided in Nei and Tajima (1981b) and Waples (1989a).

Estimates of N_e derived by these method-of-moment estimators generally have substantial sampling variances, and negative estimates of N_e are even possible. Clearly, if $t/(2N_e) \ll 1/(2n_0) + 1/(2n_1)$, observed fluctuations in allele frequencies will be largely a consequence of sampling error, so the utility of the overall approach becomes diminishingly small in populations with large effective sizes. Assuming equal sample sizes for each locus, the sampling variance of \hat{N}_e is

$$\text{Var}(\hat{N}_e) \simeq \left(\frac{8N_e^4}{t^2 M} \right) \left(\frac{1}{4N_e^2} + \frac{1}{N_e t \bar{n}} + \frac{1}{t^2 \bar{n}^2} \right) \quad (4.19)$$

where M denotes the number of independent allelic comparisons and \tilde{n} is the harmonic mean of the per-locus sample sizes in the two generations (Pollak 1983). In general, M , t , and \tilde{n} will be under the control of the investigator, so Equation 4.19 provides a useful basis for designing an optimal sampling strategy. For example, a doubling of M will reduce the sampling variance by one half, whereas a doubling of the sampling interval (t), which may often be less costly, has a much greater effect.

The sampling distribution of the composite function $M[\hat{F}/E(F)]$, where $E(F)$ denotes the expected value, is expected to be approximately χ^2 in form, with M degrees of freedom (Lewontin and Krakauer 1973; Nei and Tajima 1981b), and this fact can be used to construct confidence intervals for N_e by substituting the critical χ^2 values for \hat{F} into Equation 4.18a, e.g., using the values of F at the 2.5% and 97.5% cumulative probability levels to yield 95% confidence limits. However, using computer simulations, Goldringer and Bataillon (2004) found that the χ^2 assumption can be significantly violated when there is a minor allele with frequency < 0.1 , there is large number of alleles (as with microsatellites) or the number of generations between sampling times is large. In Chapter 9, the issue of temporal change in allele frequencies will be revisited from a different perspective—testing the hypothesis that an observed magnitude of change is inconsistent with random genetic drift for an assumed value of N_e , or equivalently estimating the largest value of N_e that is consistent with the observed change being entirely due to drift.

Because of their simple heuristic interpretations, method-of-moments estimators, like those just noted, are highly popular approaches for estimating population parameters. However, on a single summary statistic, such methods do not fully utilize the information in a set of samples. A more powerful approach to estimating N_e from sequential samples involves the use of ML procedures (and their Bayesian extensions) to yield estimates that best explain the entire distribution of observed allele frequencies conditional on sample sizes (Williamson and Slatkin 1999; Anderson et al. 2000; Berthier et al. 2002). These methods are highly demanding computationally, a demand that increases with N_e , although Wang (2001), Beaumont (2003), Tallmon et al. (2004), Anderson (2005), and Bollback et al. (2008) have presented computationally efficient approximations.

Single-sample Estimators

Because of the practical difficulties in obtaining temporal sequences of samples, especially in species such as vertebrates and land plants with long generation times, a number of methods have been developed for estimating N_e from the information contained in just a single sample. Only a brief overview of such methods will be provided here. One of the most commonly applied single-sample estimators is the LD method, already outlined above. Under the assumption of drift-mutation-recombination equilibrium, estimates of $\rho_L = 4N_e c_L$ can be obtained, so if the recombination rate between the loci under consideration is known, then $\hat{\rho}_L/(4c_L)$ will provide an estimate of N_e (Hill 1981). Likewise, if the mutation rate per nucleotide site (per generation) is known, any estimate of $\theta = 4N_e u$ can be converted to an estimate of long-term N_e using $\hat{\theta}/(4u)$. Again, being based on simple summary statistics, these estimators do not utilize all of the information inherent in a sample of alleles, and hence are not likely to provide the most efficient estimates of N_e . Alternative, highly computationally intense coalescent sampling methods have been developed to estimate various population-genetic parameters, including N_e , mutation and recombination rates, and other demographic parameters (e.g., population growth rates and degree of subdivision), using the genealogical information inherent in samples of population sequences (Kuhner 2008).

A second approach, applicable only to randomly mating species, relies on observed amounts of excess heterozygosity relative to Hardy-Weinberg expectations. The basis of this procedure is the random deviation in allele frequency that develops among the two sexes as a consequence of stochastic sampling of gametes in the preceding generation. In effect, the two sexes are being viewed as two random samples of gametes here—and the smaller the value of N_e , the larger the expected deviation between the sexes (Robertson 1965;

Pudovkin et al. 1996; Luikart and Cornuet 1999). Such variation among the sexes causes excess heterozygosity in the progeny generation by elevating the likelihood that each sex will contribute an alternate allele to the offspring.

A third single-sample method attempts to estimate the fraction of pairs of randomly sampled offspring from a population that are either full or half-sibs (Wang 2009). This method relies on statistical procedures for deriving estimates of relatedness with molecular markers. As in the case of the heterozygosity-excess approach, information on a large number of informative markers is required, and a random sampling scheme is essential. These last two approaches are restricted to very small population sizes (on the order of 100 reproductive adults or fewer), which are required to generate detectable deviations from Hardy-Weinberg expectations and detectable numbers of sib pairs.

Empirical Observations

In Chapter 3, we found that the numerous demographic factors influencing the effective size of a population almost always do so in a downward direction. Applications of the methods outlined above provide some indication as to the magnitude of this reduction relative to the actual size of a population (N). Because the temporal-fluctuation method requires a small enough N_e to yield meaningful results on a reasonable time scale, not surprisingly, almost all estimates using this technique derive from large-bodied (relatively small N) vertebrate species. In a survey of studies on mostly low-fecundity species, Frankham (1995) found an average N_e/N of ~ 0.11 , whereas a subsequent study with a much larger sample obtained an average of 0.14 (Palstra and Ruzzante 2008).

It is likely that the $\sim 90\%$ reduction in N_e suggested by these studies is a considerable *underestimate* of the situation for many nonvertebrate species and even many vertebrates. For example, as noted in Chapter 3, high-fecundity fish in spatially variable environments appear to have $N_e/N < 0.001$ (Hedrick 2005). In addition, many unicellular species have conspicuous phases of asexual reproduction that can encourage the rapid proliferation of a small number of clones, generating N_e/N ratios much lower than 0.001 via genetic hitchhiking. Strongly inbreeding species (e.g., self-fertilizing plants) may also approach such extremes. Finally, one of the major shortcomings of the temporal-fluctuation approach to estimating N_e may be its tendency to overlook rare, but quantitatively significant, phases in which genomic regions are exposed to strong selective sweeps at linked loci (Chapter 8).

Example 4.1. Hill (1981) noted that estimates of N_e based on the amount of standing LD between tightly linked markers are more a function of the long-term population history while LD measures between more loosely linked markers are reflective of recent history. Hayes et al. (2003) seized upon this observation to suggest that by using estimates of $\rho_L = 4N_e c_L$ for different values of c_L (i.e., known genetic-map distances between sites), one could, in effect, estimate the effective population sizes at different times in the past. In particular, for a model of linear population-size change (growth or decline), they suggested that LD between markers with recombination frequency c_L yields estimates of N_e at roughly $1/(2c_L)$ generations in the past.

To apply this approach, Tenesa et al. (2007) scored $\sim 10^6$ SNPs to examine LD at various intrachromosomal distances for four different human populations, and Figure 4.3a shows the result for a Utah population of European ancestry. For given slices of time, the various points indicate the separate estimates based on each of the 22 autosomes. Note both the consistency of estimates over autosomes and the very recent expansion of population size. Similar studies in humans were performed by Sved et al. (2008) and McEvoy et al. (2011). In contrast, when Hayes et al. (2003) and Flury et al. (2010) applied this approach to modern dairy cattle, they concluded that N_e had dramatically *declined* from historical values, presumably reflecting the bottlenecking effects of selection for improved milk production (Figure 4.3b).

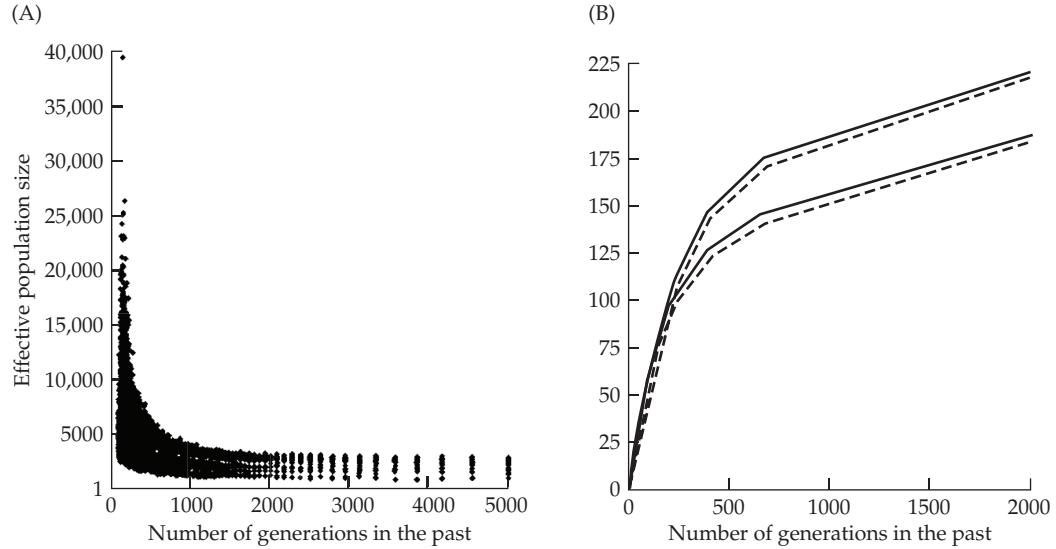

Figure 4.3 Estimates of historical values of N_e using linkage-disequilibrium between large numbers of pairs of markers with different genetic-map distances. The estimates were pooled into categories with different values of c (between markers), with the bin-specific values of $1/(2c)$ serving as estimates of the time in the past (in generations) for which the categories provide estimates of N_e . The latter is calculated by using the simplified version of Equation 4.14 given the average estimate of r^2 and c for the bin. **A:** Estimates of historical changes in N_e for a Utah population of European extraction. For a given generation time slice, the points represent an estimate based on the markers from each of the 22 human autosomes. Note the rapid increase in N_e in the recent past. (After Tenesa et al. 2007.) **B:** Estimates for the Swiss Eringer breed of cattle. Here, the different curves represent different assumptions used to correct estimates of ρ for sampling effects and different estimates of the fine-scale recombination rates. Regardless of the assumptions involved, it is clear that in contrast to the results for the human population, N_e has dramatically declined over the past 500 years. (After Flury et al. 2010.)

MUTATION RATE

The long-term evolution of complex traits ultimately depends on the input of new variation via mutation, which is a function of the rate at which new mutations arise at the DNA level and their influence at the phenotypic level, the combined effects defining the overall rate of polygenic mutation (LW Chapter 12). Here, we continue to focus specifically on the DNA-sequence level, with u being defined as the rate of mutation per nucleotide site per generation. Because mutations arise at an extremely low rate at most nucleotide sites, the direct estimation of u is formidably challenging, with most approaches relying on procedures that enrich the pool of experimentally derived mutations in an effectively neutral fashion (so that selection does not bias the outcome). Here, we review the two most commonly used methods of enrichment: (1) long-term genome-wide accumulation of mutations in isolated lineages with tiny effective population sizes; and (2) short-term isolation of conspicuous mutants at single marker loci from large populations raised on selective media.

Divergence Analysis

The most conceptually simple approach to estimating u , which is frequently applied to mul-

ticellular organisms with fairly long generation times, is to perform a mutation-accumulation experiment (LW Chapter 12), whereby a set of initially genetically identical (and usually homozygous, if not clonal) lines are passed through repeated population bottlenecks. For example, with the self-fertilizing nematode *Caenorhabditis elegans* and the plant *Arabidopsis thaliana*, an ancestral line can be repeatedly selfed to ensure homozygosity, with the progeny of one parent being used to synchronously initiate a set of parallel lines, each subsequently maintained by single-progeny descent. With each line having an effective population size of just one individual under this design, essentially all mutations that do not cause lethality or complete sterility (the vast majority of mutations) will accumulate independently at a rate u per site, in accordance with the neutral theory (Chapter 2). Under self-fertilization, newly arisen mutations are fixed or lost in just two generations on average, so after several dozens to hundreds of generations of mutation accumulation, nearly all mutations can be detected as fixed homozygotes by sequencing a subset of lines. Typically, nearly all lines will be identical at individual nucleotide sites (reflecting the ancestral state), with mutations in specific lines appearing as single-line outliers.

Letting n denote the number of sites surveyed, L the number of lines, T the average number of generations per line, and m the number of observed mutations summed over lines and sites, the mutation rate per site is estimated as

$$\hat{u} = m/(nLT) \quad (4.20a)$$

with sampling variance of

$$\sigma^2(\hat{u}) \simeq \hat{u}/(nLT) \quad (4.20b)$$

The latter expression implies a coefficient of sampling variation for \hat{u} of $(unLT)^{-1/2}$, which is the inverse of the square root of the expected number of observed mutations in the assay.

Example 4.2. A commonly used variant of the laboratory mutation-accumulation experiment for estimating mutation rates exploits the information inherent in natural populations, relying on presumptively neutral sequences from isolated but closely related species. Recall from Chapter 2 that the long-term rate of nucleotide substitution at neutral sites is equal to the mutation rate regardless of N_e , and from above that the average nucleotide heterozygosity of random sites within a species has expected value $4N_e u$. Thus, for two sister taxa that became isolated t generations in the past, the expected divergence of orthologous neutral sequences (number of substitutions per site) is $d = 2tu + 4N_e u$, assuming equal N_e in both taxa. At $t = 0$, $d = 4N_e u$ (the average divergence of randomly sampled alleles in the ancestral population), whereas as $t \rightarrow \infty$, $d \simeq 2tu$ (a widely used approximation in applications of molecular clocks for dating evolutionary events). Rearranging, and using $\bar{\theta}_H$, the average within-species nucleotide diversity at silent sites as the estimate of $4N_e u$, we obtain an estimator for the mutation rate, $\hat{u} = (\hat{d} - \bar{\theta}_H)/(2t)$.

Nachman and Crowell (2000) used this approach to obtain an estimate of the mutation rate for humans from sequences of 12 unexpressed pseudogenes in human and chimpanzee. Because they are nontranscribed, such stretches of DNA are expected to fulfill the assumptions of neutrality. The average number of substitutions per site separating the two species was $\hat{d} = 0.0133$. A broad geographic survey of within-species variation in 49 noncoding (and presumably largely neutral) regions yielded estimates of 0.00087 for human and 0.00134 for chimpanzee (Yu et al. 2003), implying $\bar{\theta}_H = 0.00110$. Nachman and Crowell assumed a divergence time of 5 million years, and an average generation time of 20 years, implying $t \simeq 250,000$ generations. Substitution into the preceding expression then gives an estimated mutation rate of 2.44×10^{-8} per site per generation for base-substitution mutations. Strictly speaking, this is an average over the chimpanzee and human lineages.

Short-term Enrichment

The preceding approach employs a strategy of augmenting the pool of observable mutations by passing lines through a large number of generations. The advantage of such a protocol is that mutations are equally enriched throughout the genome, minimizing the chances that the mutational profile will be biased by making observations at any particular target locus. However, with genome-wide mutation-accumulation analysis, an enormous number of sites (typically many tens of millions) need to be searched to obtain just a few dozen mutations.

An alternative approach, which is widely applied to microbial cultures, focuses on reporter constructs (specific marker loci at which at least a subset of mutations causes obvious phenotypic changes). Here, the emphasis is on the efficient screening of a very large pool of cells in a relatively short period of time for a small subset of mutations, e.g., exponentially growing an initially nonmutant stock to a population size in excess of the reciprocal of the mutation rate (so there will be more than one mutational event in the culture), and then isolating the subset of cells that have acquired a mutation at a locus that is nonessential in the background environment but permits subsequent growth on a selective medium (Luria and Delbrück 1943). From estimates of the total number of mutant and nonmutant cells in the culture, it is then possible to determine the mutation rate per cell division.

For the marker approach to yield reliable estimates of u , a good deal of knowledge must exist on the molecular features of the target locus. Because mutant cells reproduce during culture expansion, the relationship between the number of mutant cells observed in a population and the actual number of mutational events that produced them is generally not one-to-one. Thus, the first challenge is to convert the observed number of mutant cells to the number of mutations leading to them (m). In addition, because not all mutations produce an observed phenotype, the second challenge is to determine the fraction of mutations that are detectable at the target locus (d). The true number of mutations is estimated by m/d . Finally, in order to determine the mutation rate per nucleotide site, one must know the mutational target size (n , in base pairs).

Several methods exist for estimating the number of unique mutational events from the observed numbers of mutant and nonmutant cells in short-term experiments, with broad overviews provided by Rosche and Foster (2000) and Angerer (2001a, 2001b). Suppose a large series of replicate cultures is developed, and one then simply scores the fraction of cultures at the end point that are completely free of mutations (p_0). Assuming that the number of mutational events per culture is Poisson distributed with expectation m , the expected frequency of mutation-free cultures is then simply

$$E(p_0) = e^{-m} \quad (4.21)$$

Rearrangement leads to the estimator $\hat{m} = -\ln(p_0)$, which ignores the sampling bias resulting from the error in estimating p_0 . This approach works well when m is on the order of 0.5 to 2.5, but with more extreme values, p_0 will be close enough to 0.0 or 1.0 that meaningful estimates are not possible unless the number of cultures is enormous. A second disadvantage of this approach is its failure to use most of the information in the set of cultures, as the distribution of mutant numbers among replicate cultures is completely ignored. Full use of such information can be incorporated into a maximum-likelihood framework (e.g., Lea and Coulson 1949; Sarkar et al. 1992).

Example 4.3. The mutation rate in an exponentially growing culture can be estimated by considering the expected temporal dynamics of the frequency of mutant cells in the population. Letting f_0 be the initial frequency of mutations, r be the rate of exponential growth of the numbers of cells in the culture (assumed to be identical for cells that are mutant and nonmutant

at the marker locus), and u_o be the rate of mutation to an observable phenotype per cell division, the expected frequency after t time units is

$$f_t = f_0 + (1 - f_0)(1 - e^{-u_o r t}) \quad (4.22a)$$

This follows from the fact that $e^{-u_o r t}$ is the probability that a descendant of a nonmutant cell has not acquired a detectable mutation after $r t$ cell divisions. Note that if one starts with a mutation-free culture ($f_0 = 0$) and the cumulative probability of mutation ($\simeq u_o r t$) is $\ll 1$, the expected fraction of mutant cells will increase in an essentially linear fashion at a rate of $u_o r$.

Because of the stochastic nature of mutations, results from single cultures are not reliable with this approach. Thus, motivated by the original design of Luria and Delbrück (1943), most studies of microbial mutation grow a moderate number of initially (putatively) mutation-free cultures up to an arbitrarily large population size and then survey the frequency of mutants at the end point of each culture. Rearrangement of the preceding expression yields the relevant point estimator of the mutation rate to observable phenotypes,

$$\hat{u}_o = -\frac{\ln[(1 - f_0)/(1 - f_t)]}{r t} \quad (4.22b)$$

Because $N_t = N_0 e^{r t}$ under exponential growth, where N_0 and N_t are the total numbers of cells in the culture at times 0 and t , so long as the observed mutant frequencies are < 0.1 , so that $\ln(1 - f) \simeq -f$, Equation 4.22b further simplifies to

$$\hat{u}_o \simeq \frac{f_t - f_0}{\ln(N_t/N_0)} \quad (4.22c)$$

which is simply the rate of accumulation of observable mutations per cell division.

Drake (1991) argued that this essentially deterministic view of the rate of increase of mutants is unlikely to hold very well until a culture has reached a large enough size to harbor at least some mutations, which is expected to take several generations. Taking the view that a reasonable benchmark is the point at which a culture is expected to contain a single mutant, which implies $u_o N = 1$, $f_0 = u_o$ and $N_0 = 1/u_o$ can be used as an arbitrary starting point, which, after substitution into Equation 4.22c, leads to

$$\hat{u}_o \simeq \frac{f_t - \hat{u}_o}{\ln(\hat{u}_o N_t)} \quad (4.22d)$$

Given just the total number of cells, N_t , and the frequency of mutants at the end point, f_t , this expression can be solved recursively to obtain the estimate \hat{u}_o . When data are available from multiple cultures, f_t is generally taken to be the *median* frequency of mutants, as the mean can be strongly biased if the sample includes any “jackpot” cultures that happened to have acquired a mutation during an early cell division.

Conversion of the rate of origin of *observable* mutations, u_o , to an estimate of the mutation rate at the nucleotide level requires that the fraction of detectable mutations at the marker locus (d) be known. Many mutations have no phenotypic effects, e.g., because they arise at silent sites or at amino-acid replacement sites that have no substantive effect on the causal locus. To determine the fraction of undetectable mutations, a large number of independent mutant cells can be sequenced to ascertain the molecular basis of the changes at the target locus and the degree to which these are concentrated at particular sites. Generally, because the mutation rate per nucleotide site is quite low, no more than a single change is found within any particular sequenced gene, so there is little ambiguity as to the identity of causal mutations.

For base-substitutional mutations, Drake (1991) made the following argument for obtaining an estimate of d . Assuming that all mutations causing premature translation termination (so-called nonsense mutations) cause functional changes that are detectable, and then letting n_n denote the number of such mutations observed in the sequenced sample, the expected total number of base-substitutional mutations per sequence in the sample (whether recorded as mutants or not) is $64n_n/3$. This follows from the fact that of the 64 possible triplet codons, three encode for chain termination (in most species), and it assumes random mutation to all 64 codons. Thus, letting n_o denote the total number of observed base-substitutional mutations in

the set of sampled sequences (missense and nonsense mutations), $\hat{d} = n_o/(64n_n/3)$ provides an estimate of the fraction of base-substitutional mutations that are detectable (if all detected base-substitutional mutations were to termination codons, implying no effects of missense mutations, $n_o/n_n = 1$, and $\hat{d} = 3/64$). If n is the length of the target sequence (in base pairs) over which mutations are detectable (generally assumed to be the length of the coding region, which could be an overestimate), an estimator for the base-substitution mutation rate per nucleotide site is then

$$\hat{u} = \frac{\hat{u}_o}{\hat{d}n} \quad (4.22e)$$

Example 4.4. To indirectly estimate the human mutation rate, Kondrashov (2003) took advantage of records on genetic pathologies attributable to dominant mutations at known causal loci. The population frequency of genetic disorders (I , incidence) caused by dominant autosomal mutations provides a simple basis for estimating the mutation rate to defective alleles. This is because the expected frequency of a dominant deleterious allele under selection-mutation balance is $p \simeq u/s$, where u is the mutation rate to defective alleles (per gene copy), and s is the selective disadvantage of affected (heterozygous) individuals (Equation 7.6b). For a severe disorder, the frequency of the deleterious allele will be so small that essentially all affected individuals are heterozygotes, implying an incidence of the disorder very close to $2p(1-p) \simeq 2p = 2u/s$. Thus, the mutation rate to dominant defective alleles can be estimated as $sI/2$. (For a dominant mutation that leads to complete loss of reproductive fitness, $s = 1$, and the incidence is simply equal to $2u$, as each functional parental allele has a probability u of mutating to a defective product.)

The remaining challenge is to convert the total rate of observed mutations at a locus to the underlying rate at the level of individual nucleotide sites. This can be accomplished by employing a strategy similar in spirit to that advocated by Drake (1991). For each disorder in the survey of Kondrashov (2003), a large sample of affected individuals (whose parents were known to be nonmutant) had both of their alleles sequenced to identify the nature of the newly arisen, causal mutations. Assuming all insertion and deletion mutations had detectable effects, the total detectability of mutations could then be calculated from the incidence of chain-terminating base-substitutional mutations, as outlined in Example 4.3. Although Kondrashov's (2003) survey involved 32 different genetic disorders (each determined by a unique locus), we will simply present the calculations for one such analysis, and conclude with a summary of all results.

Familial adenomatous polyposis is a genetic disorder known to be caused by dominant mutations in the adenomatous polyposis coli (APC) tumor-suppressor gene, arising at an estimated rate of $u_o = 7 \times 10^{-6}$ per gene copy per generation. Of the 799 mutations validated by sequencing and deemed to be causal, 202 involved nonsense base substitutions, with the remaining 597 being associated with major lesions, insertions, and deletions of various sorts. Assuming that the total number of base substitutional mutations (when extrapolated to unaffected mutants) is $202 \times (64/3)$, and that all insertions and deletions are detectable, the overall detectability is estimated as $799/[597 + (202 \times 64/3)] = 0.163$. From the pool of affected individuals subjected to sequencing, a fraction 0.325 exhibited no causal mutation (presumably because the mutation resided outside of the sequenced target exons, which summed to 4803 sites). The estimated total mutation rate at the locus is therefore $(7 \times 10^{-6}) \times 0.675 / (4803 \times 0.163) = 6.0 \times 10^{-9}$ per site per generation, a fraction of which, $1 - \{597/[597 + (202 \cdot 64/3)]\} = 0.878$, involves base-substitutional mutations.

When these approaches are extended to the remaining 31 loci, the estimated average total mutation rate to base-substitutional changes is 1.70×10^{-8} per site per generation, averaged over both sexes. A subsequent estimate involving a larger number of loci underlying human genetic disorders and somewhat different assumptions yielded an estimate of 1.29×10^{-8} (Lynch 2009b).

More recently, direct estimates of the human mutation rate have been generated by whole-genome sequencing in known lines of descent. For example, from information on portions of Y chromosomes separated by 13 generations of paternal-line descent, Xue et al. (2009) obtained a base-substitutional mutation rate estimate of 1.73×10^{-8} after scaling across the sexes to account for the lower rate of mutation in females. Three additional studies, involving autosomal sequences of parent-offspring trios, all yield sex-averaged estimates close to 1.2×10^{-8} (Conrad

et al. 2011; Campbell et al. 2012; Kong et al. 2012).

Taken together, these estimates point to a sex-averaged base-substitutional mutation rate of $\sim 1.4 \times 10^{-8}$ for humans, which is significantly lower than the phylogenetic estimate reported in Example 4.2 (2.44×10^{-8}). A number of factors might account for the elevated rate based on interspecies divergence: an incorrect estimate of the time of divergence between the human and chimpanzee lineages; an incorrect estimate of the amount of heterozygosity at initial divergence; inaccurate estimates of average generation times since the time of divergence; an elevated rate of mutation in the chimpanzee lineage; a recent decline in the human mutation rate; the operation of some selection on the sites analyzed in the comparative study; etc. The main point is that estimates of the mutation rate derived from phylogenetic data are subject to numerous sources of potential error, the magnitude of which is generally unknown (and in some cases unknowable). Short-term studies are less vulnerable to these uncertainties.

Evolution of the Mutation Rate

Whole-genome sequence analyses of mutation-accumulation lines have made clear that substantial variation in the mutation rate exists among species (Lynch et al. 2016). In all organisms, the bulk of small-scale mutations involve single base-substitutions, with the ratio of insertion and deletion mutations to the former typically being on the order of 0.1 (Lynch et al. 2016). Base-substitutional mutation rates in bacterial species are generally in the range of 10^{-10} to 10^{-9} per nucleotide site per generation, with a mean of 4×10^{-10} . Rates in unicellular eukaryotes are lower, in the range of 8×10^{-12} to 5×10^{-10} per nucleotide site per generation, with a mean of 2×10^{-10} (Table 4.2). On a per-generation basis, base-substitutional mutation rates are substantially higher in multicellular species, averaging 3.6×10^{-9} per nucleotide site in invertebrates, 1.3×10^{-8} per nucleotide site in the great apes, and 4.5×10^{-9} per nucleotide site in land plants. Thus, it appears that mutation rates are higher in multicellular than in unicellular species, and that among unicellular lineages, eukaryotes have higher levels of replication fidelity than do bacteria.

What are the likely mechanisms driving these sorts of differences? One obvious distinction among the above-mentioned groups is that multicellular species experience multiple germline cell divisions per generation, e.g., ~ 10 for *C. elegans*, 36 for *D. melanogaster*, 40 for *A. thaliana*, and 200 for *H. sapiens* (Drost and Lee 1995; Kimble and Ward 1998; Crow 2000; Lynch 2010a), whereas there is one cell division per generation in unicellular species. If most mutations arise as replication errors, one would then expect the per-generation mutation rate to scale across yeast : *C. elegans* : *D. melanogaster* /*A. thaliana* : human in an $\sim 1 : 10 : 38 : 200$ ratio. However, the per-generation mutation-rate scaling implied by the results given above is less extreme, approximately $1 : 6 : 25 : 57$. Mutation rates of microsatellite loci, which mutate via changes in nucleotide-motif repeat numbers, are also magnified with the level of multicellularity, but the ratio of per-generation mutation rates for such loci, $\sim 1 : 50 : 13,400$ for unicellular eukaryotes, invertebrates, and mammals (Seyfert et al. 2008), is much more extreme than the scaling of germline-cell division number. Thus, it appears that additional factors, including those independent of replication, must be responsible for the pattern exhibited in Table 4.2.

As with all phenotypic traits, the rate of mutation is subject to the forces of natural selection (Baer et al. 2007). However, selection on the mutation rate is unusual in that the fitness effects associated with a mutator or antimutator allele are generally manifested only indirectly through the mutational changes induced at other fitness-related loci. This raises the question as to whether mutation rates are typically held at optimum intermediate levels by stabilizing selection so as to somehow maximize the long-term rate of adaptive evolution, or simply pushed to their physiologically defined lower limits so as to minimize deleterious-mutation accumulation. If replication-error rates are maintained at higher levels than can be explained by constraints on cellular processes, the next obvious question is why dramatically higher mutation rates would be selectively promoted in multicellular relative

to unicellular species, despite the fact that most mutations are deleterious (LW Chapter 12).

The central difficulty with arguments that invoke long-term benefits of elevated mutation rates is that high mutation rates are much more likely to evolve in predominantly asexual populations (the situation in many unicellular species, but not multicellular taxa), as an absence of recombination is essential if novel mutator alleles are to be pulled to fixation via linkage to induced beneficial mutations (Johnson 1999a; Sniegowski et al. 2000; Wilke et al. 2001; André and Godelle 2006; Denamur and Matic 2006). Yet, as noted above, it is among sexually reproducing multicellular eukaryotes that the highest mutation rates are consistently observed.

Despite substantial theoretical research, it has proven quite difficult to avoid the conclusion that mutation rates are predominantly driven downwardly by the transient linkage of mutator alleles to their recurrent deleterious side effects (Sturtevant 1937; Leigh 1970, 1973; Johnson 1999b; Lynch et al. 2016). Occasionally, a mutator allele may be brought to high frequency by hitchhiking with a tightly linked beneficial mutation (Clune et al. 2008; Desai and Fisher 2011), but such events are expected to be transient, as they are quickly followed by loss of the mutator phenotype by either recombinational decoupling or reversion of the mutation rate.

To see why recurrent deleterious mutation imposes selection against mutator alleles, note that any allele that magnifies the mutation rate (hereafter, designated as a mutator allele) will necessarily generate statistical associations with deleterious germline mutations induced at linked and unlinked loci. The duration of such disequilibria will depend on the rate of recombination between the mutator and affected loci, but because new associations will arise recurrently in each generation by mutation, an equilibrium background mutation load will eventually be reached, with alleles that impose higher mutation rates developing a higher associated deleterious load.

Consider a locus relevant to fitness that recombines at rate c with respect to the mutator locus. If, in the heterozygous state, the mutator induces deleterious mutations at the fitness locus at an elevated rate Δu per gene with a reduction in fitness equal to hs per induced mutation, the selective disadvantage of the mutator allele induced by linkage disequilibrium with this particular fitness locus is

$$s_d \simeq \frac{hs \cdot \Delta u}{1 - (1 - hs)(1 - c)} \quad (4.23a)$$

assuming $\Delta u \ll hs$ (Kimura 1967; Dawson 1999). An intuitive feeling for the structure of this equation can be obtained by noting that hs is the rate of removal of a deleterious mutation by selection, and c is the rate of recombination between the mutator allele and the fitness locus. The denominator is then equivalent to the per-generation rate of loss of associated fitness load for the mutator allele by either selection or recombination. The numerator is the rate of input of new fitness load per generation, so the selective disadvantage at equilibrium is simply the ratio of the rates of gain and loss of associated fitness load per generation. For unlinked loci ($c = 0.5$), this expression reduces to

$$s_d \simeq \frac{2hs \cdot \Delta u}{1 + hs} \quad (4.23b)$$

whereas in the absence of recombination ($c = 0.0$),

$$s_d = \Delta u \quad (4.23c)$$

These results indicate that the strength of selection opposing the downward drive of mutation rate is much weaker in sexual than in asexual species.

The total disadvantage of a mutator allele is obtained by summing the correlated load across all fitness-related loci. Thus, from Equation 4.23c, provided the equilibrium load associated with selection-mutation balance is reached, the total magnitude of selection against

a mutator allele in an asexual population is simply equal to the elevation in the genome-wide deleterious mutation rate (ΔU , summed over all fitness-relevant loci), independent of the effects of the mutations. However, for a sexual species, the total disadvantage of a mutator must take into consideration mutations arising both on the chromosome carrying the mutator and on all other unlinked loci, as only tightly linked loci remain in association with the mutator for more than a few generations. Assuming L chromosomes, each measuring one Morgan in length (below), and a haploid genome-wide increase in the deleterious mutation rate of ΔU , after accounting for the spatial distribution of random mutations, the total induced selection coefficient against the mutator allele is found to be

$$s_{d,T} \simeq \frac{2hs \cdot \Delta U(L - 1 + \phi)}{L(1 + hs)} \quad (4.24a)$$

where

$$\phi = 1 + \ln \left(\frac{1 + hs - (1 - hs)e^{-1}}{2hs} \right) \quad (4.24b)$$

is the approximate elevation in the average induced fitness effect of mutations on the mutator-bearing chromosome relative to that on the other $L - 1$ unlinked chromosomes (Lynch 2008b). For $0.001 < hs < 0.1$, which fully covers the range of average mutational effects found in empirical studies (LW Chapter 12), ϕ is in the range of 2 to 7. Thus, the selective disadvantage of a mutator allele in a sexual species is close to twice the product of the heterozygous fitness effect of new mutations (hs) and the haploid genome-wide increase in the deleterious mutation rate (ΔU) unless the chromosome number is very small, and even then not likely to be much more than a few-fold higher. The factor by which $s_{d,T}$ exceeds $hs \cdot \Delta U / (1 + hs)$ is equivalent to the average number of generations that an induced deleterious mutation remains associated with the mutator responsible for its origin (and as can be seen from Equation 4.23b, this factor is two for unlinked loci).

Because single amino-acid substitutions in DNA-processing proteins may have arbitrarily small effects on the mutation rate, and because existing mutation rates are already so low that there is little further room for improvement (the maximum possible reduction being the mutation rate itself), these results imply that the long-term selective disadvantage of many mutator alleles may be sufficiently small (relative to the power of genetic drift) to render them immune to the eyes of natural selection (Chapter 7). Thus, because there is a substantial decline in N_e from microbes to small invertebrates to vertebrates and large land plants (Lynch 2007), it is plausible that the elevation of mutation rates in multicellular lineages is not simply an inevitable outcome of an inherent physiological limitation in such species, but rather a consequence of the diminished ability of natural selection to enhance the level of replication fidelity in small- N_e species (Lynch 2011; Jain and Nagar 2013).

Several observations are consistent with this **drift-barrier hypothesis**. First, for the set of species with adequate data, there is an inverse relationship between the mutation rate per nucleotide site per generation (u) and N_e (Sung et al. 2012). Second, empirical observations on the molecular machinery involved in DNA replication and repair indicate that these processes are indeed more error-prone in taxa with higher overall mutation rates (Lynch 2008a, 2008b, 2011). Third, u is also inversely proportional to the number of functional genes in a genome (Drake et al. 1998; Massey 2008; Ness et al. 2012; Sung et al. 2012; Lynch et al. 2016). The latter relationship is expected because, as noted above, selection operates on the total rate of deleterious-mutation production across the genome, which increases with the number of functionally relevant nucleotides in the genome. Finally, long-term laboratory-evolution experiments starting with mutator strains of microbes often reveal a gradual reduction in the mutation rate resulting from the spontaneous accumulation of changes at diverse genomic locations (Tröbner and Piechocki 1984; Notley-McRobb et al. 2002; Herr et al. 2011; Weigloss et al. 2013; Williams et al. 2013). Such observations clearly demonstrate that, even in microbes where the efficiency of selection is expected to be strong, the loci underlying replication fidelity have not been driven to a point where further improvement is no longer possible. The central point here is that one of the primary determinants of

Table 4.2 Base-substitution mutation rates (u , in units of 10^{-9} per nucleotide site per generation) for a diversity of eukaryotic species derived from whole-genome sequencing of mutation-accumulation lines or parent-offspring trios.

the evolutionary features of a population, the mutation rate itself, is subject to substantial evolutionary modification, with the effective population size and the functionally effective genome size dictating the degree to which selection can reduce the replication-error rate and/or levels of repair efficiency.

RECOMBINATION RATE

Although it is extraordinarily difficult to estimate recombination rates at specific nucleotide sites, some compelling general statements can be made about *average* levels of recombination over entire genomes. Such information derives from high-density genetic maps constructed from observed rates of meiotic crossing-over between molecular markers, now available for hundreds of eukaryotes thanks to the widespread availability of highly variable markers such as microsatellites. Genetic maps are based on mapping functions that attempt to convert observed recombination frequencies into the expected numbers of crossover events between pairs of markers (LW Chapter 14). Strictly speaking, such maps measure the frequency of crossover events, and generally do not include the added contributions of gene conversion, which can cause the recombination rate between very closely spaced sites to exceed by several-fold the expectation based on distant markers that are predominantly rearranged by crossovers (Equations 4.16a through 4.16c). Chromosome lengths are generally reported in units of **Morgans** (one Morgan equaling one crossover), with the sum of these lengths over all chromosomes giving the total map length.

Although eukaryotic genome sizes (total numbers of nucleotides) vary by four orders of magnitude, the range of variation in genetic-map lengths among species is only about ten-fold, with the averages for various phylogenetic groups deviating by only five-fold (Table 4.3). A simple physical constraint explains such behavior. During meiosis, there are

Table 4.3 Basic features of the physical and genetic maps of various eukaryotic groups, derived from a large survey of mapping studies involving high-density molecular markers. The grouping “Other unicellular species” includes algae, apicomplexans, ciliates, kinetoplastids, and oomycetes. Numbers in parentheses denote standard errors, and n denotes the number of species surveyed. Map lengths and mean chromosome (Chr.) sizes are in units of Morgans (M).

Group	Total Map Length	Genome Size (Mb)	Haploid Chr. No.	Mean Chr. Size (M)	n
Fungi	18.3 (2.2)	36.4 (3.2)	11.9 (1.2)	1.86 (0.36)	19
Other unicellular sps.	10.9 (1.2)	80.9 (23.3)	12.9 (1.2)	0.96 (0.18)	11
Arthropods	18.1 (3.7)	679.6 (172.4)	16.1 (3.4)	1.20 (0.18)	15
Mollusks	9.2 (1.1)	1270.7 (177.2)	13.3 (1.6)	0.71 (0.09)	6
Nematodes	4.5 (1.2)	97.6 (2.5)	7.3 (1.3)	0.59 (0.05)	3
Fish	16.0 (2.3)	1185.4 (190.5)	25.1 (0.6)	0.63 (0.08)	15
Birds	23.1 (5.4)	1334.0 (48.6)	39.6 (0.4)	0.58 (0.14)	5
Mammals	23.9 (2.5)	3222.0 (108.1)	22.1 (2.2)	1.10 (0.07)	19
Angiosperms	15.9 (1.6)	2020.3 (434.2)	13.2 (0.9)	1.19 (0.07)	44

typically no more than two crossover events per chromosome (one per arm), so that average chromosome lengths are generally on the order of one Morgan, regardless of chromosome size. Thus, because phylogenetic increases in genome size are generally associated with increases in chromosome size rather than chromosome number (Table 4.3), there is little variation in the total amount of meiotic crossing over per genome across a vast swath of life.

These observations lead to a simple structural model for the average recombination rate per physical distance across a genome (\bar{c}). Letting G be the total number of bases per haploid genome, and N be the haploid number of chromosomes per genome, G/N is the mean physical length of chromosomes. Letting C be the average number of crossovers (Morgans) per chromosome per meiosis, then $\bar{c} \simeq CN/G$, assuming that C is independent of chromosome size. If this model is correct, a regression of \bar{c} on G on a log scale should have a slope not significantly different from -1.0, with the vertical distribution (residual deviations) around the regression line being defined largely by variation in CN (the total number of crossovers per genome). The data closely adhere to this predicted pattern, with the smallest genomes of microbial eukaryotes having recombination rates per physical distance that are \sim 1000 times greater than those for the largest multicellular land plants (which have \sim 1000 times larger genomes but approximately the same numbers of chromosomes) (Figure 4.4). Over this entire gradient, a smooth, overlapping decline in recombination intensity across unicellular species, invertebrates, vertebrates, and land plants reflects the general increase in genome sizes across these eukaryotic domains (Lynch 2007).

These observations suggest that the vast majority of the variance in the average recombination rate among eukaryotic species is simply due to variation in genome size and chromosome number. It should be noted, however, that even in the highest-density genetic maps, adjacent markers are generally separated by tens of thousands to millions of base pairs, so that measures of *average* levels of recombination for particular chromosomes can obscure fine-scale features. Indeed, up to 100-fold differences in recombination rates can exist among regions within chromosomes, with highly localized **recombinational hotspots** existing in well-studied species (Petes 2001; de Massy 2003; Jeffreys et al. 2004; Myers et al. 2005; Arnheim et al. 2007; Coop et al. 2008; Mancera et al. 2008).

Evolution of the Recombination Rate

As in the case of the mutation rate, considerable effort has been devoted to understanding how selection might favor recombination modifiers in various contexts (e.g., Feldman et al. 1996; Barton and Otto 2005; Keightley and Otto 2006; Barton 2010; Hartfield et al. 2010). As

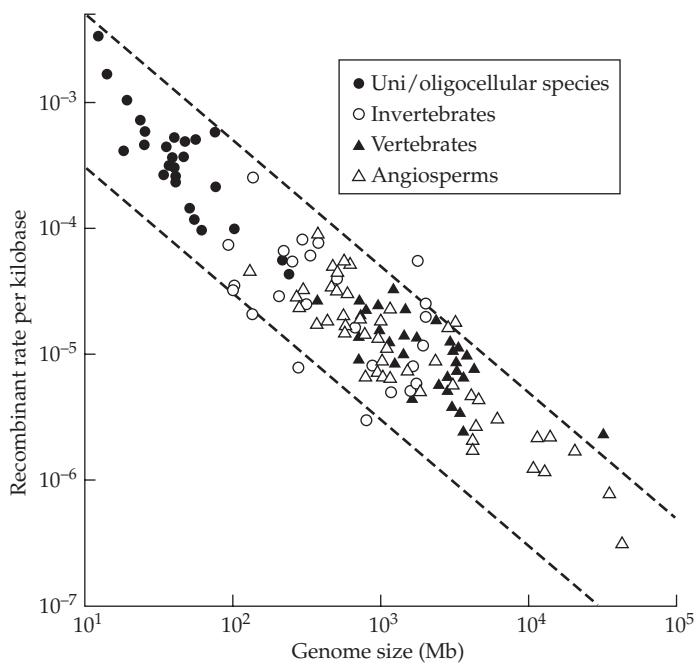

Figure 4.4 Average rates of recombination per physical distance for four major groupings of eukaryotes, determined from information on total physical and genetic map sizes. The two dashed lines have slopes of -1.0 in accordance with the theory discussed in the text. Letting C be the average number of crossovers, and N be the number of chromosomes, the top line assumes $CN = 50$, i.e., 50 chromosomes with an average length of 1.0 Morgans, 25 with average lengths of 2.0 Morgans, 100 with average lengths of 0.5 Morgans, etc. The lower line assumes $CN = 3$. For the plotted species, C is in the range of 0.3 to 3.1 (with one exception) and N is in the range of 3 to 44. (From Lynch et al. 2011.)

just noted, however, the fact remains that the vast majority of eukaryotic variation in the genome-wide amount of recombination per physical distance can be explained by a simple and largely invariant physical model of meiosis, leaving very little residual variation to be potentially assigned to mechanisms of adaptive fine-tuning. Thus, with a near-universal rule of approximately one crossover per chromosome arm, one could argue that if selection is involved at all in recombination-rate evolution, it generally operates in a way to minimize the amount of meiotic recombination across the genome. Dumont and Payseur (2007) find that variation in recombination rates across mammalian species evolves in a manner that cannot even be discriminated from the expectations of a neutral model.

Because it minimally involves three-locus dynamics in finite populations (one for the recombination modifier and two for the relevant loci under selection), most population-genetic theory on the evolution of recombination-rate modifiers has no simple analytical solutions available and so relies heavily on computer simulations. The basic motivation underlying all such work is the general principle that natural selection often encourages the build-up of repulsion disequilibria between alleles affecting fitness, i.e., the joint accumulation of gametes with different constitutions but essentially equivalent total fitness (Chapters 5 and 16). In principle, recombinational release of such hidden genetic variance can lead to more efficient selection for joint combinations with high fitness (Chapter 7). Two features of genetic systems might encourage such behavior.

First, **synergistic epistasis** (with fitness declining at an increasing rate with increasing numbers of deleterious alleles) tends to promote a selective advantage for recombination,

as this will enhance the rate of production of double mutants and their more efficient (two in single events) promotion/elimination by selection (Eshel and Feldman 1970; Kondrashov 1988; Charlesworth 1990; Barton 1995b). In contrast, **diminishing-returns epistasis** (with fitness declining at a diminishing rate with increasing numbers of deleterious alleles) has the opposite effect, encouraging reduced recombination rates. As the evidence on the general incidence of these two forms of epistasis is mixed at best (Chapter 7) and the effectiveness of synergistic epistasis is greatly diminished when the single-locus effects of mutations are unequal (an issue ignored in most theory, but certainly the case in reality; Butcher 1995), the role of epistasis in the evolution of recombination rates remains unclear from an empirical perspective.

Second, as already noted in Chapter 3 and further elaborated on in Chapter 7, even in the absence of nonadditive gene action, linkage reduces the efficiency of selection on multi-locus systems, although the effect is expected to be more pronounced in larger populations harboring larger numbers of cosegregating loci. Plausible arguments have been made that the power of selection of modifiers increasing the recombination rate by this mechanism (i.e., improving the efficiency of selection among linked loci) may substantially outweigh that resulting from epistasis, even when synergistic effects are common (Felsenstein and Yokoyama 1976; Otto and Barton 2001; Pálsson 2002; Otto and Lenormand 2002; Iles et al. 2003; Barton and Otto 2005; Keightley and Otto 2006; Roze and Barton 2006).

What remains unclear is the extent to which modifiers of the recombination rate ever arise with substantial enough effects to be promoted by these kinds of associative effects. Most attempts to study the matter theoretically have focused on rather extreme situations in which either selection coefficients or the magnitude of the modifier's effect on the recombination rate are very large. Some approximations suggest that even under these conditions, the selective advantage of the modifier can be quite small (Barton and Otto 2005), perhaps too small to overcome the likelihood of being lost by drift in most cases. Nevertheless, empirical observations suggest that strong directional selection in artificial selection programs sometimes leads to the evolution of higher recombination rates (Barton and Otto 2005), and recombination-modifier models may be relevant to the more general issue of the adaptive significance of sexual versus asexual reproduction, where the former entails segregation of unlinked loci as well as recombination among linked loci.

GENERAL IMPLICATIONS

The results summarized above allow for several general statements about the intensities of mutation, recombination, and random genetic drift experienced by natural populations. As these three features define the population-genetic environment within which selection processes occur, such knowledge provides a powerful resource for understanding the limits of molecular, genomic, and phenotypic evolution and how these vary across phylogenetic lineages.

First, although the direct estimation of N_e in large populations is essentially impossible with current techniques, from information on within-population variation at putatively neutral sites, there are a number of ways to estimate the composite parameter $\theta = 4N_e u$ (or $2N_e u$ for haploids), which is equivalent to the ratio of the magnitudes of the power of mutation and drift. With direct estimates of the mutation rate (u) now available for a number of taxa, it is then also possible to estimate the long-term effective population size of a species by factoring the latter out from estimates of θ . For example, noting that the average estimate of θ for unicellular eukaryotes is 0.057 and that the average estimate of u for base-substitutional mutations in such species is $\sim 2 \times 10^{-10}$ (Table 4.2), the average N_e for such species appears to be on the order of 6×10^8 individuals if haplidity is assumed (and half that if diploidy is assumed). These estimates are likely to be somewhat downwardly biased as selection can reduce variation at silent sites in large microbial populations. When using an average θ of 0.026 and u of 3.6×10^{-9} for invertebrates, average N_e for this grouping is

$\sim 2 \times 10^6$. Likewise, when using $\theta = 0.0011$ (Example 4.1) and $u = 1.4 \times 10^{-8}$ (Example 4.4), long-term N_e for the human population is $\sim 20,000$.

Similar indirect inferences can be made from estimates of $\rho = 4N_e c_0$. For example, from Table 4.1, the average estimate of ρ for *Drosophila* species is 0.0807, whereas that for humans is ~ 0.0006 , and for annual plants and long-lived trees is 0.0134 and 0.0050, respectively. From the genetic map data contributing to Figure 4.4, average c_0 ($\times 10^{-8}$ per site per generation, based on crossovers alone) is 2.14 for *Drosophila*, 1.28 for humans, 1.59 for annual plants, and 2.93 for trees. These results imply average values of N_e of $\sim 10^6$ for *Drosophila*, 12,000 for humans, 210,000 for annual plants, and 43,000 for trees. The consistency of the results when both approaches are applied to *Drosophila* and humans is compelling.

These estimates of N_e should be considered simply as broad indicators, as θ and ρ (and therefore N_e) can vary by at least an order of magnitude among species within major phylogenetic groups and probably within species as well, owing to long-term temporal fluctuations (Lynch 2006). Moreover, because the mean coalescence time for a random pair of alleles is $2N_e$ generations in a diploid species (Chapter 2), polymorphism-based estimates of N_e are expected to be reasonable approximations of the average conditions experienced over only the past $\sim 2N_e$ generations. Nevertheless, several general conclusions can be made: (1) the magnitude of the power of random genetic drift increases by a factor of 10^4 from unicellular eukaryotes to large multicellular species; (2) long-term effective population sizes are generally orders of magnitudes smaller than the actual numbers of breeding adults within species, probably largely as a consequence of the effects of selection on mutations physically linked on chromosomes (Chapters 3 and 8); and (3) it is possible that no eukaryotic species, even the most enormous microbial populations, has ever had a long-term N_e much beyond 10^{10} , owing to the stochastic effects of selective sweeps and background selection.

Second, a long-standing puzzle in evolutionary genetics has been that the within-species level of variation at putatively neutral sites is nearly independent of actual population sizes (Lewontin 1974). Given that such variation is expected to scale with N_e and that the numbers of individuals in bacterial species are many orders of magnitude greater than those for species of vertebrates and land plants, Lewontin dubbed this observation the **paradox of variation**. We now know that a strict linear increase in θ with absolute population size is unexpected owing to the effects of selection acting on linked loci (Chapters 3 and 8). Nevertheless, given the estimates of N_e just presented, one might still expect an increase of θ on the order of 10^4 over this gradient of organisms. However, the observed range is only two orders of magnitude (Nei 1983; Lynch 2007; Leffler et al. 2012).

The reason for this discrepancy is made clear by the preceding summary. The mutation rate u is not independent of N_e , but instead strongly declines with increasing N_e , thereby partly compensating for the direct influence of N_e on θ . As a consequence, it appears that in no species does the power of mutation exceed that of random genetic drift (i.e., θ is always much smaller than 1.0). Moreover, because estimates of ρ are also always well below 1.0, the same conclusion can be drawn with respect to the relative magnitudes of the power of recombination per nucleotide site and that of random genetic drift.

Third, it can be concluded that the ratio of the power of mutation to that of recombination increases substantially with genome size (which exhibits a strong increasing gradient with organismal size, from unicellular eukaryotes to vertebrates and land plants; Lynch 2007). Using the regression relationship in Figure 4.4 and additional information on mutation rates and genome sizes (Lynch 2010a), for eukaryotic genomes of size 10^1 , 10^2 , 10^3 , and 10^4 Mb, average u/c_0 is ~ 0.00076 , 0.028, 1.01, and 36.5, respectively. These extrapolations are consistent with the indirect (polymorphism-based) estimates of u/c_0 implied in Table 4.1, which are subject to substantial sampling error but nonetheless fall in the range of 1 to 100 for animals and land plants (with genome sizes in the range of 100 to 10^4 Mb).

These ideas need to be tempered by the fact that for closely spaced sites, gene conversion causes the recombination rate to be elevated relative to that expected on the basis of crossing over alone. From Equations 4.16b and 4.16c, the degree of inflation is $\simeq 1/x$, where x is the fraction of recombination events resulting in a crossover. As x is typically in the

neighborhood of 0.1 (Lynch et al. 2016), this implies that the effective value of u/c_0 may be as much as 10 times lower than the values suggested above. On the other hand, with the emerging data suggesting that most recombination events are concentrated at a small number of hotspots, the recombination rate at most nucleotide sites will be much lower than the average, implying that except near hotspots, u/c_0 will be higher than implied with the use of average c_0 values.

5

The Population Genetics of Selection

Theoretical population genetics is surely a most unusual subject. At times it appears to have little connection with the parent subject on which it must depend, namely observation and experimental genetics, living an almost inbred life of its own. Warren Ewens (1994, p. 186)

Selection is the focus of much of this book, and here we lay the foundations for the response to selection on quantitative traits by first considering scenarios involving one or two loci. There are two fundamental reasons for starting here. First, in some settings, the trait of interest is indeed largely controlled by a single major gene, in which case the models introduced here are directly applicable. Second, these relatively simple population-genetic models form the foundation for models of the selection response when trait variation is controlled by multiple loci. Short-term prediction of the response of a quantitative trait to selection is done under the assumption of either constant genetic variances (Chapter 13) or predictable changes in the genetic variance from linkage disequilibrium (Chapter 16). Over longer time scales, allele-frequency change alters the genetic variances, and one- and low-locus population-genetic models are central to evaluating how these changes are influenced by the underlying genetic architecture of a trait (Chapters 24–28).

One key assumption of this chapter is that population size is effectively infinite, meaning that there is no effect of drift. A second assumption is that precise fitness values can be assigned to individual genotypes—one knows W_g , the average fitnesses for all genotypes g at the locus (or loci) of interest. Conversely, in the typical quantitative-genetic setting, fitness is defined for phenotypes, not genotypes, with $W(z)$ denoting the average fitness of individuals with phenotypic value z , with little regard for their underlying genotypes. We connect these different views of fitness at the end of the chapter, showing how selection on phenotypes maps into selection on an underlying locus, and forging a fundamental connection between the population-genetic and quantitative-genetic views of selection.

We start with a review of single-locus selection theory, highlighting how the dynamical equations for allele-frequency change can also be expressed in terms of quantitative-genetic parameters (average excesses) for fitness. While single-locus theory is essentially complete, when two or more loci are involved, gametic-phase disequilibrium is usually generated. If this occurs, single-locus equations for allele-frequency change no longer hold and no completely general statement can be made about the behavior of a system under selection.

This lack of a general theory can be addressed in one of two ways. First, exact results are available for particular two-locus models, and we present these to offer some guidance for the behavior of models with more loci. Second, rather than following the underlying changes in gametic frequencies (as required for multilocus models), we instead can approximate their impact on the expected change of the mean of a trait. We touch upon this trait-based approach at the end of this chapter by showing how single-locus approximations lead to the classic breeder's equation. General approximations for the behavior of traits under selection are further developed in Chapter 6.

SINGLE-LOCUS SELECTION: TWO ALLELES

Consider the simplest selection model: one locus with two alleles (A, a) and constant genotypic fitnesses of W_{AA} , W_{Aa} , and W_{aa} . The analysis of selection on such systems dates back to a series of papers by Haldane from 1924 to 1932 (summarized in Haldane 1932b; see Clark 1984 and Crow 1992 for overviews of Haldane's fascinating life and legacy). We

Table 5.1 Genotype frequencies after viability selection. Here, p is the frequency of allele A , genotypes are in Hardy-Weinberg frequencies before selection, and \bar{W} is the mean population fitness (Equation 5.1a).

Genotype	AA	Aa	aa
Frequency before selection	p^2	$2p(1-p)$	$(1-p)^2$
Fitness	W_{AA}	W_{Aa}	W_{aa}
Frequency after selection	$p^2 \frac{W_{AA}}{\bar{W}}$	$2p(1-p) \frac{W_{Aa}}{\bar{W}}$	$(1-p)^2 \frac{W_{aa}}{\bar{W}}$

deal first with **viability selection**, in which case W is the probability of survival from birth to reproductive age. Under this model, once adults reach reproductive age, there is no difference in mating ability and/or fertility between genotypes. Differential survival changes p , the initial frequency of allele A , to a new frequency, p' , in prereproductive (but post-selection) adults. Under the assumption of an effectively infinite population size, random mating then ensures that the offspring's genotypic frequencies are in Hardy-Weinberg proportions. However, as we will show below, if parental genotypes differ in fertility, offspring genotypes will generally not be in Hardy-Weinberg proportions.

Viability Selection

Consider the change in the frequency p of allele A over one generation, $\Delta p = p' - p$. As shown in Table 5.1, the number of AA individuals following selection is proportional to $p^2 W_{AA}$, the frequency of AA genotypes before selection multiplied by their genotypic fitness. To ensure that post-selection frequencies sum to one, we divide this proportion by a normalization constant, the **mean population fitness** (the average fitness of a randomly chosen individual),

$$\bar{W} = p^2 W_{AA} + 2p(1-p) W_{Aa} + (1-p)^2 W_{aa} \quad (5.1a)$$

Proceeding similarly for the other genotypes allows us to fill out the entries in Table 5.1.

From these new genotypic frequencies, the frequency of A after selection is

$$p' = \text{freq}(AA \text{ after selection}) + \frac{1}{2} \text{ freq}(Aa \text{ after selection})$$

and applying the results in Table 5.1 gives the expected change in the frequency of A as

$$\Delta p = p' - p = p \left(p \frac{W_{AA}}{\bar{W}} + (1-p) \frac{W_{Aa}}{\bar{W}} - 1 \right) \quad (5.1b)$$

This equation can also be expressed using the **relative fitnesses** W_{ij}/\bar{W} , abbreviated as w_{ij} , with mean fitness then scaling to $\bar{w} = 1$. Throughout, we will adhere to a notation whereby upper-case W corresponds to some absolute measure of fitness, and lower-case w corresponds to relative fitness.

If we assign the genotypes $aa : Aa : AA$ fitnesses of $1 : 1+s(1+h) : 1+2s$, Equation 5.1b becomes

$$\Delta p = \frac{sp(1-p)[1+h(1-2p)]}{\bar{W}} \quad (5.1c)$$

As shown in Figure 5.1, a graph of Δp as a function of p provides a useful description of the allele-frequency dynamics under selection. In particular, allele frequencies that satisfy

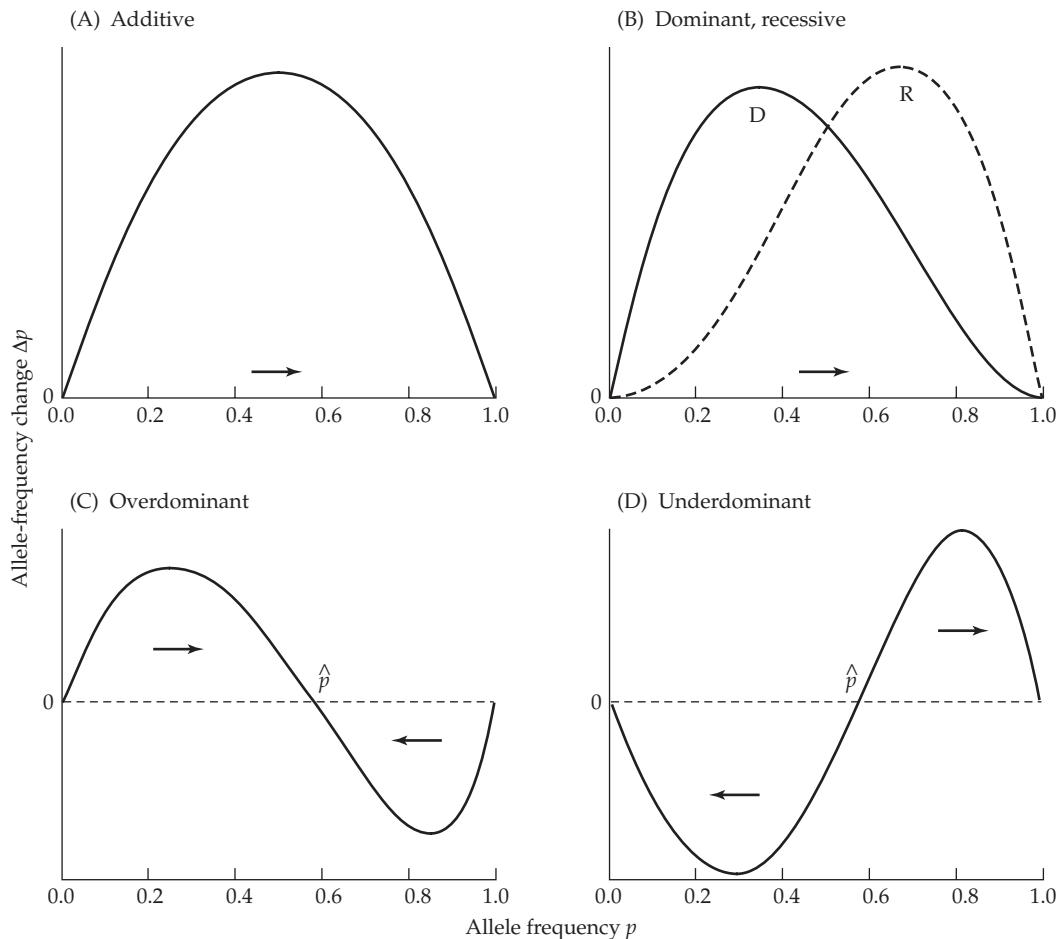

Figure 5.1 A plot of allele-frequency change Δp as a function of p is a useful device for examining how frequencies change under selection. If $\Delta p > 0$, the frequency of A increases (moves to the right), as indicated by the right-pointing arrow. If $\Delta p < 0$, the frequency of A decreases (left-pointing arrow). If $\Delta p = 0$, the allele frequencies are at equilibrium. **(A)** **Directional selection** with additive fitnesses favoring allele A . For $p \neq 0, 1$; $\Delta p > 0$, and p increases to one, with the rate of change becoming symmetric about $p = 1/2$. **(B)** Directional selection with dominance and allele A favored. Curve D corresponds to allele A dominant, and curve R to A recessive. Here the response is *asymmetric* about $p = 1/2$. In both cases, $\Delta p > 0$ (provided $p \neq 0, 1$), and the frequency of A increases to 1. **(C)** **Overdominant selection**, where the heterozygote is more fit than either homozygote (Example 5.4), has an internal equilibrium frequency of \hat{p} . For frequencies above the equilibrium, $\Delta p < 0$ and the frequency decreases to \hat{p} ; whereas if p is less than \hat{p} , $\Delta p > 0$ and the allele frequency increases to \hat{p} . Thus, \hat{p} is a *stable equilibrium*. **(D)** With **underdominant selection**, the heterozygote is less fit than either homozygote. Again, there is an internal equilibrium allele frequency, but in this case it is *unstable*. If $p < \hat{p}$, p decreases toward zero, while if $p > \hat{p}$, p increases toward one. The result is fixation of either A or a , depending on the starting allele frequency.

$\Delta p = 0$ (i.e., no allele-frequency change after selection) are called **equilibrium frequencies**, which we denote by \hat{p} . Regardless of the values of s or h , trivial **boundary equilibria** exist when only one allele is present ($\hat{p} = 0$ or 1). Equation 5.1c shows that an **internal equilibrium**, in which both alleles are segregating, requires $1 + h(1 - 2\hat{p}) = 0$, which yields $\hat{p} = (1 + h)/(2h)$. Thus either $h > 1$ (**overdominance**) or $h < -1$ (**underdominance**) is required to ensure $0 < \hat{p} < 1$. However, the equilibrium behavior is very different in these two cases. The situation $h > 1$ represents a **stable equilibrium**, in which following a small perturbation from \hat{p} , selection returns the allele frequency to \hat{p} (Figure 5.1C). In contrast,

with $h < -1$, there is an **unstable equilibrium**, selection sends the allele frequency *away* from \hat{p} which following a small perturbation (Figure 5.1D).

Example 5.1. Letting $p = \text{freq}(A)$, what is Δp when $W_{AA} = 1 + 2s$, $W_{Aa} = 1 + s$, and $W_{aa} = 1$? These are **additive fitnesses**, with each copy of allele A adding an amount s to the fitness. In this case, mean fitness simplifies to $\bar{W} = 1 + 2sp$ (there is an average of $2p$ A alleles per individual, each of which increments fitness by s), and applying Equation 5.1c (setting $h = 0$) yields

$$\Delta p = \frac{sp(1-p)}{1+2sp} \quad (5.2a)$$

Noting that a first-order Taylor expansion (in s) yields $1/(1+2sp) = 1 - 2sp + O(s^2)$, for $|s|$ small, we have

$$\Delta p = sp(1-p)[1 - 2sp + O(s^2)] = sp(1-p) + O(s^2) \quad (5.2b)$$

The notation $O(s^2)$ denotes terms of order s^2 , which are negligible for $|s| \ll 1$.

The only equilibrium allele frequencies under this model are $\hat{p} = 0$ and $\hat{p} = 1$. If A is favored by selection ($s > 0$), then $\Delta p > 0$ for $0 < p < 1$ and the frequency of A increases to one, regardless of the starting point (Figure 5.1A). Here $\hat{p} = 1$ is a stable equilibrium point while $\hat{p} = 0$ is unstable, because if even a few copies of A are introduced, selection drives them to fixation. In contrast, if allele a is favored ($s < 0$), the frequency of allele A declines to zero regardless of the starting point and $\hat{p} = 0$ is stable, while $\hat{p} = 1$ is unstable.

Expected Time for Allele-frequency Change

A key issue in selection theory is the expected time required for a given amount of allele-frequency change. Assuming that s and sh are small (i.e., there is weak selection, so that $\bar{W} \simeq 1$), we can ignore \bar{W} in Equation 5.1.c as a first-order approximation (see Example 5.1). Equation 5.1.c then shows that the change in allele frequency p under weak selection is approximated by the differential equation

$$\frac{dp}{dt} = sp(1-p)[1 + h(1-2p)] \quad (5.3a)$$

For additive selection ($h = 0$), this has a simple solution of

$$p_t = \frac{p_0}{p_0 + (1-p_0)e^{-st}} \quad (5.3b)$$

where p_t is the frequency of allele A at time t . Often of greater interest is t_{p_t, p_0} , the expected time required to move from initial frequency of p_0 to target value of p_t . From Equation 5.3a, this is given by the integral

$$t_{p_t, p_0} = \frac{1}{s} \int_{p_0}^{p_t} \frac{dx}{x(1-x)[1+h(1-2x)]} \quad (5.3c)$$

Crow and Kimura (1970) presented explicit results for several important cases. If fitnesses are additive ($h = 0$)

$$t_{p_t, p_0} \simeq \frac{1}{s} \ln \left(\frac{p_t(1-p_0)}{p_0(1-p_t)} \right) \quad (5.3d)$$

whereas if A is recessive ($h = -1$)

$$t_{p_t, p_0} \simeq \frac{1}{2s} \left[\ln \left(\frac{p_t(1-p_0)}{p_0(1-p_t)} \right) - \frac{1}{p_t} + \frac{1}{p_0} \right] \quad (5.3e)$$

and finally, if A is dominant ($h = 1$)

$$t_{p_t, p_0} \simeq \frac{1}{2s} \left[\ln \left(\frac{p_t (1 - p_0)}{p_0 (1 - p_t)} \right) + \frac{1}{1 - p_t} - \frac{1}{1 - p_0} \right] \quad (5.3f)$$

Example 5.2. Consider the time for a favored allele to move from a frequency of 0.1 to a frequency of 0.5. For an additive allele, Equation 5.3d yields

$$t \simeq s^{-1} \ln \left(\frac{0.5 (1 - 0.1)}{0.1 (1 - 0.5)} \right) = \frac{2.2}{s} \text{ generations}$$

On the other hand, from Equations 5.3e and 5.3f, $t \simeq 1.5/s$ generations when A is dominant, and $t \simeq 5.1/s$ generations when A is recessive. The faster rate of response for a rare dominant allele occurs because A is fully exposed in heterozygotes ($W_{Aa} > W_{aa}$), while its fitness effects are completely hidden in heterozygotes when recessive ($W_{AA} > W_{Aa} = W_{aa}$). Conversely, this same feature slows down the rate of response of a dominant when A is common, as only rare aa homozygotes will be selected against.

Differential Viability Selection on the Sexes

Up to now we have assumed there is equal selection operating on both sexes, but this need not be the case. To accommodate this complication, again assume there is random mating, an autosomal locus, and viability selection, but let x be the current frequency of allele A in males and y be the current value in females. The genotype frequencies following random mating and their fitnesses can be represented as

Genotype	AA	Aa	aa	Mean
Frequency	yx	$x(1 - y) + y(1 - x)$	$(1 - x)(1 - y)$	
Male fitness	W_{AA}	W_{Aa}	W_{aa}	\bar{W}
Female fitness	V_{AA}	V_{Aa}	V_{aa}	\bar{V}

As in Table 5.1, the frequencies of surviving genotypes in males and females are equal to the product of their starting values and relative fitnesses. For example, $yx W_{AA}/\bar{W} = yx w_{AA}$ and $yx V_{AA}/\bar{V} = yx v_{AA}$ are the frequencies of AA among surviving males and females, respectively. The frequency of A in males after selection is the sum of the postselection frequency of AA plus half that of Aa , giving the recursion equation for the allele frequency in males as

$$x' = \frac{xy W_{AA} + (1/2)[x(1 - y) + y(1 - x)] W_{Aa}}{\bar{W}} \quad (5.4a)$$

$$= xy w_{AA} + (1/2)[x(1 - y) + y(1 - x)] w_{Aa} \quad (5.4b)$$

where

$$\bar{W} = xy W_{AA} + [x(1 - y) + y(1 - x)] W_{Aa} + (1 - x)(1 - y) W_{aa} \quad (5.4c)$$

with an analogous expression for y' in females obtained by replacing W by V . These new values (x', y') are then used for the next iteration. Kidwell et al. (1977) explored the conditions under which differential selection in the sexes can maintain variation (i.e., support a stable polymorphism). For additive selection, they found that **antagonistic selection** (meaning that the sign of the selection coefficients differs between sexes, with A favored in one sex and a in the other), can stably maintain variation *only* if the absolute values of selective

differences are fairly close to each other. Strong disproportional selection in one sex will remove variation. See Kidwell et al. (1977) for an analysis of more complex cases.

Frequency-dependent Selection

Although we have been assuming that the genotypic fitnesses W_{ij} are constants, this need not be the case. The fitness of a genotype may be a function of the other genotypes in the population, giving rise to **frequency-dependent selection**. For example, when a rare genotype has a selective advantage due to avoidance of a search image by a predator, its fitness declines as its frequency increases. Alleles at self-incompatibility loci in plants also have a fitness advantage when rare because successful gametes must fuse with those carrying different alleles.

If genotype fitness varies with allele frequencies, Equation 5.1 still holds, provided we replace the constant values of W_{ij} by the functions $W_{ij}(p)$. One interesting feature of frequency-dependent selection is that mean population fitness need not increase over time. Indeed, Wright (1948a) provided a simple two-allele example where mean fitness strictly decreases over time.

Frequency-dependent selection can maintain a polymorphism when rare alleles have the highest fitness. Such a situation is often called **balancing selection**, but some caution is in order when using this term as it is also used for constant-fitness overdominance. Wright and Dobzhansky (1946) noted just how subtle this distinction can be, showing that both fitness models (frequency-dependence and overdominance) can generate identical allele-frequency dynamics. Thus, the two models cannot be distinguished from allele-frequency data alone. Indeed, Denniston and Crow (1990) and Lachmann-Tarkhanov and Sarkar (1994) showed that for *any* set of constant fitnesses, there is always an alternative frequency-dependent fitness set that generates the same exact allele-frequency dynamics.

Making a case for balancing selection via rare-genotype advantage requires making direct estimates of genotype fitnesses at different allele frequencies. Genotype fitnesses are expected to be constant under overdominance, but they change under frequency-dependence. An example of this approach was provided by Fitzpatrick et al. (2007), who examined the *foraging* gene of *Drosophila melanogaster* and found that the alternative *sitter* and *rover* alleles have their highest fitnesses when rare.

Finally, a (somewhat) related topic is the fate of alleles whose selection coefficients randomly fluctuate over generations. The important feature in this case is that the allele with the highest (*arithmetic*) mean absolute fitness, $\mu_s = E[s]$, is not necessarily the winner. Rather, the allele with the highest *geometric* mean fitness wins (Dempster 1955a; Haldane and Jayakar 1963; Gillespie 1973, 1977; Orr 2007). The geometric mean can be approximated as $\mu_s - \sigma_s^2/[2\mu_s]$, so that the variance matters as well. Hence an allele that is less fit on average (i.e., has a smaller μ_s), can still win if it has a lower variance.

Fertility/Fecundity Selection

We have also been assuming no differential fertility/fecundity (we treat these two terms as synonymous), meaning that all combinations of genotypic pairs produce, on average, the same number of offspring. Obviously, this is often not true. To treat this problem formally, the average number of offspring produced by the (ordered) cross of an $A_i A_j$ male with an $A_k A_l$ female is denoted by the **fertility fitness**, f_{ijkl} . In this fully general case, it is no longer sufficient to simply follow allele frequencies. Rather, we must follow *genotypic* frequencies, and the resulting dynamics can quickly become very complex. For example, mean viability can easily decrease if the genotypes with low viability have sufficiently high fertility.

Bodmer (1965) and Kempthorne and Pollak (1970) further explored some of the consequences of fertility selection. A key result was that if the fertility fitnesses are multiplicative,

$$f_{ijkl} = f_{ij} \cdot f_{kl}$$

meaning that the average fertility of the cross is simply the product the fertility fitnesses for each genotype (as opposed to a specific value for each cross), then if w_{ij} is the viability fitness, the evolutionary dynamics proceed as with viability selection with fitness $w_{ij} f_{ij}$.

Sexual Selection

A final complication is **sexual selection**, non-random mating based on traits involved in mate choice (Chapter 29). In many species, mate choice is at least partly based on trait values, either through male-male competition for access to females or through female choice of specific males. Sexual selection for particular traits can result in very interesting evolutionary dynamics, especially when sexually preferred trait values conflict with natural selection (viability and/or fertility selection).

Example 5.3. An interesting example of the consequences of sexual selection was presented by Muir and Howard (1999). As exotic genes are introduced into domesticated species to create transgenic organisms, there is a biosafety concern in the potential genetic risk of the introduced transgene. If the gene “escapes” into a wild population, will it increase in frequency, be neutral, or quickly be lost by negative selection? Muir and Howard (1999, 2001) and Howard et al. (2004) developed population-genetic models to assess such risk and used them to understand the fate of a transgenic strain of the Japanese medaka fish (*Oryzias latipes*). After insertion of a human growth-hormone gene under a fish-specific promoter, the resulting transgenic fish grows faster and to a much larger size than a normal medaka. While such a genetic transformation may be a boon for aquaculture, what would happen if the growth-hormone gene found its way into natural medaka populations? Muir and Howard found that transgenic fish have only 70% of the survival rate of normal fish. Based on this strong viability selection, one might think that any transgenes that escape would quickly be lost. However, Muir and Howard found that larger fish have a roughly four-fold mating advantage relative to smaller fish. Based on these parameter values, any escaped transgene will spread, as the mating advantage more than offsets the survival disadvantage. However, simulation studies find a potentially more ominous fate under these parameter values. The transgene not only spreads, but it eventually may drive the population to extinction as a consequence of the reduction in viability. Muir and Howard coined the term **Trojan gene** for such settings. Such genes may also arise naturally. A potential example was given by Dawson (1969), who found that a newly arisen eye color mutation in *Tribolium castaneum* rapidly increased in frequency in tandem with the rate at which the line went extinct in a competition experiment.

WRIGHT'S FORMULA

A more compact and insightful way to express allele-frequency change was presented by Sewall Wright, one of the founding fathers (with Fisher and Haldane) of modern selection theory. Because

$$\begin{aligned}\frac{d\bar{W}}{dp} &= \frac{d(p^2W_{AA} + 2p(1-p)W_{Aa} + (1-p)^2W_{aa})}{dp} \\ &= 2pW_{AA} + 2(1-2p)W_{Aa} - 2(1-p)W_{aa}\end{aligned}\quad (5.5a)$$

a little algebra shows that Equation 5.1b can be written as

$$\Delta p = \frac{p(1-p)}{2\bar{W}} \frac{d\bar{W}}{dp} = \frac{p(1-p)}{2} \frac{d\ln\bar{W}}{dp}\quad (5.5b)$$

The last step follows from the chain rule for differentiation,

$$\frac{d\ln f(x)}{dx} = \frac{1}{f(x)} \frac{df(x)}{dx}$$

Equation 5.5b is **Wright's formula** (1937), which holds provided the genotypic fitnesses are constant and **frequency independent** (not themselves functions of allele frequencies, which

can be formally stated as $\partial W_{ij}/\partial p_k = 0$ for all i, j , and k). Normal derivatives are used in Equation 5.5b as there is just a single variable, the allele frequency p .

Example 5.4. Consider a locus with two alleles and genotypic fitnesses

$$W_{AA} = 1 - t, \quad W_{Aa} = 1, \quad \text{and} \quad W_{aa} = 1 - s$$

Letting $p = \text{freq}(A)$, Wright's formula can be used to find Δp and the equilibrium allele frequencies. Here mean fitness is given by

$$\begin{aligned}\bar{W} &= p^2(1-t) + 2p(1-p)(1) + (1-p)^2(1-s) \\ &= 1 - tp^2 - s(1-p)^2\end{aligned}$$

Taking derivatives with respect to p results in

$$\frac{d\bar{W}}{dp} = 2[s - p(s+t)]$$

which, upon substituting into Wright's formula, results in

$$\Delta p = \frac{p(1-p)[s - p(s+t)]}{1 - tp^2 - s(1-p)^2}$$

Alternatively, substituting these fitnesses into Equation 5.1b recovers the same result.

Setting $\Delta p = 0$ yields three equilibrium solutions: $\hat{p} = 0$, $\hat{p} = 1$, and, most interestingly,

$$\hat{p} = s/(s+t)$$

which corresponds to $d\bar{W}/dp = 0$, a necessary condition for a local extremum (maximum or minimum) in \bar{W} . Recall from calculus that this extremum is a maximum when $d^2\bar{W}/dp^2 = -2(s+t) < 0$, and a local minimum when this second derivative is positive. With selective overdominance ($s, t > 0$), the heterozygote has the highest fitness, implying $\Delta p > 0$ when $p < \hat{p}$, and $\Delta p < 0$ when $p > \hat{p}$ (Figure 5.1C). Thus, *selection retains both alleles in the population*, as first shown by Fisher (1922). With overdominance, \hat{p} is also the allele frequency that maximizes \bar{W} .

With selective underdominance ($s, t < 0$), the heterozygote has lower fitness than either homozygote. Although there is still an equilibrium, $\hat{p} = s/(s+t)$ corresponds to a local minimum of \bar{W} (as $d^2\bar{W}/dp^2 > 0$) and is therefore unstable—if p is the slightest bit below \hat{p} , it decreases to zero, while if p is the slightest bit above \hat{p} , it increases to one (Figure 5.1D). In contrast to selective overdominance, *selective underdominance removes, rather than maintains, genetic variation*, with the initial starting frequencies determining which allele is fixed.

Example 5.5. A classic example of selective overdominance is sickle-cell anemia, a disease due to a recessive allele at the beta hemoglobin locus. *SS* homozygotes suffer periodic life-threatening health crises due to their red blood cells being sickle-shaped. *SS* individuals often have near-zero fitness (due to their low survival to reproductive age), and ordinarily this would be expected to result in a very low frequency of the *S* allele. However, in malaria-infested regions, *SN* heterozygotes (*N* denoting the “normal” allele) have increased resistance to malaria relative to *NN* homozygotes.

A sample of 12,387 West Africans yielded 9365 *NN*, 2993 *NS*, and 29 *SS* individuals (Nussbaum et al. 2004), giving a frequency of *S* as

$$\frac{(1/2) \cdot 2993 + 29}{12,387} = 0.123$$

Assuming the frequency of S is at its selective equilibrium, what is the strength of selection against NN individuals due to malaria? Writing the fitnesses of the SS , SN , and NN genotypes as $1 - t$, 1, and $1 - s$ respectively, the result from Example 5.4 is an equilibrium frequency of $s/(s + t)$ for allele S . Setting this equal to 0.123 implies that

$$t = \frac{(1 - 0.123)}{0.123} s = 7.120 s \quad \text{or} \quad s = 0.140 t$$

If SS individuals are either lethal ($t = 1$) or have only 10% fitness ($t = 0.9$), then $s = 0.140$ and 0.126, respectively. In other words, relative to NN individuals, heterozygotes have a 13% to 14% fitness advantage due to increased malaria resistance.

Example 5.6. A common model in evolutionary genetics considers a trait (determined by a number of loci) that is experiencing stabilizing selection, with some intermediate phenotypic value θ favored (Chapters 28–30). Given that intermediate phenotypes are favored, naively one might think that heterozygotes (whose phenotypes are between those of the two homozygotes) are favored, resulting in selective overdominance. However, the application of Wright's formula to the allelic dynamics at one of the underlying loci shows that this is *not* the case.

To demonstrate this, we need to express the mean fitness \bar{W} in terms of the allele frequency p_i at some focal locus. To do so, we start with a standard model for stabilizing selection, a **Gaussian fitness function**, with the expected fitness of an individual with trait value z given by

$$W(z) = e^{-(z-\theta)^2/\omega^2}, \quad \text{with } \omega^2 > 0$$

Akin to the variance in a Gaussian (i.e., normal) distribution, ω^2 measures the strength of selection against the trait, with larger values indicating weaker selection (fitness declining more slowly as we move away from θ). Letting $s = 1/\omega^2$, Barton (1986) showed that if phenotypes are normally distributed with a mean of μ and a variance of σ^2 , then (assuming weak selection, $\sigma^2 \ll \omega^2 = 1/s$) the mean fitness is

$$\bar{W} \simeq e^{-[\sigma^2 + (\mu - \theta)^2]/(2\omega^2)}, \quad \text{implying} \quad \ln \bar{W} \simeq -s[\sigma^2 + (\mu - \theta)^2]/2 \quad (5.6a)$$

Because the mean and variance are functions of the allele frequencies over all loci, our concern is now the partial derivative with respect to the allele frequency p_i at our focal locus. Applying the chain rule,

$$\begin{aligned} \frac{\partial \ln \bar{W}}{\partial p_i} &= -(s/2) \frac{\partial [\sigma^2 + (\mu - \theta)^2]}{\partial p_i} \\ &= -(s/2) \left[\frac{\partial \sigma^2}{\partial p_i} + 2(\mu - \theta) \frac{\partial \mu}{\partial p_i} \right] \end{aligned} \quad (5.6b)$$

Now suppose that n diallelic fully additive loci underlie this character (no dominance or epistasis), with the genotypes $b_i b_i$, $B_i b_i$, and $B_i B_i$ at each locus i having effects 0, a_i , and $2a_i$. Letting p_i be the frequency of allele B_i , the trait mean is some baseline value m plus the genetic contributions, while the trait variance is the additive-genetic plus environmental variances,

$$\mu = m + 2 \sum_{i=1}^n a_i p_i \quad \text{and} \quad \sigma^2 = 2 \sum_{i=1}^n a_i^2 p_i (1 - p_i) + \sigma_E^2 \quad (5.6c)$$

where the additive-genetic variance expression (LW Equation 4.23b) assumes no linkage disequilibrium. From Equation 5.6c,

$$\frac{\partial \mu}{\partial p_i} = 2 a_i \quad \text{and} \quad \frac{\partial \sigma^2}{\partial p_i} = 2 a_i^2 (1 - 2p_i) \quad (5.6d)$$

Wright's formula (Equation 5.5b) returns the expected change in the frequency of allele B_i as

$$\Delta p_i = \frac{p_i(1-p_i)}{2} \left(\frac{\partial \ln \bar{W}}{\partial p_i} \right)$$

which, upon substituting Equation 5.6d into Equation 5.6b, yields

$$\Delta p_i = s a_i \left(\frac{p_i(1-p_i)}{2} \right) [a_i(2p_i - 1) + 2(\theta - \mu)] \quad (5.6e)$$

Thus, even if the population mean μ coincides with the phenotypic optimum θ , there remains the potential for selection on the underlying loci, as in this special case Equation 5.6e reduces to

$$\Delta p_i = a_i^2 s p_i (1-p_i) (p_i - 1/2) \quad (5.6f)$$

This is a form of selective *underdominance*, with $\hat{p}_i = 1/2$ being unstable, as $\Delta p_i < 0$ for $p_i < 1/2$, while $\Delta p_i > 0$ for $p_i > 1/2$. Hence, selection for an optimum phenotype tends to drive allele frequencies toward fixation, *removing*, rather than retaining, variation at underlying loci (Robertson 1956).

Adaptive Topographies and Wright's Formula

The surface $\bar{W}(p)$ of mean population fitness as a function of allele frequency forms an **adaptive topography**, showing which p value or values maximize mean fitness. Examples are shown in Figure 5.2, which plots $\bar{W}(p)$ for the same settings as in Figure 5.1. Note that stable equilibria correspond to local maxima (Figure 5.2C) and unstable equilibria correspond to local minima in mean fitness (Figure 5.2D). Because $p(1-p) \geq 0$, Wright's formula implies that the sign of Δp is the same as the sign of $d \ln \bar{W}/dp$, implying that *allele frequencies change to locally maximize mean fitness*. Wright's formula thus suggests a powerful geometric interpretation of the mean-fitness surface $\bar{W}(p)$ —the local curvature of the fitness surface largely describes the behavior of the allele frequencies. In a random-mating population with constant W_{ij} , allele-frequency changes move the population toward the nearest local maximum on the fitness surface.

However, evolution toward maximum fitness is only guaranteed when the assumptions underlying Wright's formula hold (e.g., single-locus viability selection with constant genotypic fitnesses). Further, in a strict mathematical sense, mean fitness need not increase to a local maximum. If the initial allele frequencies are such that mean population fitness is exactly at a local minimum, allele frequencies do not change, as $d \ln \bar{W}/dp = 0$ (Example 5.4). However, this case is biologically trivial, as the resulting equilibrium is unstable—any amount of genetic drift moves allele frequencies away from this minimum, with mean fitness subsequently increasing to a local maximum.

SINGLE-LOCUS SELECTION: MULTIPLE ALLELES

Extending single-locus models from two to multiple alleles is a straightforward process and also reveals connections between quantitative-genetic concepts and the behavior of population-genetic models. In particular, multiple-allele models can be framed in terms of the average excess (LW Chapter 4) of each allele on fitness, which then leads into a discussion of how the additive genetic variance in fitness influences the selection response (allele-frequency change).

Marginal Fitnesses and Average Excesses

For a locus with n alleles under viability selection and random mating, the frequencies of the $A_i A_j$ heterozygotes and $A_i A_i$ homozygotes after selection are $2 p_i p_j W_{ij}/\bar{W}$ and $p_i^2 W_{ii}/\bar{W}$.

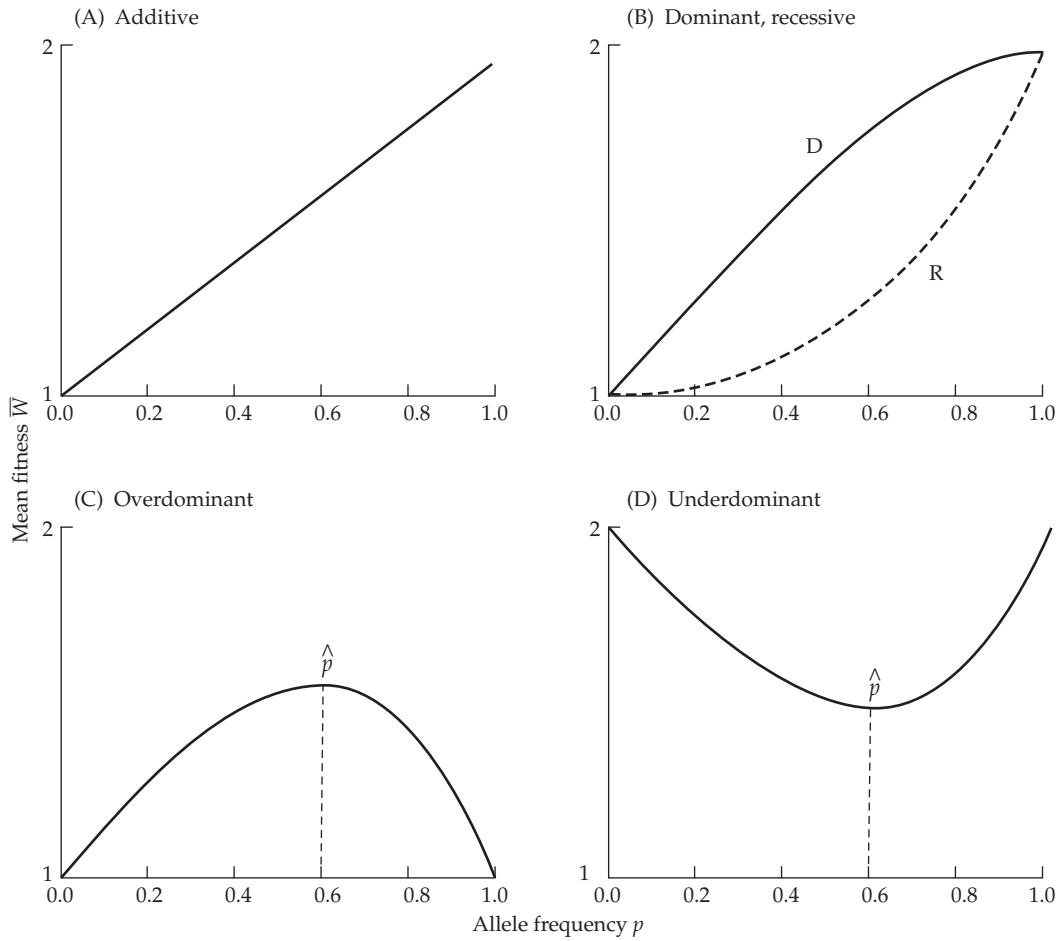

Figure 5.2 Plots of mean population fitness, $\bar{W}(p)$, as a function of allele frequency p (as in Figure 5.1). In all cases, the best genotype has a fitness of 2.0 and the worst has a fitness of 1.0. (A) Directional selection with additive fitness, with allele A favored. (B) Directional selection with dominance, with allele A favored. The upper curve (D) is for A dominant and the lower (R) is for A recessive. In both (A) and (B), mean fitness is maximized at the stable equilibrium point ($p = 1$). (C) With overdominant selection, fitness is maximized at the stable equilibrium point \hat{p} . (D) With underdominant selection, fitness is *minimized* at the unstable internal equilibrium point \hat{p} .

As in Table 5.1, for a biallelic locus, this follows from weighting the (random-mating) frequency of a genotype before selection by its fitness, with

$$\bar{W} = \sum_{i=1}^n \sum_{j=1}^n p_i p_j W_{ij}$$

The frequency of allele A_i in survivors is the postselection frequency of the $A_i A_i$ homozygote plus half the postselection frequencies of all $A_i A_j$ heterozygotes, a sum that simplifies to

$$p'_i = \frac{p_i}{\bar{W}} \sum_{j=1}^n p_j W_{ij} = p_i \frac{W_i}{\bar{W}} \quad (5.7a)$$

where

$$W_i = \sum_{j=1}^n p_j W_{ij} \quad (5.7b)$$

is the **marginal fitness** of allele A_i , i.e., the expected fitness of an individual carrying one copy of A_i and a second randomly chosen allele. Further,

$$\bar{W} = \sum_{i=1}^n p_i W_i$$

so one can also express mean fitness as the average of the marginal fitnesses.

Note that, unlike *genotypic* fitness (W_{ij}), the marginal fitness W_i is a function of the allele frequencies and hence *is expected to change over time*. The concept of marginal fitness can be understood as follows: under random mating, if one allele is known to be A_i , then with probability p_j , the other will be A_j and the resulting fitness will be W_{ij} . Summing over all possible alleles recovers Equation 5.7b. If $W_i > \bar{W}$ (individuals carrying A_i have a higher fitness than a random individual), then A_i will increase in frequency. If $W_i < \bar{W}$, A_i will decrease in frequency. Finally, if $W_i = \bar{W}$, the frequency of A_i will be unchanged. From Equation 5.7a, the expected allele-frequency change is

$$\Delta p_i = p'_i - p_i = p_i \frac{W_i - \bar{W}}{\bar{W}} \quad (5.7c)$$

which implies that at a polymorphic equilibrium (e.g., $\hat{p}_i \neq 0, 1$),

$$W_i = \bar{W} \text{ for all } i \text{ with } 0 < \hat{p}_i < 1 \quad (5.7d)$$

Thus, at an equilibrium, *all segregating alleles have the same marginal fitness*.

Marginal fitnesses provide a direct connection between single-locus and quantitative-genetic theory. Recalling that the **average excess** of allele A_i is the difference between the mean of individuals carrying a copy of A_i and the population mean (LW Equation 4.16), we immediately see that $(W_i - \bar{W})$ is the average excess in absolute fitness of allele A_i , implying that

$$s_i = (W_i - \bar{W}) / \bar{W} = w_i - 1 \quad (5.8a)$$

is the average excess in *relative* fitness. Like W_i , s_i is a function of allele frequencies, and thus changes as these change. Equation 5.7c can therefore be expressed as

$$\Delta p_i = p_i s_i \quad (5.8b)$$

Thus, at equilibrium, *the average excess in fitness of each allele equals zero*. As there is then no variation in the average excesses, it immediately follows that the *additive genetic variance in fitness is also zero* at the equilibrium allele frequencies, as a nonzero additive genetic variance requires variation in the average excesses (see LW Equation 4.23a).

Equilibrium Frequencies With Multiple Alleles

As with a single locus with two alleles, mean fitness never decreases with n alleles at a single locus (again assuming constant fitnesses, viability selection, and random mating). The classical short proof for this was given by Kingman (1961a). A more interesting question involves the number of polymorphic equilibria that exist with two (or more) segregating alleles. In particular, how many equilibria with all n alleles polymorphic are possible? Kingman (1961b) showed that such a system either has no such equilibria, exactly one, or an infinite number (a line or hyperplane of solutions). We can see this from Equation 5.7d, as the equilibrium marginal fitnesses for all segregating alleles are identical, e.g., $\hat{W}_i = \hat{W}_1 = \bar{W}$ for $i = 2, \dots, n$. Because each marginal fitness is a linear function of the n equilibrium allele frequencies (Equation 5.7b), there are $n - 1$ linear equations in terms of the equilibrium frequencies for the n alleles (as the allele frequencies are constrained to sum to one), with

$$\hat{W}_i = \sum_{j=1}^n W_{ij} \hat{p}_j = \hat{W}_1 = \sum_{j=1}^n W_{1j} \hat{p}_j \text{ for } i = 2, \dots, n$$

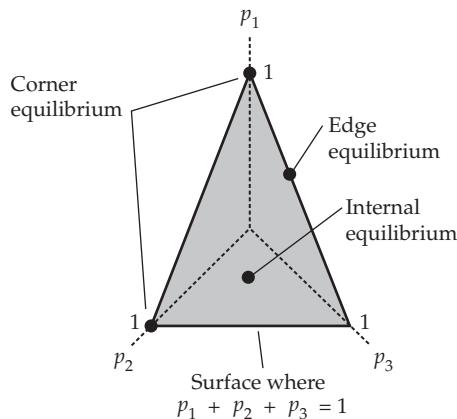

Figure 5.3 The simplex for three alleles, namely the space of all possible allele frequencies, subject to the constraint that they must sum to 1. Note that the plane of possible values intersects each allele-frequency axis at a value of 1 for that allele, and 0 for all others. Within the simplex, three types of equilibria are possible. Corner equilibria occur when one allele has frequency 1; these are monomorphic equilibria, with no genetic variation. Polymorphic equilibria can either be edge equilibria, when at least two (but not all) allele frequencies are nonzero (here alleles 1 and 3 are segregating while allele 2 is absent), or internal equilibria, wherein all alleles are segregating.

With a linear system of $n - 1$ equations and $n - 1$ unknowns, there will be either zero, one, or infinitely many solutions. An example of the latter is that when all the $W_{ij} = 1$, any set of allele frequencies is stable, as this is just the neutral condition.

A more profound result obtained by Kingman is that the existence of a single internal (and stable) equilibrium for all n alleles requires the fitness matrix \mathbf{W} (whose ij th element is W_{ij}) to have exactly one positive and at least one negative eigenvalue (Appendix 5). More generally, if \mathbf{W} has m positive eigenvalues, then, at most, $n - m + 1$ alleles can be jointly polymorphic.

Internal, Corner, and Edge Equilibria and Basins of Attraction

With more than two alleles, a number of different types of equilibria are possible, and some notation is helpful for characterizing these types. With n possible alleles, the space of potential allele frequencies is given by the **simplex** defined by the constraint $\sum_i^n p_i = 1$. Figure 5.3 shows this for the three-allele case, which is a section of a two-dimensional plane. With n alleles, the resulting simplex is a section of an $n - 1$ dimensional hyperplane. We can distinguish between three types of equilibria based on their location on the simplex. **Corner equilibria** are those for which the frequency of one allele is 1, and hence all others are 0, corresponding to a corner of the simplex (Figure 5.3). With n alleles, there are n corner equilibria. With **edge equilibria**, the values of one (or more) of the allele frequencies are 0, while the rest are nonzero, i.e., two (or more) alleles are segregating in the population. Finally, we can have an **internal equilibrium**, in which all alleles are segregating (all $\hat{p}_i > 0$). Thus, polymorphic equilibria correspond to either edge equilibria (not all alleles are segregating) or internal equilibria (all are segregating). Kingman's (constant-fitness) result states there is either no internal equilibrium, a single unique one, or a surface (such as a line or plane) embedded within the simplex.

Far more important than the existence of equilibria is their stability. As noted above, when allele frequencies at an unstable equilibrium are perturbed, they depart the neighborhood of this equilibrium value. Conversely, departures from the nearby vicinity of a stable equilibrium are followed by returns to the equilibrium. If we have a surface of equilibria (as might occur if two or more alleles have identical fitnesses), then we can also have a surface of **neutrally stable equilibria**. In such cases, provided we perturb the allele frequencies

along the equilibrium surface, the subsequent allele frequencies do not change over time (the neutral Hardy-Weinberg condition is one such example).

When multiple stable equilibria exist, the initial conditions (history) of the process have a great influence on the final value reached. We saw this with underdominance (Example 5.4) where, if the population starts with frequency in the open interval $(0, \hat{p})$, $p \rightarrow 0$, while if the population starts in the open interval $(\hat{p}, 1)$, $p \rightarrow 1$. Thus, with multiple stable equilibria, there is a **basin of attraction** for each equilibrium value. Akin to rainfall over a wide area ending up in different rivers depending on which watershed basin it originally fell into, the domain of attraction for a stable equilibrium value is that region in the simplex within which starting allele frequencies eventually converge to the stable equilibrium of interest. In very special situations, one can use mathematical tools to determine such basins (e.g., Hofbauer and Sigmund 1988). More typically, however, one must systematically sample starting values within the simplex (e.g., using a grid of points) and then numerically iterate the equations of response to determine where the frequencies eventually converge.

Wright's Formula With Multiple Alleles

With only two alleles, Equation 5.5b (under the assumption of frequency-independent fitnesses) completely describes the evolutionary dynamics in terms of a single variable (the frequency of either allele). To express Equation 5.7c in a form analogous to Equation 5.5b, we again assume that $\partial W_{ij}/\partial p_k = 0$ for all i, j , and k (i.e., frequency-independent fitnesses). Taking the partial derivative of mean fitness with respect to p_i , the frequency of allele A_i ,

$$\frac{\partial \bar{W}}{\partial p_i} = \frac{\partial}{\partial p_i} \left(\sum_j^n \sum_k^n p_j p_k W_{jk} \right) = 2 \sum_k^n p_k W_{ki} = 2W_i \quad (5.9a)$$

Hence,

$$W_i = \frac{1}{2} \frac{\partial \bar{W}}{\partial p_i} \quad (5.9b)$$

Further, note that

$$\bar{W} = \sum_{j=1}^n p_j W_j = \frac{1}{2} \sum_{j=1}^n p_j \frac{\partial \bar{W}}{\partial p_j} \quad (5.9c)$$

Hence,

$$W_i - \bar{W} = \frac{1}{2} \left(\frac{\partial \bar{W}}{\partial p_i} - \sum_{j=1}^n p_j \frac{\partial \bar{W}}{\partial p_j} \right) \quad (5.9d)$$

Substituting Equation 5.9d into Equation 5.7c gives the allele-frequency change as

$$\Delta p_i = \frac{p_i}{2\bar{W}} \left(\frac{\partial \bar{W}}{\partial p_i} - \sum_{j=1}^n p_j \frac{\partial \bar{W}}{\partial p_j} \right) \quad (5.10)$$

This is the multiple-allele version of Equation 5.5b.

It is important to stress that Wright (1937) himself presented a different (and incorrect) version of his formula for multiple alleles, namely

$$\Delta p_i = \frac{p_i(1-p_i)}{2\bar{W}} \frac{\partial \bar{W}}{\partial p_i}$$

which appears widely in the literature. Comparing this with the two-allele version (Equation 5.5b), it is easy to see how Wright became seduced by this extension of his (correct) two-allele formula. In various subsequent descriptions of the multiple-allele version, Wright attempted to justify his 1937 expression by suggesting that it was not a normal partial

derivative, but rather a measure of the gradient in mean fitness along a direction in which the relative proportions of the other alleles do not change (Wright 1942, 1955). However, Edwards (2000) showed that even this interpretation is not correct and presented the correct expression for Wright's (1942, 1955) later interpretation (Edwards' expression still differs from Equation 5.10 and lacks a transparent interpretation).

For a compact way to write Equation 5.10, recall that $(\partial \bar{W}/\partial p_i)(1/\bar{W}) = \partial \ln(\bar{W})/\partial p_i$, which yields

$$\Delta p_i = \sum_{j=1}^n G_{ij} \cdot \frac{\partial \ln \bar{W}}{\partial p_j} \quad (5.11a)$$

where

$$G_{ij} = \begin{cases} p_i(1-p_i)/2 & i = j \\ -p_i p_j / 2 & i \neq j \end{cases} \quad (5.11b)$$

Equation 5.11a can be written in matrix form as

$$\Delta \mathbf{p} = \frac{1}{\bar{W}} \mathbf{G} \nabla \bar{W} = \mathbf{G} \nabla \ln(\bar{W}) \quad (5.12a)$$

where $\Delta \mathbf{p}$ is the vector of all allele-frequency changes,

$$\nabla \bar{W} = \begin{pmatrix} \partial \bar{W} / \partial p_1 \\ \vdots \\ \partial \bar{W} / \partial p_n \end{pmatrix} \quad (5.12b)$$

is the gradient vector of all first partial derivatives, and the elements of the $n \times n$ **genetic variance-covariance matrix \mathbf{G}** are given by Equation 5.11b.

Recall from vector calculus (Appendix 6) that the greatest local change in the value of $f(\mathbf{x})$ occurs by moving in the direction given by ∇f . Thus, $\nabla \bar{W}$ (and hence $\nabla \ln(\bar{W})$) is the direction of allele-frequency change that maximizes the local change in mean fitness. However, the *actual* vector of change in allele frequencies is rotated away from $\nabla \ln(\bar{W})$ by the matrix \mathbf{G} . The genetic matrix \mathbf{G} thus constrains the rate of selection response, a prelude to the theme of genetic constraints that arises in multivariate trait selection (Chapter 13).

It can be shown that Equation 5.12a implies $d\bar{W}/dt \geq 0$ (see Example A6.7), but unlike the diallelic case, the sign of Δp_i need not equal the sign of $\partial \ln \bar{W} / \partial p_i$. Alleles with the largest values of $p_i(1-p_i) |\partial \ln \bar{W} / \partial p_i|$ dominate the change in mean population fitness and hence dominate the allele-frequency dynamics. As these initially dominating alleles approach their equilibrium frequencies under selection (values where $|\partial \ln \bar{W} / \partial p_i| \approx 0$), other alleles begin to dominate the dynamics of \bar{W} , with their frequencies changing in a way that continues to increase mean population fitness.

Changes in Genotypic Fitnesses, W_{ij} , When Additional Loci are Under Selection

All of the preceding results for allele-frequency change at a locus under selection assume that the genotypic fitnesses W_{ij} remain constant over generations. Changes in the environment can obviously compromise this assumption, as can frequency-dependent effects (such as rare-genotype advantage). A more subtle issue arises when additional loci influence fitness. Because the fitness of $A_i A_j$ is the average fitness over all multilocus genotypes containing these alleles, when linkage disequilibrium is present, correlations between alleles within gametes can create a dependency between the average fitness value of $A_i A_j$ and the frequency of at least one allele at this locus (Example 5.7). In this case, the assumption that $\partial W_{ij} / \partial p_k = 0$ can fail and Wright's formula no longer holds. A complete description of the allele-frequency dynamics then requires following *all* loci under selection. As we will show, this is not trivial, as it requires modeling more than just the allele-frequency changes at each locus. Selection generates nonrandom associations (linkage, or gametic-phase, disequilibrium) among loci, requiring us to model the dynamics of multilocus *gamete* frequencies to

account for both the frequencies of alleles over all loci and the disequilibria between them. If gamete-frequency changes due to recombination occur on a much shorter time scale than changes due to selection, linkage disequilibrium is expected to be negligible, and Wright's formula can be applied as a good approximation to certain quantitative-genetic problems (e.g., Barton 1986; Barton and Turelli 1987; Hastings and Hom 1989).

Example 5.7. Consider two diallelic loci with alleles A, a and B, b , and let $p = \text{freq}(A)$ and $q = \text{freq}(B)$. The frequency of the gametes AB and Ab are $pq + D$ and $p(1-q) - D$, respectively, where D is the linkage disequilibrium between these two loci (Equation 2.18). The marginal (or **induced**) fitness W_{AA} of AA individuals (the fitness of AA averaged over all genetic backgrounds) is

$$W_{AA} = W_{AABB} \cdot \Pr(AABB|AA) + W_{AABb} \cdot \Pr(AABb|AA) + W_{AAbb} \cdot \Pr(AAbb|AA)$$

These conditional weights, such as $\Pr(AABB|AA)$, are the conditional probabilities of the two-locus genotype (here $AABB$) given a single-locus genotype (here AA), and are obtained from the standard formula for conditional probability, $\Pr(x|y) = \Pr(x,y)/\Pr(y)$, as follows. Under random mating $\Pr(AA) = p^2$, while $\Pr(AABB)$ is the probability of getting AB gametes from both parents; or, from above, $\text{Freq}(AB)^2 = (pq + D)^2$, giving $\Pr(AABB|AA) = (pq + D)^2/p^2$. Similar results for the remaining two B locus genotypes results in

$$W_{AABB} \frac{(pq + D)^2}{p^2} + W_{AABb} \frac{2(pq + D)[p(1-q) - D]}{p^2} + W_{AAbb} \frac{[p(1-q) - D]^2}{p^2}$$

In the absence of linkage disequilibrium ($D = 0$), the marginal fitness reduces to

$$W_{AA} = W_{AABB} \cdot q^2 + W_{AABb} \cdot 2q(1-q) + W_{AAbb} \cdot (1-q)^2$$

which is independent of p , the frequency of A . In this special case, even though the marginal fitness of AA changes as the frequency q of allele B changes, Wright's formula (Equation 5.5b) for the change in the frequency p of allele A still holds, as the fitness of AA does not depend on p . However, when $D \neq 0$, W_{AA} is a complex function of p, q , and D , so that $\partial W_{AA}/\partial p \neq 0$ and Wright's formula does not hold. It is worth noting that even if $D = 0$ initially, disequilibrium is typically built up by selection (Chapters 16 and 24), although it may be sufficiently small for Wright's formula to serve as a good approximation.

SELECTION ON TWO LOCI

When fitness is influenced by n biallelic loci, we cannot generally predict how genotype frequencies will evolve by simply considering the n sets of single-locus allele-frequency change equations (Equation 5.7a). The major complication is *gametic-phase disequilibrium*, which (if present) thwarts the prediction of gamete frequencies from simple allele frequencies alone (Chapter 2; LW Chapter 5). In addition, the marginal fitnesses W_{ij} associated with any one of the loci can themselves be functions of the frequencies of alleles at other loci (see Example 5.7). These complications necessitate following *gamete* rather than *allele* frequencies, requiring many more equations. Further, when disequilibrium and/or epistasis in fitness occur, complicated multiple equilibria can result. Although most forms of selection generate some disequilibrium even between unlinked loci (Chapter 16), if selection is weak relative to recombination, disequilibrium is often very small. However, as we will see in Chapter 16, even small disequilibrium values can be cumulatively rather significant when summed over a large number of loci underlying quantitative-trait variation.

We focus here on the simplest case of two diallelic loci (alleles A, a and B, b) with random mating and frequency-independent viability selection. Even in this case, the general behavior with constant fitnesses has not been solved outside of a few special cases, and the development of theory beyond two loci is still in a rather embryonic stage (but see Kirkpatrick et al. 2002). Our purpose is simply to introduce some of the complications that arise due to gametic-phase disequilibrium, rather than to examine the theory in detail. For comprehensive reviews, see Karlin (1975), Nagylaki (1977a, 1992a), Hastings (1990b, 1990c), Bürger (2000), Christiansen (2000), and Ewens (2004).

Dynamics of Gamete-frequency Change

Denote the frequencies of the four different gametes by x_i , where

$$\begin{aligned} \text{freq}(g_1) &= \text{freq}(AB) = x_1 & \text{freq}(g_2) &= \text{freq}(Ab) = x_2 \\ \text{freq}(g_3) &= \text{freq}(aB) = x_3 & \text{freq}(g_4) &= \text{freq}(ab) = x_4 \end{aligned}$$

Under random mating (the random union of gametes), the frequency of the different (unordered) genotypes is given by

$$\text{freq}(g_i g_j) = \begin{cases} 2x_i x_j & \text{for } i \neq j \\ x_i^2 & \text{for } i = j \end{cases}$$

Let the fitness of an individual formed from gametes g_i and g_j be $W_{g_i g_j} = W_{g_j g_i}$ (we use the $g_i g_j$ subscript notation to stress that these fitnesses are for specific *gametic*, as opposed to *allellic*, combinations). $W_{g_1 g_4}$ and $W_{g_2 g_3}$ are of special note, being the fitness of *cis* (AB/ab) and *trans* (Ab/aB) double heterozygotes, respectively. One would normally expect these two genotypes to have equal fitness, but certain genetic interactions (such as position effects) can sometimes complicate matters. In addition, if the two loci being considered are themselves in gametic-phase disequilibrium with other loci affecting fitness, *cis* and *trans* fitnesses will appear to differ due to fitness associated with loci not considered (Turelli 1982). Denoting the gamete frequencies after selection by x'_i , with constant viability selection ($W_{g_i g_j}$ constant), no *cis-trans* effect ($W_{g_1 g_4} = W_{g_2 g_3}$), and discrete nonoverlapping generations, the gametic recursion equations become

$$x'_1 = [x_1 W_{g_1} - c D W_{g_1 g_4}] / \bar{W} \quad (5.13a)$$

$$x'_2 = [x_2 W_{g_2} + c D W_{g_1 g_4}] / \bar{W} \quad (5.13b)$$

$$x'_3 = [x_3 W_{g_3} + c D W_{g_1 g_4}] / \bar{W} \quad (5.13c)$$

$$x'_4 = [x_4 W_{g_4} - c D W_{g_1 g_4}] / \bar{W} \quad (5.13d)$$

where c is the recombination fraction between loci, $D = x_1 x_4 - x_2 x_3$ is a measure of gametic-phase disequilibrium, and W_{g_i} is the average fitness of a g_i -bearing individual (the marginal fitness of gamete g_i), with

$$W_{g_i} = \sum_{j=1}^4 x_j W_{g_i g_j} \quad \text{and} \quad \bar{W} = \sum_{i=1}^4 x_i W_{g_i} \quad (5.13e)$$

These equations are due to Kimura (1956) and Lewontin and Kojima (1960). Observe that selection can change gamete frequencies by changing allele frequencies and/or by changing the amount of gametic-phase disequilibrium. Because the four gamete frequencies sum to one, Equations 5.13a–5.13d can be expressed in terms of three equations. Alternatively, one can also parameterize this set of equations using another set of three variables, namely, the allele frequencies p and q for the two loci and their disequilibrium, D .

Equations 5.13a–5.13d are similar in form to the multiple-allele equation (and identical to Equation 5.7a when c or D equals zero). Unlike allele frequencies (which do not change in

the absence of selection under our assumption of infinite population size), gamete frequencies *can* change from generation to generation due to changes in D from recombination, even in the absence of selection (Chapter 2; LW Chapter 5). If D is zero and remains zero after selection (as occurs when fitnesses are **multiplicative** across loci, so that $W_{ijkl} = W_{ij}W_{kl}$), then the new gamete frequency is simply given by the product of the new allele frequencies, e.g., $x'_1 = p'_A p'_B$, and the dynamics can be followed by considering each locus separately (i.e., following Δp_A and Δp_B). However, except in this and a few other special cases, these two-locus equations turn out to be extremely complex. Indeed, as we detail below, there is no general analytic solution for even the simple model of constant fitnesses and viability selection, except when certain symmetry patterns (such as additivity) hold among the fitnesses (Table 5.2).

Example 5.8. If loci have effects on both fitness and on a character not under selection, an incorrect picture as to which characters are under selection can result. The following example, modified from Robertson (1967), illustrates some of the problems that can arise. Let loci **A** and **B** affect fitness (perhaps through some unmeasured character) in addition to influencing character z , which is not itself under selection, with the following fitnesses and character values:

	Fitness			Character z		
	AA	Aa	aa	AA	Aa	aa
BB	1.0	1.1	1.0	BB	2	2
Bb	1.1	1.2	1.1	Bb	2	2
bb	1.0	1.1	1.0	bb	1	1

Alleles A and B are dominant for the character z , while fitness increases with the number of loci that are heterozygous.

Assume that there is gametic-phase equilibrium and that the frequencies of alleles A and B are both $2/3$, in which case $\bar{W} = 1.089$, $\mu_z = 1.78$, and the expected fitnesses for each phenotype become

z	0	1	2
$W(z)$	1.00	1.05	1.10

For example, $AAbb$, $Aabb$, $aaBb$, and $aaBB$ all have a trait value of one, and (under linkage equilibrium), each of these genotypes has frequency of $4/81$, for a total frequency of $16/81$. The expected fitness for $z = 1$ is therefore

$$\frac{4/81 (W_{AAbb} + W_{Aabb} + W_{aaBb} + W_{aaBB})}{16/81} = \frac{1.0 + 1.1 + 1.1 + 1.0}{4} = 1.05$$

If we measured the value of z and fitness in a random sample of individuals from this population, we would conclude that z is under directional selection and expect the trait mean μ_z to increase over time. However, applying two-locus theory (numerical iteration of Equations 5.13a–5.13d) shows that at equilibrium, $p_A = p_B = 1/2$, $\bar{W} = 1.1$, and $\mu_z = 1.50$. Hence, despite the initial positive correlation between z and W , selection causes μ_z to *decline* from its initial starting value of 1.78.

Gametic Equilibrium Frequencies, Linkage Disequilibrium, and Mean Fitness

Now let us consider the equilibrium behavior of two-locus systems. The equilibrium value \hat{D} represents the balance between recombination driving disequilibrium to zero and selection generating new disequilibrium. Bounds on \hat{D} for general two-locus systems were given by Hastings (1981b, 1986). A nonzero value of \hat{D} requires epistasis in fitness (nonadditive

fitnesses *across loci*), and such a nonzero value has implications for the behavior of mean population fitness. To see this, first note that at equilibrium, the gamete frequencies remain unchanged ($\hat{x}'_i = \hat{x}_i$), and Equation 5.13a becomes

$$\hat{x}_i = [\hat{x}_i \hat{W}_{g_1} - c \hat{D} W_{g_1 g_4}] / \bar{W}, \quad \text{or} \quad \bar{W} = \hat{W}_{g_i} - c W_{g_1 g_4} \frac{\hat{D}}{\hat{x}_i}$$

Similarly, Equations 5.13b–5.13d yield

$$\bar{W} = \hat{W}_{g_i} + \eta_i c W_{g_1 g_4} \frac{\hat{D}}{\hat{x}_i}, \quad \text{where} \quad \eta_i = \begin{cases} -1 & \text{for } i = 1, 4 \\ 1 & \text{for } i = 2, 3 \end{cases} \quad (5.14)$$

If linkage is complete ($c = 0$), then all marginal fitnesses are equal at equilibrium and equilibrium mean fitness is at a local maximum. This second result follows because complete linkage causes the system to behave like a single locus with four alleles, meaning that Kingman's (1961a) result that equilibrium mean fitness is at a local maximum applies. However, when $c \neq 0$, then because in general $\hat{D} \neq 0$ (there is gametic-phase disequilibrium at the equilibrium gamete frequencies), the equilibrium gametic fitnesses are a function of the recombination frequency c . What is most interesting is that when $\hat{D} \neq 0$, the marginal gametic fitnesses W_{g_i} are *not* equal, and equilibrium mean fitness is not at a local maximum. Indeed, it can be shown that mean fitness often decreases as the equilibrium values are approached. Typically, this decrease is quite small, but it no longer holds that mean fitness always increases under constant-fitness viability selection (Kojima and Kelleher 1961).

Example 5.9. A simple example shows that mean fitness in a two-locus model can continuously decline toward an equilibrium value, as opposed to the continual increase to an equilibrium seen with one locus. Suppose the fitness of $AaBb$ is $1 + s$ (where $s > 0$), while all other genotypes have a fitness of 1. If we form a population by crossing $AABB$ and $aabb$ parents, then all F_1 individuals will be $AaBb$ and the mean population fitness is $1 + s$. In each subsequent generation, mean population fitness decreases as the frequency of $AaBb$ double heterozygotes will be reduced by recombination until equilibrium is reached (which takes several generations even if $c = 1/2$). For example, if $s = 0.1$, $\bar{W} = 1.1$ for the F_1 , while iteration of Equations 5.13a–5.13d shows $\bar{W} = 1.025$ at equilibrium (under loose linkage).

Results for Particular Fitness Models

There are a number of ways to parameterize the general two-biallelic-locus fitness model (Table 5.2). Under the assumption of no *cis/trans* effects, there are eight free parameters (one of the nine fitnesses can always be normalized to one). When fitnesses are additive *across loci* (i.e., no epistasis but the possibility of dominance at each locus), two-locus systems (or multi-locus systems for that matter) will be well behaved in that there is at most one polymorphic equilibrium for any given set of segregating alleles, at which \bar{W} is at a local maximum (Karlin and Liberman 1979). While D is zero at equilibrium in such cases, selection generates non-zero D during the sojourn to the equilibrium value for the gamete frequencies.

In contrast to this fairly simple equilibrium behavior under additive fitnesses, when epistasis in fitness exists, the behavior of gamete frequencies can be extremely complicated. For example, with sufficiently tight linkage and certain fitness values, there can be as many as nine polymorphic equilibria (many of which may be stable) for the symmetric viability model given in Table 5.2 (Hastings 1985). Hence, even with constant fitnesses, the final equilibrium state is potentially highly sensitive to initial conditions. Further, stable limit cycles can also exist, where equilibria are no longer point values (Akin 1979, 1982; Hastings

Table 5.2 Alternative parameterizations and specific models for viability selection on two loci.

			General Fitness		
		BB	Bb	bb	
AA		W_{AABB}	W_{AABb}	W_{AAbb}	
Aa		W_{AaBB}	W_{AaBb}	W_{Aabb}	
aa		W_{aaBB}	W_{aaBb}	W_{aabb}	

			Fitness Additive Between Loci		
		BB	Bb	bb	
AA		$1 - a - b$	$1 - a$	$1 - a - c$	
Aa		$1 - b$	1	$1 - c$	
aa		$1 - d - b$	$1 - d$	$1 - d - c$	

			Symmetric Viability		
		BB	Bb	bb	
AA		$1 - a$	$1 - b$	$1 - d$	
Aa		$1 - e$	1	$1 - e$	
aa		$1 - d$	$1 - b$	$1 - a$	

1981a), although point equilibria always exist if epistasis and/or selection are sufficiently weak (Nagylaki et al. 1999).

Example 5.10. The symmetric viability model (Table 5.2) arises in certain models of stabilizing selection on a character determined by additive loci. Suppose that two loci contribute in a completely additive fashion (e.g., no dominance or epistasis) to a character z under stabilizing selection, with $W(z) = 1 - s(z - 2)^2$, which implies an optimal phenotypic value of two. Fitness functions of this general form were first introduced by Wright (1935a, 1935b) with his **quadratic optimum model**. Assuming that each capital letter allele adds one to z (and that there is no environmental variance), the resulting phenotypic and fitness values are

Character value z			Fitness			
	AA	Aa	aa	AA	Aa	aa
BB	4	3	2	$1 - 4s$	$1 - s$	1
Bb	3	2	1	$1 - s$	1	$1 - s$
bb	2	1	0	1	$1 - s$	$1 - 4s$

Hence, while the trait has a completely additive genetic basis, the (nonlinear) mapping from phenotype to fitness introduces epistasis in fitness. This is an important point: simply showing that a *trait* under selection has an additive genetic basis is *not* sufficient to imply that *fitnesses* are also additive.

Phenotypic Stabilizing Selection and the Maintenance of Genetic Variation

We have seen that when the heterozygote is favored at a *single* locus, selection maintains both alleles (Example 5.4). However, Example 5.6 showed that when a number of loci underlie a trait with an additive genetic basis under stabilizing selection, underdominant selection occurs (encouraging the removal, rather than the maintenance, of genetic variation). All of this begs a simple question (with a very complex answer): under what conditions does stabilizing selection maintain genetic variation at a number of loci? This is one of many questions that follow from one of the most perplexing observations in quantitative genetics—the maintenance of high levels of genetic variation for most traits under apparent stabilizing selection. We consider this in earnest in Chapter 28, confining our remarks here

to the prospect that selection alone can maintain variation.

As detailed below in Example 5.11, even Wright's simple quadratic optimum model with additive gene action exhibits considerable complexity. Further, in the virtually certain event that the double heterozygote does not exactly correspond to the optimal phenotypic value, the fitness matrix immediately becomes asymmetric, leaving the general (and hence unsolved) two-locus model, with all of its potentially complex behavior. This is also true with epistasis in the trait under selection.

Where does all this modeling leave us? As we detail in Example 5.11, analysis of the highly symmetric Wright model (equal allelic effects, a quadratic fitness function, and a double heterozygote value equal to the optimal phenotypic value) shows that stabilizing selection on an additive trait cannot maintain variation. As we start to disrupt these symmetries (e.g., by allowing unequal allelic effects), we find conditions under which stabilizing selection can maintain variation at one or both loci. Indeed, superficially minor issues, such as subtle differences in fitness functions or noncorrespondence between the double heterozygote and optimal trait value, can result in qualitatively different behavior relative to the Wright model.

What happens when we move beyond two loci? Ironically, the situation may start to become simpler again. Bürger and Gimelfarb (1999) simulated stabilizing selection under the generalized Wright model and found, for randomly generated parameter sets (linkage, allelic effects, and strength of selection) that roughly 17% of two-locus systems maintained alleles at both loci at equilibrium. However, as they considered three-, four-, and five-locus systems, this probability (of two or more loci being polymorphic at equilibrium) fell dramatically, to < 0.5% in the five-locus models.

As one adds more loci (while keeping the range of phenotypic values constant), the effects of selection on any individual locus will be reduced and the behavior of many models will become much simpler. For example, Hastings and Hom (1989, 1990) showed that, under weak selection, the number of polymorphic loci that can be maintained by stabilizing selection is bounded above by the number of independent traits under selection. Thus, with sufficiently weak selection, stabilizing selection on k independent traits can maintain variation at no more than k loci, implying that if only one trait is under stabilizing selection under these conditions, *at most* only one underlying locus will be polymorphic. As Example 5.6 showed, it can easily be the case that *no* loci remain polymorphic (in the absence of new mutation). We examine these issues in more detail in Chapter 28.

In summary, analyses of strong-selection two-locus models instill caution about general statements of selection in multilocus systems. These concerns are quite valid when a major gene (or genes) accounts for most of the variation in the trait of interest. However, if selection tends to be weak relative to recombination (as might be expected in systems with a large number of loci with equal effects), the response under such genetic architectures may have a simpler and more predictable behavior. As reviewed in the next chapter, the assumption of weak selection on individual loci is the basis of several general statements about the behavior of fitness and trait evolution under weak selection (on the individual underlying loci), such as the breeder's equation. While any such general statements are not true in all settings (as the strong-selection two-locus results bear out), they may be largely true in many biological settings.

Example 5.11. We now consider the generalized two-locus version of Wright's quadratic optimum model, which provides significant insight into many of the issues concerning the maintenance of variation strictly by selection. This model has been examined by numerous authors (e.g., Wright 1935a, 1935b; Hastings 1987a; Gavrilets and Hastings 1993, 1994a; Bürger and Gimelfarb 1999), and we follow the excellent treatment of Bürger (2000, pp. 204–210). Willensdorfer and Bürger (2003) presented a similar analysis for Gaussian selection.

The generalized model makes four key assumptions. First, fitness is a quadratic function of the phenotypic value z , $W(z) = 1 - sz^2$, with an implicit optimum at $z = 0$. Second, the

genotypic value of the double heterozygote exactly corresponds with the phenotypic optimum. Third, there are no environmental effects. Fourth, the trait under stabilizing selection has a completely additive genetic basis (no dominance or epistasis). Thus $-a_1 : 0 : a_1$ are the genotypic values at the first locus (corresponding to $aa : Aa : AA$), while the values for the second locus are $-a_2 : 0 : a_2$ (corresponding to $bb : Bb : BB$).

While Wright's original analysis (and that of several other authors) assumed that allelic effects are identical ($a_1 = a_2$), the generalized version allows for $a_1 \geq a_2$. The resulting trait values become

	aa	Aa	AA
bb	$-(a_1 + a_2)$	$-a_2$	$a_1 - a_2$
Bb	$-a_1$	0	a_1
BB	$a_2 - a_1$	a_2	$a_1 + a_2$

Substituting these trait values into the quadratic fitness function shows that this model corresponds to the symmetric viability model given in Table 5.2, with

$$a = s(a_1 + a_2)^2, \quad b = sa_2^2, \quad d = s(a_1 - a_2)^2, \quad e = sa_1^2$$

Note that there is a relationship among these selection coefficients, $a + d = 2(b + e)$, which follows from the quadratic fitness function used.

Depending on parameter values, this model can have up to 11 equilibria, 7 of which are potentially stable (but not simultaneously so). There are always four trivial **corner equilibria** corresponding to each of the four gametes being fixed. The equilibria corresponding to either AB or ab being fixed are always unstable, but the other two corner equilibria, corresponding to Ab or aB being fixed, are potentially stable (as they yield more intermediate phenotypic values). There may also be two **edge equilibria**, corresponding to fixation at one locus and segregation at the other. For either of these edge equilibria to be admissible (the equilibrium x_i values lying on the simplex), a_1 must exceed $2a_2$ (given our ordering of $a_1 \geq a_2$), and hence the designation of **A** as the major locus. By definition, disequilibrium is zero at both the corner and edge equilibria.

Finally, there are three potential internal equilibria. The first is the so-called **symmetric equilibrium**, where both loci are segregating with all alleles at frequency 1/2, with gamete frequencies

$$\hat{x}_{AB} = \hat{x}_{ab} = \frac{1}{4} + \hat{D}_{AB} \quad \text{and} \quad \hat{x}_{Ab} = \hat{x}_{aB} = \frac{1}{4} - \hat{D}_{AB}$$

where $\hat{D}_{AB} < 0$, i.e., the AB and ab gametes are underrepresented (see Bürger 2000 for the value of \hat{D}_{AB}). This implies hidden genetic variation, with the additive variance for this trait increasing in the event of cessation of selection and the subsequent restoration of linkage equilibrium by recombination. (Chapter 16). While there is additive variance in the *trait* under selection at the equilibrium mean, as we will see in the next chapter (Example 6.6), there is no additive variance in *fitness* at equilibrium. Although the symmetric internal equilibrium seems straightforward, there can also be two other stable interior equilibria, the so-called **unsymmetric equilibria**. The expressions for these are complex (see Bürger 2000, p. 205), and their existence requires that the recombination fraction lie in a narrow range (see Figure 5.4).

For this model there are four mutually exclusive regions of the parameter space that correspond to different stable equilibria (Figure 5.4). In region 0, only the two corner equilibria (with either Ab or aB fixed) are stable. Note that if the two loci have equal effects ($a_2/a_1 = 1$, as Wright originally assumed), these are the only stable equilibria, and stabilizing selection leads to the removal of variation from both loci. In Region 1, the two edge equilibria (with the major locus being polymorphic and **B** fixed for either bb or BB), are the only stable equilibria. Note that this requires both rather uneven effects ($a_1 \geq 2a_2$) and recombination sufficiently large relative to selection. Finally, there are two regions where the internal equilibrium is stable. The very narrow Region 2b corresponds to the two stable unsymmetric internal equilibria, which requires a very specific relationship between selection and recombination. Region 2a corresponds to uneven allelic effects and recombination that is weak relative to selection, where a symmetric equilibrium exists.

Thus, provided allelic effects are uneven and selection is strong relative to recombination, selection can maintain both alleles at both loci (Kearsey 1968; Kearsey and Gale 1968; Nagylaki 1989a; Gavrilets and Hastings 1993, 1994a, 1994b). Gavrilets and Hastings showed

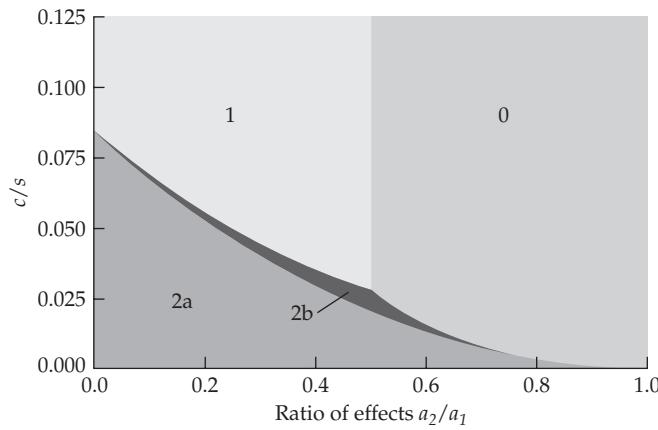

Figure 5.4 Different regions of equilibrium behavior under the generalized quadratic optimal model (Example 5.11). Here s is the strength of phenotypic selection, c is the recombination rate between loci, and a_1 and a_2 are the additive effects for alleles at the two loci (with $a_1 \geq a_2$). Region 0 corresponds to corner equilibria (Figure 5.3), where the population is fixed for a single gamete. Region 1 corresponds to edge equilibria, where the major locus is segregating and the minor locus is fixed. Region 2 corresponds to conditions where selection maintains polymorphisms at both loci (an internal equilibria). In region 2b, this equilibrium is unsymmetric (allele frequencies are unequal), while it is symmetric (all alleles have frequency 1/2) in region 2a. Wright's classic (1935a, 1935b) analysis, which assumes $a_2/a_1 = 1$, places the system in region 0, with the system fixed for a single gamete type (which varies depending on starting conditions). (After Bürger and Gimelfarb 1999.)

that, with strong selection, the mean trait value at equilibrium does not necessarily coincide with the optimum fitness value, so in general $\hat{\mu}_z \neq 0$. Hence, at equilibrium, there can be the appearance of apparent directional selection.

The final subtlety is that very different results can arise from a simple change in the fitness function, for example from a quadratic to a Gaussian (Gimelfarb 1996b). Under a quadratic fitness function, $a + d = 2(b + e)$, which reduces what is normally a cubic equation for the equilibrium value of D to a quadratic equation (Gimelfarb 1996b). Under a Gaussian, this relationship no longer holds and the resulting equilibrium structure is potentially more complex. Indeed, Gimelfarb (1996b) showed that under sufficiently strong Gaussian selection, very unusual behavior can occur, such as the appearance of two internal symmetric equilibria with D values of opposite sign.

SELECTION ON A QUANTITATIVE TRAIT LOCUS

While population genetics is concerned with how the frequencies of specific *genotypes* change under selection, quantitative genetics is concerned with the evolution of composite features of these underlying genetic changes, i.e., the change in the mean or additive genetic variance of a *trait* under selection. Population-genetic models assume that we know the genotype-specific fitnesses and use these to generate expressions for the change in allele (one locus) or gamete (multiple-locus) frequencies. In contrast, quantitative genetics assumes fitness to be a function, $W(z)$, of the phenotypic value z of the focal trait. The connection between these two approaches starts by considering how selection on a particular trait maps into the average excess s_i in fitness for an allele at a locus underlying this trait.

Monogenic Traits

The simplest situation arise when a single locus (with alleles A_1, \dots, A_n) entirely determines the genetic variation in the trait of interest, with $p_{ij}(z)$ denoting the distribution of character values for an individual of genotype A_iA_j . The genotypic fitness is the average of $W(z)$ over the distribution of phenotypes for this genotype,

$$W_{ij} = \int W(z) p_{ij}(z) dz \quad (5.15a)$$

In many situations, we expect environmental values to be (roughly) normally distributed about the mean genotypic value, so that $p_{ij}(z) \sim N(\mu_{ij}, \sigma_{ij}^2)$, where μ_{ij} and σ_{ij}^2 are the phenotypic mean and variance for genotype A_iA_j . If the mean and variance are known for each genotype, and no other loci influence variation in z , then the W_{ij} are constant from one generation to the next (assuming no frequency-dependent selection or changes in the environment), and the values from Equation 5.15a can be substituted into Equation 5.1b or Equation 5.7c to directly compute the change in allele frequencies.

Likewise, if $p_i(z)$ denotes the phenotypic distribution for individuals carrying an A_i allele, the average fitness of individuals carrying an A_i allele is

$$W_i = \int W(z) p_i(z) dz \quad (5.15b)$$

Again, this can be directly substituted into Equation 5.7c to compute Δp_i . Note, however, that while $p_{ij}(z)$ can be independent of allele frequency, this is not the case for $p_i(z)$.

Many Loci of Small Effect Underlying the Character

When two or more loci underlie the character of interest, Equations 5.15a and 5.15b become problematic because the conditional densities $p_{ij}(z)$ and $p_i(z)$ are likely to change in each generation as selection changes the genotype frequencies at other loci. Ideally, we would like to have an approximation that uses only the unconditional phenotypic distribution $p(z)$ and some simple property of the locus being considered. Fortunately, in many situations, the average excess α_i of the trait (LW Chapter 4) provides such a connection for loci of small effect. It will prove slightly easier to work with relative fitnesses, so we will use $w(z) = W(z)/\bar{W}$, the expected relative fitness of an individual with phenotypic value z , throughout.

Following Bulmer (1971a) and Kimura and Crow (1978), assume that the average excess is small relative to the variance of z , as would occur if many loci of roughly equal effect underlie the character or if there are large environmental effects. Because having a copy of A_i increments the phenotype on average by α_i , as is shown in Figure 5.5, the conditional phenotypic distribution is, to a good approximation, the unconditional phenotypic distribution shifted by α_i , which can be written as

$$p_i(z) \simeq p(z - \alpha_i) \quad (5.16a)$$

Nagylaki (1984) showed that this approximation is correct only to linear order, e.g., to terms of order α_i (a point that we return to below). Alternatively, we could also consider the distribution given the *genotype* at this locus (rather than a specific *allele*), in which case

$$p_{ij}(z) \simeq p(z - a_{ij}) \quad (5.16b)$$

applies, where a_{ij} is the average deviation from the overall trait mean for an individual of genotype A_iA_j (again, this is correct only to linear order).

The approximation given by Equation 5.16a motivates two alternative expressions for the relative fitness, w_i . First, we have, directly that

$$w_i = \int w(z) p_i(z) dz \simeq \int w(z) p(z - \alpha_i) dz \quad (5.17a)$$

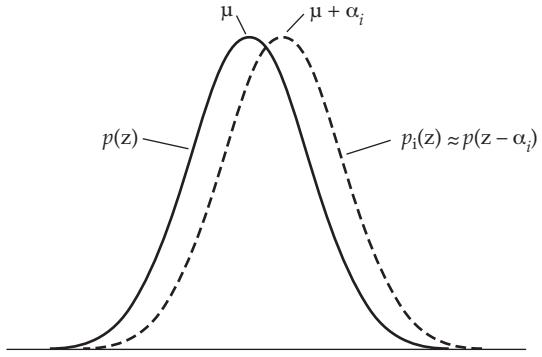

Figure 5.5 The unconditional phenotypic distribution $p(z)$ has a mean of μ , while the conditional phenotypic distribution $p_i(z)$ for an individual carrying a copy of allele A_i has a mean of $\mu + \alpha_i$, the mean plus the average excess for allele A_i . If α_i is small, then (to order α_i) we can approximate $p_i(z)$ by $p(z - \alpha_i)$, which shifts the phenotypic distribution to the right (for $\alpha_i > 0$) by α_i . This is only approximate, as knowing which allele is present at one locus decreases the genetic variance and results in the conditional phenotypic distribution having a (slightly) smaller variance.

(Bulmer 1971a; Kimura and Crow 1978). Alternatively, following Kimura and Crow (1978), a change of variables results in

$$w_i \simeq \int w(z + \alpha_i) p(z) dz \quad (5.17b)$$

For certain phenotypic distributions and fitness functions, these integrals can be evaluated exactly (Latter 1965a; Lynch 1984). However, even in these cases, the resulting w_i values are still only approximations because Equation 5.16a itself is only approximate. When the integral cannot be evaluated, a Taylor series expansion provides a useful approximation, often without having to completely specify the phenotypic distribution and/or fitness function. If the average excess α_i for the trait value is small,

$$p(z - \alpha_i) \simeq p(z) - \alpha_i \frac{dp(z)}{dz} \quad (5.18a)$$

$$w(z + \alpha_i) \simeq w(z) + \alpha_i \frac{dw(z)}{dz} \quad (5.18b)$$

Substituting into Equations 5.17a and 5.17b and recalling that $\int w(z) p(z) dz = 1$ yields the average excess in relative fitness (Equation 5.8b) as

$$s_i = w_i - 1 \simeq -\alpha_i \int w(z) \frac{dp(z)}{dz} dz \quad (5.19a)$$

and

$$s_i = w_i - 1 \simeq \alpha_i \int p(z) \frac{dw(z)}{dz} dz \quad (5.19b)$$

Equation 5.19a is applicable if the phenotypes are distributed continuously. For meristic (i.e., discrete) traits, Equation 5.19b applies provided $w(z)$ is differentiable (the integral is replaced by a weighted sum over the discrete trait values). Note that Equations 5.19a and 5.19b connect population genetics (the average excess s_i in fitness) with quantitative genetics ($w(z)$ and the average excess α_i in the trait value).

The integrals in Equations 5.19a and 5.19b represent the change in fitness associated with linear deviations of a character value from its mean (i.e., directional selection). To see

this, consider the case in which phenotypic values are normally distributed, with a mean of μ and a variance of σ_z^2 at the population level,

$$p(z) = (2\pi\sigma^2)^{-1/2} \exp\left(\frac{-(z-\mu)^2}{2\sigma^2}\right) \quad (5.20a)$$

which upon differentiation results in

$$\frac{dp(z)}{dz} = -\left(\frac{z-\mu}{\sigma_z^2}\right)p(z) \quad (5.20b)$$

Substituting into Equation 5.19a yields

$$\begin{aligned} s_i &\simeq \frac{\alpha_i}{\sigma_z^2} \int w(z) \cdot (z - \mu) p(z) dz \\ &= \frac{\alpha_i}{\sigma_z^2} \left(\int z w(z) p(z) dz - \mu \int w(z) p(z) dz \right) = \frac{\alpha_i}{\sigma_z^2} (\mu^* - \mu) \end{aligned} \quad (5.20c)$$

The first integral is the mean μ^* after selection because $w(z)p(z)$ is the density of z following selection, while the second integral is one because $\bar{w} = 1$. Noting that the directional selection differential (the within-generation change in the mean from selection; Chapter 13) is $S = \mu^* - \mu$, we have

$$s_i \simeq \alpha_i \left(\frac{S}{\sigma_z^2} \right) = \bar{i} \left(\frac{\alpha_i}{\sigma_z} \right) \quad (5.21)$$

where $\bar{i} = S/\sigma_z$ is the standardized selection differential (or selection intensity; Chapter 13). Hence, to first order, the selection on an individual allele of small effect is approximately equal to its standardized average excess in the trait value (α_i/σ_z) multiplied by the selection intensity on the trait. As noted by Kimura and Crow (1978) and Milkman (1978), this approximation (Equation 5.21) is a well-known result for certain fitness functions, e.g., truncation selection (Haldane 1930; Griffing 1960a), and is a good approximation for arbitrary fitness functions when z is normally distributed.

One consequence of the first-order expression in s_i corresponding to the effects of directional selection is that for strictly stabilizing selection (i.e., no directional selection component), the first-order terms are zero, and we must consider second-order terms in order to have a proper approximation for s_i (to account for the fact that conditioning on the allelic state slightly reduces the variance). We will return to this point shortly.

A Population-genetic Derivation of the Breeder's Equation

The classic expression for the expected response R (the change in mean) of a single trait to selection is the **breeder's equation**, $R = h^2 S$ (Chapter 13). This expression is typically derived by assuming a linear midparent-offspring regression with slope h^2 , although a few additional, and subtle, assumptions are required (Chapter 6). Here we show how the breeder's equation is obtained as an approximation of a population-genetic model of the response. As developed in Example 5.12 (below), the expected response, R_k , from a single locus k can be expressed in terms of the average effects, $\alpha_{k,i}$, on the trait and the average excesses on relative fitness, $s_{k,i}$, for all alleles at locus k , and the dominance deviations $\delta_{k,ij}$ for all pairs of alleles, with

$$R_k = 2 \sum_i \alpha_{k,i} s_{k,i} p_{k,i} + \sum_{i,j} \delta_{k,ij} p_{k,i} s_{k,i} p_{k,j} s_{k,j} \quad (5.22)$$

where the sums are taken over all n_k alleles at the focal locus k . Recalling Equation 5.19, we can write $s_i \simeq \alpha_i I$, with I being the appropriate integral, which results in

$$R_k = I \sum_i 2 \alpha_{k,i}^2 p_{k,i} + I^2 \sum_{i,j} \delta_{k,ij} \alpha_{k,i} \alpha_{k,j} p_{k,i} p_{k,j} \quad (5.23a)$$

Assuming no epistasis, the total response, R , is simply the sum of all n single-locus responses,

$$R = \sum_{k=1}^n R_k = I \sum_{k=1}^n \sum_i^{n_k} 2 \alpha_{k,i}^2 p_{k,i} + I^2 \sum_{k=1}^n \sum_{i,j}^{n_k} \delta_{k,ij} \alpha_{k,i} \alpha_{k,j} p_{k,i} p_{k,j} \quad (5.23b)$$

This expression also holds when linkage disequilibrium is present, although the average excesses, average effects, and dominance deviations are expected to be different from their linkage-equilibrium values. For a random-mating population under linkage equilibrium, the first double sum is simply the additive genetic variance of this trait (LW Equation 4.23a). Assuming no epistasis and no linkage disequilibrium, summing over all loci yields a response of

$$R \simeq I \sigma_A^2 + I^2 \sum_{k=1}^n \sum_{i,j}^{n_k} \delta_{k,ij} \alpha_{k,i} \alpha_{k,j} p_{k,i} p_{k,j} \quad (5.23c)$$

As shown in Equation 5.21, if phenotypic values are normally distributed before selection, $I = S/\sigma_z^2$, and the response becomes

$$R = h^2 S + \frac{S^2}{\sigma_z^4} \sum_{k=1}^n \sum_{i,j}^{n_k} \delta_{k,ij} \alpha_{k,i} \alpha_{k,j} p_{k,i} p_{k,j} \quad (5.23d)$$

which recovers the breeder's equation, $R = h^2 S$ (response equals heritability times selection differential), plus a correction term. Still assuming there is no epistasis, in the absence of dominance (all $\delta_{k,ij} = 0$), the second term is zero. Even with dominance, the second term is of lower order than the first, and it vanishes as the number of underlying loci becomes large (Example 5.12). One way to view the correction term is to recall that when dominance is present, the parent-offspring regression is slightly nonlinear (LW Chapter 17), while the breeder's equation assumes linearity (among other things; see Chapter 6).

While the preceding derivation assumed normally distributed phenotypes, *exact* normality requires that the genotypic values at *each* locus be normally distributed (Nagylaki 1984). Because there are only a finite number of alleles, and hence a discrete number of genotypic values, this never holds exactly (see Chapter 24), but if the number of loci is large, the central limit theorem implies that the genotypic distribution is approximately normal. This points out one of the central assumptions of many quantitative-genetic selection models: *the number of loci is assumed to be sufficiently large that the amount of phenotypic variation attributable to any single locus is small, and hence the amount of selection on any locus is also small.* At its limit, we have the **infinitesimal model** (Chapter 24): an effectively infinite number of loci, each contributing an infinitesimal amount to the total phenotype. As the number of loci approaches infinity, the second sum in Equation 5.23d becomes vanishingly small (Example 5.12), and we recover the breeder's equation even when dominance is present.

Another class of models (Kimura 1965a; Lande 1975) allows for $n \geq 1$ loci by assuming there is a normal distribution of allelic effects at each locus underlying the character (effectively assuming an infinite number of alleles per locus). These two models (infinite number of loci versus infinite number of alleles at n loci) represent extreme approximations to the view that a moderate number of loci, each with a moderate number of alleles, underlie many quantitative characters. Chapter 24 explores these and other models in greater detail.

Example 5.12. Here we derive Equation 5.22, the expected response to selection associated with a single locus. Again, for ease of presentation, we suppress the subscripting indicating this locus. Assuming random mating, Equation 5.8b gives the single-generation allele-frequency dynamics as $p'_i = p_i(1 + s_i)$, where s_i is the average excess in relative fitness for allele A_i . To map these changes in allele frequencies into changes in mean genotypic values, we decompose

the genotypic value of $A_i A_j$ as $G_{ij} = \alpha_i + \alpha_j + \delta_{ij}$, where α_i is the average effect of A_i on the character value, δ_{ij} is the dominance deviation (LW Chapter 4), and the trait is scaled to initially have a mean of zero, with $E[G_{ij}] = E[\alpha_i] = E[\delta_{ij}] = 0$.

The contribution of this locus to the change in mean phenotype after a generation of selection and random mating is

$$\begin{aligned} R_k &\simeq \sum_{i,j} G_{ij} p_i' p_j' - \sum_{i,j} G_{ij} p_i p_j = \sum_{i,j} G_{ij} p_i(1+s_i) p_j(1+s_j) - \sum_{i,j} G_{ij} p_i p_j \\ &= \sum_{i,j} G_{ij} p_i p_j (1+s_i+s_j+s_i s_j - 1) \\ &= \sum_{i,j} (\alpha_i + \alpha_j + \delta_{ij}) p_i p_j (s_i + s_j) + \sum_{i,j} (\alpha_i + \alpha_j + \delta_{ij}) p_i p_j s_i s_j \end{aligned} \quad (5.24a)$$

The $\sum G_{ij} p_i p_j$ term is the mean contribution before selection, which is zero, and hence vanishes. The careful reader will note that we made an approximation by using the decomposition of G_{ij} instead of decomposition of G'_{ij} in the very first sum, as we used the approximation

$$G'_{ij} \simeq \alpha_i + \alpha_j + \delta_{ij}$$

for

$$G'_{ij} = \alpha'_i + \alpha'_j + \delta'_{ij}$$

Because α_i and δ_{ij} are functions of the allele frequencies, they change as p_i changes, but we have assumed that these deviations are much smaller than the change in p_i itself (so that $\alpha'_i \simeq \alpha_i$ and $\delta'_{ij} \simeq \delta_{ij}$). To simplify Equation 5.24a further, recall (LW Chapter 4) that the additive and dominance effects are defined such that

$$\sum_i \alpha_i p_i = 0 \quad \text{and} \quad \sum_i \delta_{ij} p_i = 0 \quad (5.24b)$$

Separating the first term of Equation 5.24a into two parts based on s_i and s_j and applying Equation 5.24b yields

$$\begin{aligned} &\sum_{i,j} (\alpha_i + \alpha_j + \delta_{ij}) p_i p_j s_i + \sum_{i,j} (\alpha_i + \alpha_j + \delta_{ij}) p_i p_j s_j \\ &= 2 \sum_j s_j p_j \left(\alpha_j \sum_i p_i + \sum_i (\alpha_i + \delta_{ij}) p_i \right) \\ &= 2 \sum_j s_j p_j (\alpha_j \cdot 1 + 0 + 0) = 2 \sum_j \alpha_j s_j p_j \end{aligned}$$

Likewise, a little more algebra (Nagylaki 1989b, 1991) simplifies the second sum in Equation 5.24a to yield a final expression for the expected contribution to response from locus k as

$$R_k = 2 \sum_j \alpha_j s_j p_j + \sum_{i,j} \delta_{ij} p_i s_i p_j s_j \quad (5.24c)$$

recovering Equation 5.22.

Note, however, that while the first term of Equation 5.24c recovers the breeder's equation, the second term

$$B_k = \sum_{i,j} \delta_{ij} p_i s_i p_j s_j$$

is a measure of departure from the breeder's equation at the focal locus (k). Nagylaki (1991) showed that the total departure over all loci $B = \sum_k B_k$ is bounded by

$$|B| \leq \left(\sum_{k=1}^n \sigma_{D(k)}(z) \right) \cdot \frac{\sigma_A^2(w)}{2}$$

where $\sigma_{D(k)}(z)$ is the square root of the dominance genetic variance in the character contributed by locus k , and $\sigma_A^2(w)$ is the additive variance in relative fitness. If all n loci underlying the character are identical (the **exchangeable model**), this bound reduces to

$$|B| \leq \frac{\sigma_D(z) \cdot \sigma_A^2(w)}{2\sqrt{n}}$$

where $\sigma_D^2(z) = n\sigma_{D(k)}^2(z)$ is the total dominance genetic variance for the trait. Hence, assuming there is no epistatic genetic variance, even if dominance is present, as the number of loci increases, any departure from the breeder's equation will become increasingly small.

Correct Quadratic Terms for s_i

As mentioned earlier, the approximations given by Equations 5.16a and 5.16b are correct only to linear order, whereas quadratic (second-order) terms are required to properly account for selection acting directly on the trait variance. One source of error is that the conditional distribution of phenotypes for individuals carrying a particular allele has a lower variance than the unconditional phenotypic distribution. Partial knowledge of the genotype reduces the uncertainty in genotypic value, with the phenotypic variance of individuals with a fixed genotype at the k th locus being $\sigma^2 - \sigma_k^2$, where σ_k^2 is the contribution of the k th locus to the total phenotypic variance (Bulmer 1971a; Lynch 1984; Nagylaki 1984; Walsh 1990). In the absence of epistasis, gametic-phase disequilibrium, and genotype-environment interaction/correlation,

$$\sigma_k^2 = \sum_{i,j}^{n_k} a_{ij}^2 p_i p_j$$

where $a_{ij} = G_{ij} - \mu_G$ is the deviation of the genotypic value from the genotypic mean and n_k is the number of alleles at locus k (Nagylaki 1984; Walsh 1990).

Using an expansion that accounts for this reduction in variance, Hastings (1990a) showed that s_i is approximated to quadratic order by

$$s_i \simeq -I_1 \alpha_i + \frac{I_2}{2} \left[\sum_j a_{ij}^2 p_j - \sigma_k^2 \right] \quad (5.25a)$$

where

$$I_1 = \int w(z) \frac{dp(z)}{dz} dz \quad \text{and} \quad I_2 = \int w(z) \frac{d^2p(z)}{dz^2} dz \quad (5.25b)$$

Note that I_1 is simply the integral in Equation 5.19a and measures the effects of selection on the mean. For a normally distributed trait, substituting Equation 5.20b into the expression for I_1 yields

$$I_1 = \int w(z) \frac{dp(z)}{dz} dz = - \int w(z) \left(\frac{z - \mu}{\sigma_z^2} \right) p(z) dz = -\frac{\mu^* - \mu}{\sigma_z^2} = -S/\sigma_z^2 \quad (5.25c)$$

Hastings (1992) showed how this approach extends to a locus influencing n characters under selection.

The I_2 term measures the effect of selection on the variance. To see this, again suppose that the phenotypes are normally distributed. Differentiating Equation 5.20b a second time yields

$$\frac{d^2p(z)}{dz^2} = -\frac{p(z)}{\sigma_z^2} + \frac{(z - \mu)^2}{\sigma_z^4} p(z) \quad (5.26a)$$

and a bit of algebra (Example 5.13) yields

$$I_2 = \frac{\delta(\sigma_z^2) + S^2}{\sigma_z^4} \quad (5.26b)$$

where $\delta(\sigma_z^2)$ is the within-generation change in phenotypic variance due to selection (Chapters 16 and 24). While we use δ for both dominance and within-generation change, the distinction between δ_{ij} (the dominance associated with ij), and $\delta(\sigma_z^2)$, the within-generation change in σ_z^2 , should be obvious from context. The reason for using $\delta(\sigma_z^2)$ is that it will be important in subsequent chapters to distinguish between a within-generation change $\delta(\sigma_z^2)$ and a between-generation change $\Delta(\sigma_z^2)$.

If phenotypes are normally distributed, $-I_1 = S/\sigma_z^2$ (Equation 5.25c), yielding

$$s_i \simeq \alpha_i \frac{S}{\sigma_z^2} + \frac{\delta(\sigma_z^2) + S^2}{2\sigma_z^4} \left[\sum_j a_{ij}^2 p_j - \sigma_k^2 \right] \quad (5.27a)$$

When alleles are completely additive, $a_{ij} = \alpha_i + \alpha_j$ and the term in brackets reduces to $\alpha_i^2 - \sum_j \alpha_j^2 p_j$. Substituting this improved value of s_i into Equation 5.22 and summing over all loci gives the response to selection (under a completely additive model) as

$$R = h^2 S + \frac{\delta(\sigma_z^2) + S^2}{2\sigma_z^4} \sum_{k=1}^n \sum_i^{n_k} (\alpha_{k,i})^3 p_{k,i} \quad (5.27b)$$

where the subscript k on the α_i and p_i terms reminds the reader that these can vary over loci.

As shown by Equation 29.16a, selection acting on the mean still results in a change in the variance, with $\delta(\sigma_z^2) = -S^2$. In this case, the second term of Equation 5.27b is zero and we recover the breeder's equation. More generally, however, if selection is also acting directly on the trait variance (such as, but not limited to, stabilizing or disruptive selection), $\delta(\sigma_z^2)$ departs from $-S^2$ (Chapter 29). Because the double sum in Equation 5.27b is the skewness in the genotypic distribution, if skew is present, changes due to selection on the variance also change the mean (Figure 29.7). Equation 5.27b raises several issues that will be examined in detail in Chapter 24. In particular, even if the distribution of *phenotypes* is normal, the response still depends on rather fine details (such as the third moment of allelic effects *at each locus*) of the distribution of *genotypic* values.

Example 5.13. To obtain Equation 5.26b, we first substitute Equation 5.26a into Equation 5.25b

$$I_2 = \int w(z) \left(-\frac{p(z)}{\sigma_z^2} + \frac{(z - \mu)^2}{\sigma_z^4} p(z) \right) dz \quad (5.28a)$$

Next, we use a standard trick by noting that

$$\begin{aligned} (z - \mu)^2 &= [(z - \mu^*) + (\mu^* - \mu)]^2 \\ &= (z - \mu^*)^2 + 2(z - \mu^*)(\mu^* - \mu) + (\mu^* - \mu)^2 \end{aligned} \quad (5.28b)$$

with Equation 5.28a becoming

$$\begin{aligned} I_2 &= \frac{1}{\sigma_z^4} \left(-\sigma_z^2 \int w(z)p(z)dz + \int (z - \mu^*)^2 w(z)p(z)dz \right. \\ &\quad \left. + 2(\mu^* - \mu) \int (z - \mu^*)w(z)p(z)dz + (\mu^* - \mu)^2 \int w(z)p(z)dz \right) \end{aligned} \quad (5.28c)$$

Noting that $\int w(z)p(z) = \bar{w} = 1$ and that $\int f(z)w(z)p(z) = E_s[f(z)]$, namely, the expected value of $f(z)$ in the selected individuals (as $w(z)p(z)$ is the distribution of z following selection), Equation 5.28c reduces to

$$\begin{aligned} I_2 &= \frac{1}{\sigma_z^4} \left(-\sigma_z^2 + E_s[(z - \mu^*)^2] + 2(\mu^* - \mu)E_s(z - \mu^*) + (\mu^* - \mu)^2 \right) \\ &= \frac{1}{\sigma_z^4} \left(-\sigma_z^2 + \sigma_{z^*}^2 + 0 + S^2 \right) \end{aligned}$$

Here $\sigma_{z^*}^2$ denotes the variance after selection, so that $-\sigma_z^2 + \sigma_{z^*}^2 = \delta(\sigma_z^2)$, and we recover Equation 5.26b.

6

Theorems of Natural Selection: Results of Price, Fisher, and Robertson

Is there some reorientation for the expression of natural selection that may provide subtle perspective, from which we can understand our subject more deeply and analyze our problems with greater ease and greater insight? My answer is . . . that the Price equation provides that sort of reorientation. Frank (2012, p. 1003)

One of the messages from Chapter 5 is that selection, even on just one or two loci, can have very complex dynamics. Indeed, outside of the special case of frequency-independent viability selection at a single locus, selection is not even guaranteed to increase mean fitness. Nonetheless, the search for general theorems (exact mathematical expressions) of selection response has motivated population and quantitative geneticists for over 80 years. By shifting attention away from trying to model individual allele-frequency change over a large number of loci to considering the dynamics of some composite feature of these loci, such as the mean of a trait, the hope was that some general statements might hold. Here we focus on three classical “theorems”—**Fisher’s fundamental theorem of natural selection**, **Robertson’s secondary theorem of natural selection**, and **Price’s theorem**—as well as **Lush’s breeder’s equation**, summarized in Table 6.1. Ironically, these attempts to bring some order to population- and quantitative-genetic theory have instead resulted in a considerable amount of confusion and chaos in the literature.

As detailed below, the classical interpretation of Fisher’s theorem, along with Robertson’s theorem and the breeder’s equation, are all approximations (albeit often good ones), and not formal mathematical theorems. In contrast, Price’s general expression for *any* type of selection response *is* a formal theorem, as is a special case of it, the **Robertson-Price identity** for the within-generation response in a trait due to selection. A source of confusion is that the classical view assumed by most of the literature was apparently different from Fisher’s own interpretation, which *is* a formal (but not very useful) theorem. As our discussion of these various “theorems,” exact and otherwise, will highlight, it is the transmission of trait values from parent to offspring that generally induces complications and makes the theoretician’s job challenging. This can be seen in Table 6.1 by simply comparing the exact Robertson-Price result for within-generation change (S) with results for cross-generational change ($S + E[w\delta_z]$). The surprising result is not that these “theorems” are wrong, but rather that they often are reasonable-to-excellent approximations for much of the dynamics of a trait under short-term selection.

Our treatment of this rather convoluted area is structured as follows. We start with Price’s theorem, which is a *completely general* description of *any* selection response under *any* model of transmission. It does not rely on any explicit genetic model and thus serves as an ideal platform from which to examine the other “theorems.” We next turn to Fisher’s fundamental theorem, which has a rich and somewhat checkered history, in part due to Fisher’s failure to be fully explicit with his definitions. An important corollary of Fisher’s theorem is that, in the absence of mutation, selection will drive the additive variance in fitness toward zero, and we next examine some of the biological implications and misunderstandings of this result. We then turn to Robertson’s secondary theorem, which focuses on the selection response of any arbitrary trait, not just fitness. Finally, because the breeder’s equation is the basic workhorse result for much of selection theory in quantitative genetics (Chapters 13–20), we conclude by examining its robustness in some detail.

Table 6.1 General expressions for the response of a trait to selection, with fitness as an important special case. Here w denotes relative fitness (with mean value $E[w] = 1$); z , the value of an arbitrary trait; A_z , the breeding value of trait z (with A_w as the breeding value for relative fitness); R_z , the total response to selection (change in the mean across generations) of trait z (with R_w for the special case where the trait is mean fitness); ∂R_w , the partial response in mean fitness due exclusively to allele-frequency change (see the text for details); S_z , the within-generation change in z following selection but prior to gene transmission (the selection differential); and $\bar{\delta}_z$, the expected change between the mean value of a trait in selected parents and their progeny (also see text for details). Expressions denoted by † are true mathematical theorems, whereas the rest are approximations.

Fisher's Fundamental Theorem		Fisher (1930)
Classical interpretation	$R_w = \sigma^2(A_w)$	
Exact version†	$\partial R_w = \sigma^2(A_w)$	Price (1972b), Ewens (1989)
Breeder's Equation	$R_z = h_z^2 S_z$	Lush (1937)
Robertson-Price Identity†	$S_z = \sigma(w, z)$	Robertson (1966a), Price (1970)
Robertson's Secondary Theorem		
1966 version	$R_z = \sigma(w, A_z)$	Robertson (1966a)
1968 version	$R_z = \sigma(A_w, A_z)$ $= \sigma_A(w, z)$	Robertson (1968)
Price's Theorem†	$R_z = \sigma(w, z) + E(w \bar{\delta}_z)$ $= S + E(w \bar{\delta}_z)$	Price (1970)

PRICE'S GENERAL THEOREM OF SELECTION

The thoughtful reader might ask if there is a general, assumption-free statement about selection response under *any* situation. There is: namely, **Price's theorem** (Price 1970, 1972a), also referred to as the **Price equation**. Price's theorem provides a notationally elegant way to describe *any* evolutionary response. It makes *no assumptions* about the mechanism of transmission of a trait from some ancestral category (such as an individual or group) to its descendants. As such, it works for traits transmitted by standard genetics, epigenetics, and culture, and as such has been applied to everything from the evolution of languages to community structure in ecology. Recent reviews include Frank (1995, 1997, 1998, 2012), Rice (2004a), Boyd and Richerson (2005), Okasha (2006), Gardner (2008), Helanterä and Uller (2010), and Luque (2017), while van Veelen (2005; van Veelen et al. 2012) championed a more cautious use of Price's theorem.

The Life and Times of George Price

George Price was one of the most enigmatic figures in modern evolutionary biology (Frank 1995, Schwartz 2000, and Harman 2011 all reviewed Price's life and contributions). After obtaining a Ph.D. in chemistry from the University of Chicago, he worked on the Manhattan Project before joining IBM as an engineer. At age 44, Price quit his job and started working under Cedric Smith at University College London (from 1968 to 1974). In this brief tenure, he only published four solo papers and was the coauthor on two others, but in his roughly 25 total pages of publications, he made three fundamental contributions to modern evolutionary theory. In addition to Price's theorem, he introduced the power of game theory to evolutionary biology (Maynard Smith and Price 1973), and he was the first to fully grasp what Fisher had really meant by his enigmatic fundamental theorem (Price 1972b). Price left academia in 1974, working as a night janitor before giving away all his worldly possessions to homeless alcoholics and dying by his own hand in 1975 while a squatter in one of the poorest areas of London.

Price's Theorem, $R_z = \sigma(w_i z_i) + E(w_i \bar{\delta}_i)$

Price's theorem expresses the expected selection response in a trait in general terms of covariances, rather than relying on any explicit model of transmission, and as such is a *completely general description of any evolutionary response*. As succinctly stated by Rice (2004a, p. 170), “it is an exact characterization of a relationship that must hold between phenotype, fitness, selection, and evolution.” The key to Price’s equation is to first consider the effect of selection on *specific categories* (measured by how many descendants each leaves) and then consider how trait values may differ between an ancestral category and its descendants. This is an extremely subtle shift in focus, one that is easy to miss and misinterpret. However, this perspective nicely decomposes the evolutionary change (R_z) into a selection term and a remainder term due to all other forces, such as (but not limited to) imperfect transmission.

Consider selection first. Suppose there are N categories in the population, where q_i and z_i , respectively, denote the frequency of category i and the mean value for the trait of interest over all members of this category. Note that z can be *any* trait measure. For example, if x denotes the value of a trait, taking $z = (x - \mu_x)^2$ or $z = (x - \mu_x)^4$ gives the response in the variance and the fourth moment, respectively. Averaging over all categories, the mean trait value is

$$\bar{z} = \sum_{i=1}^N q_i z_i \quad (6.1)$$

Suppose that the members of category i leave a total of n_i descendants (the absolute fitness, W_i , for that category). The average number of descendants over categories (the mean fitness) is

$$\bar{W} = \sum_{i=1}^N q_i W_i \quad (6.2a)$$

The relative fitness of category i is $w_i = W_i/\bar{W}$.

Price’s key idea was to define q'_i as the frequency of all *descendants* that have category i as their *ancestor*

$$q'_i = w_i q_i \quad (6.2b)$$

Note, in particular, that q'_i is *not* the frequency of descendants *in* category i , but rather the fraction of all descendants that are *from* ancestors in category i . The focus is entirely on the categories of ancestors, *not* on which categories the descendants are in. As an example of this shift in focus, suppose our three categories of interest are the genotypes AA , Aa , and aa at a diallelic locus. In a traditional population-genetics analysis (Chapter 5), we would write equations to describe how the frequency of each category changes. Price used a different focus, considering instead the frequency of the *descendants* that come from each category. Suppose category $i = 2$ corresponds to Aa and imagine an extreme case where only Aa individuals survive. Here $q'_2 = 1$, as all offspring have Aa parents. However, in the next generation (before selection), segregation results in the genotypes AA , Aa , and aa at the frequencies 0.25, 0.5, and 0.25, i.e., all three categories are present *in the offspring*, but all have only Aa parents.

Now consider the transmission phase (which more generally includes everything other than selection). Let \bar{z}_i denote the mean value of the descendants from category i , which we can decompose as

$$\bar{z}_i = z_i + \bar{\delta}_i \quad (6.3a)$$

namely, the mean value, z_i , of their ancestors plus a deviation, $\bar{\delta}_i$, due to imperfect transmission. Taking the average over all ancestral categories, the average trait value over all the descendants becomes

$$\bar{z}' = \sum_i q'_i \bar{z}_i \quad (6.3b)$$

Recalling Equations 6.1, 6.2b, and 6.3b, the response in trait value, $R_z = \bar{z}' - \bar{z}$, becomes

$$\begin{aligned}
R_z &= \sum_i q'_i \bar{z}_i - \sum_i q_i z_i \\
&= \left(\sum_i q'_i z_i - \sum_i q_i z_i \right) + \left(\sum_i q'_i \bar{z}_i - \sum_i q'_i z_i \right) \\
&= \sum_i (q'_i - q_i) z_i + \sum_i q'_i (\bar{z}_i - z_i) \\
&= \sum_i \Delta q_i z_i + \sum_i q'_i \bar{\delta}_i
\end{aligned} \tag{6.4}$$

The second line follows by adding and subtracting $\sum q'_i z_i$, and the third by suitably gathering terms. This version of the Price equation is based on Frank (1997, 2012). The first term (containing $\Delta q_i z_i$) represents the change due to *selection based entirely on ancestral values*, or the **partial evolutionary change caused by natural selection** (Price 1972b; Ewens 1989; Frank 2012). The second term (containing $q'_i \bar{\delta}_i$) is the part of total change caused by *imperfect transmission* of ancestral values to their descendants. Equation 6.4 is conceptually very powerful, as it decomposes the response into two separate components, one strictly based on the nature of selection (Δq_i) and the other on transmission ($\bar{\delta}_i$).

Both these terms can be expressed in a more transparent form. For the first term,

$$\begin{aligned}
\sum_i \Delta q_i z_i &= \sum_i (w_i q_i - q_i) z_i = \sum_i w_i z_i q_i - \sum_i z_i q_i = E(w_i z_i) - E(z) \cdot 1 \\
&= E(w_i z_i) - E(z) \cdot E(w) \\
&= \sigma(w_i, z_i)
\end{aligned} \tag{6.5a}$$

Note that to obtain this result, we use the identity $E(w) = 1$. For the second term,

$$\sum_i q'_i \bar{\delta}_i = \sum_i q_i w_i \bar{\delta}_i = E(w_i \bar{\delta}_i) \tag{6.5b}$$

Substituting Equations 6.5a and 6.5b into Equation 6.4 yields the more traditional form of the Price equation,

$$R_z = \bar{z}' - \bar{z} = \sigma(w_i, z_i) + E(w_i \bar{\delta}_i) \tag{6.6}$$

(Price 1970, 1972a). Note that all expectations are computed with respect to the *pre-selection* frequencies of the ancestral categories (q_i). The first term is the covariance between phenotype and fitness (the within-generation change, S , in the mean of ancestral values), while the second is the fitness-weighted transmission of any changes between the value of an ancestor and the mean of its descendants.

Several equivalent expressions for the Price equation are useful in that they emphasize different features. For example, using the definition of a covariance

$$E(w_i \bar{\delta}_i) = \sigma(w_i, \bar{\delta}_i) + E(w_i) \cdot E(\bar{\delta}_i) = \sigma(w_i, \bar{\delta}_i) + E(\bar{\delta}_i) \tag{6.7a}$$

and substituting this result into Equation 6.6 yields

$$R_z = \sigma(w_i, z_i) + \sigma(w_i, \bar{\delta}_i) + E(\bar{\delta}_i) \tag{6.7b}$$

Using Equation 6.3a to combine the first two covariances in Equation 6.7b gives

$$R_z = \sigma(w_i, \bar{z}_i) + E(\bar{\delta}_i) \tag{6.7c}$$

Equation 6.7c relates the selection response to the covariance between the fitness, w_i , of an ancestor and the mean value, \bar{z}_i , of its descendants. The second term, $E(\bar{\delta}_i)$, is often thought

of as the expected change in mean value from ancestor to descendant in the absence of selection. As we will see at the end of the chapter, this interpretation is not quite correct, as this last term does contain a contribution from selection (Equation 6.38).

To summarize, if z_i denotes the average value in category i , which has a frequency of q_i before selection and a frequency of q'_i after selection, and whose offspring have average value $\bar{z}_i = z_i + \bar{\delta}_i$, then equivalent forms of Price's theorem are

$$R_z = \begin{cases} \sum_i \Delta q_i z_i + \sum_i q'_i \bar{\delta}_i \\ \sigma(w_i, z_i) + E(w_i \bar{\delta}_i) \\ \sigma(w_i, z_i) + \sigma(w_i, \bar{\delta}_i) + E(\bar{\delta}_i) \\ \sigma(w_i, \bar{z}_i) + E(\bar{\delta}_i) \end{cases} \quad (6.8)$$

As noted in Table 6.1, and as will be shown shortly (Equation 6.10), the selection differential, S , can be substituted for $\sigma(w_i, z_i)$ in the middle two expressions of Equation 6.8. As is further shown below, many of the standard approximations for evolutionary response (e.g., the breeder's equation, Fisher's fundamental theorem, Robertson's secondary theorem) follow directly from the $\sigma(w_i, z_i)$ selection term under the assumption that the residual term $E(w_i \bar{\delta}_i)$ is zero. Hence, these approximations fail when this term is significant.

While a discussion of Price's theorem often assumes the ancestor to be a parent or mid-parent and the descendants to be their offspring in the next generation, the theorem holds for *any* time interval and for *any* set of ancestors (such as a group of individuals; Chapter 22) that one wishes to consider. In this sense, Price's theorem is completely general and makes absolutely no assumptions about the mechanism of transmission of trait values from ancestors to their descendants, although it *does* make the assumption that all descendants have ancestors. This may seem trivial, but it is violated by migration, wherein an individual appears in the next generation from ancestors not considered. Kerr and Godfrey-Smith (2008) generalized the Price equation to accommodate missing ancestors and more general causal connections between ancestors and descendants.

Example 6.1. Let the ancestor (i) be the midparent (the average value of the two parents) with a phenotypic value of z_i and the descendants be the offspring in the next generation. If the average value of offspring, \bar{z}_i , is exactly the same as the value, z_i , of their ancestral midparent, then $\bar{\delta}_i = 0$ for all i and, from Equation 6.6, the response is simply $R = \sigma(w_i, z_i)$. From the Robertson-Price identity (Table 6.1, Equation 6.10), $\sigma(w_i, z_i) = S$, the selection differential, so that $R = S$ in this case of perfect transmission. However, the mean value of offspring generally differs from the average value of their parents, in which case the second term in Equation 6.6 is nonzero. The simplest transmission model is a linear midparent-offspring regression, $z_{ij} = \mu + b(z_i - \mu) + e_{ij}$. Here z_{ij} is the trait value for the j th offspring from midparent i , giving the mean value of offspring from i as $\bar{z}_i = \mu + b(z_i - \mu) + e_i$. The expected deviation then becomes

$$\bar{\delta}_i = \bar{z}_i - z_i = \mu + b(z_i - \mu) + e_i - z_i = (b - 1)(z_i - \mu) + e_i \quad (6.9a)$$

Hence,

$$\begin{aligned} E(w_i \bar{\delta}_i) &= E\{w_i [(b - 1)(z_i - \mu) + e_i]\} \\ &= (b - 1)[E(w_i z_i) - \mu E(w_i)] + E(w_i e_i) \end{aligned}$$

Recalling that $E(w_i) = 1$ gives

$$E(w_i \bar{\delta}_i) = (b - 1)[E(w_i z_i) - \mu] + E(w_i e_i)$$

From the definition of a covariance

$$\begin{aligned} E(w_i z_i) &= \sigma(w_i, z_i) + E(w_i) E(z_i) = S + 1 \cdot \mu \\ E(w_i e_i) &= \sigma(w_i, e_i) + E(w_i) E(e_i) = \sigma(w_i, e_i) + 1 \cdot 0 \end{aligned}$$

Putting these results together into Equation 6.6 yields

$$R_z = S + E(w_i \bar{\delta}_i) = S + (b - 1)(S + \mu - \mu) + \sigma(w_i, e_i) = bS + \sigma(w_i, e_i) \quad (6.9b)$$

Provided that the residual, e_i , of the midparent-offspring regression and the fitness, w_i , of the midparent are uncorrelated, $R = bS$. When these are uncorrelated and the midparent-offspring slope equals the heritability, $b = h^2$, we recover the breeder's equation. While at first blush Equation 6.9b appears to be a rather general statement about the accuracy of the breeder's equation, we made a few subtle assumptions (besides the obvious one of linearity) about the parent-offspring relationship, although we will defer discussion of these until later sections of this chapter.

Example 6.2. Consider the change in allele frequency when a single diallelic locus (alleles A and a) determines fitness. Assume random mating among the survivors, with $p = \text{freq}(A)$, and

Genotype	Frequency (before selection)	Fitness
AA	p^2	W_{AA}
Aa	$2p(1 - p)$	W_{Aa}
aa	$(1 - p)^2$	W_{aa}

To apply Price's theorem, we need to specify the categories to be followed, which we take as the alleles A and a . We index these by $i = 1$ and $i = 2$, respectively, and code their associated values as $z_1 = 1$ and $z_2 = 0$, which implies a mean value of $\bar{z} = (1 \cdot p) + (0 \cdot [1 - p]) = p$, so R_z represents the change in p . In the absence of mutation, transmission is perfect, as the descendant allele from an A allele is always A , resulting in $\bar{\delta}_i = 0$. Putting these together, Equation 6.6 becomes

$$\Delta p = R_z = \sigma(w_i, z_i) + E(w_i \cdot 0) = \sigma(w_i, z_i)$$

Under random mating, the fitness W_1 of an A allele is simply its marginal fitness (Equation 5.7b), $W_1 = pW_{AA} + (1 - p)W_{Aa}$. Similarly, $W_2 = pW_{Aa} + (1 - p)W_{aa}$ and $E(W_i) = \bar{W} = pW_1 + (1 - p)W_2$. Recalling that $w_i = W_i/\bar{W}$ and the definition of a covariance, we have

$$\Delta p = \sigma(w_i, z_i) = \frac{\sigma(W_i, z_i)}{\bar{W}} = \frac{1}{\bar{W}} \left(E(W_i z_i) - E(W_i)E(z_i) \right)$$

To show that this recovers the standard population-genetic equation for allele-frequency change, note that

$$E(W_i z_i) = \sum_{i=1}^2 W_i z_i \text{ freq(category } i) = [W_1 \cdot 1 \cdot p] + [W_2 \cdot 0 \cdot (1 - p)] = p \cdot W_1$$

Using this result along with $E(W_i) = \bar{W}$ and $E(z_i) = p$

$$\Delta p = \frac{1}{\bar{W}} (p W_1 - \bar{W} p) = p \frac{(W_1 - \bar{W})}{\bar{W}}$$

which recovers Equation 5.7c.

The Robertson-Price Identity, $S = \sigma(w, z)$

When our concern is strictly on the *within-generation* change in trait value, then $\Delta \bar{z} = \mu_z^* - \mu_z$, the difference between the fitness-weighted mean after selection (but before reproduction),

μ_z^* , and the overall mean before selection, μ_z , which is the selection differential S (Chapter 13). Because the within-generation change is not influenced by cross-generation transmission, any terms involving δ in Equation 6.6 are zero, and we recover the **Robertson-Price identity**

$$S = \sigma(w, z) \quad (6.10)$$

as first obtained by Robertson (1966a) and Price (1970). We derive this result by another route in Chapter 13, where we use this identity extensively in selection-response theory. The critical insight from Equation 6.10 is that no matter how complex the relationship between phenotype z and fitness w , the within-generation change in the mean only depends on the covariance between these measures.

The Breeder's Equation, $R = h^2 S$

Our derivation of the breeder's equation via Price's theorem (Example 6.1) made three assumptions dealing with the midparent-offspring regression that need to be highlighted. The most obvious assumption was that the parent-offspring regression is linear. Two more subtle assumptions are that the parent and offspring means are unchanged in the absence of selection, and that the regression slope b is the same for selected and unselected parents. We address these assumptions separately, by considering the impact of changing means first, then nonlinearity, and finally changes in the regression slope. While each assumption is considered in isolation, one or more may occur simultaneously.

Example 6.1 used the linear regression $z_{ij} = \mu + b(z_i - \mu) + e_{ij}$ for the j th offspring from midparent combination i (Example 6.1), which assumes that the trait mean is the same in the offspring (o) and parental populations (p) in the absence of selection ($\mu_o = \mu_p = \mu$). More generally, the parent and offspring means can differ, making the regression $z_{ij} = \mu_o + b(z_i - \mu_p) + e_{ij}$, in which case

$$\begin{aligned} \delta_i &= \bar{z}_i - z_i = \mu_o + b(z_i - \mu_p) + e_i - z_i \\ &= (b - 1)z_i - b\mu_p + \mu_o + e_i \\ &= (b - 1)(z_i - \mu_p) + (\mu_o - \mu_p) + e_i \end{aligned} \quad (6.11)$$

Following the same logic leading to Equation 6.9b yields the response to selection

$$R = bS + \sigma(w_i, e_i) + (\mu_o - \mu_p) \quad (6.12)$$

where the last term $(\mu_o - \mu_p)$ accounts for changes in mean phenotype from parent to offspring (in the absence of selection), due, for example, to the decay of linkage disequilibrium (Chapter 15), nonrandom associations of environmental values (Chapter 15), or inbreeding (Chapter 23; LW Chapter 10).

Now suppose the parent-offspring regression is nonlinear. Assuming the simplest such departure, a quadratic, makes the key point. The mean value \bar{z}_i of offspring from a midparent with phenotypic value z_i is given by

$$\bar{z}_i = a + bz_i + cz_i^2 + e_i \quad (6.13a)$$

Hence,

$$\sigma(w_i, \bar{z}_i) = b\sigma(w_i, z_i) + c\sigma(w_i, z_i^2) + \sigma(w_i, e_i) \quad (6.13b)$$

Assuming the residuals from the midparent-offspring regression are uncorrelated with the fitness of the midparent $\sigma(w_i, e_i) = 0$, Equation 6.13b becomes

$$\sigma(w_i, \bar{z}_i) = bS + c\sigma(w_i, z_i^2) \quad (6.13c)$$

From Equation 6.7c, the selection response is given by this expression plus $E(\bar{\delta}_i)$. Thus, with a nonlinear parent-offspring regression, selection on the variance z_i^2 (i.e., $\sigma(w_i, z_i^2) \neq 0$; see

Chapters 29 and 30) can enter into the response in the mean, in which case the strict linear version of the breeder's equation no longer holds.

A final source of error when using the breeder's equation is that the regression coefficient may differ between selected and unselected parents. To explicate this point, we follow Frank (1997) and consider any generalized linear predictor of some value z_i for individual i from k underlying predictor variables x_{i1}, \dots, x_{ik} ,

$$z_i = \sum_{j=1}^k b_j x_{ij} + e_i \quad (6.14)$$

For example, an individual's phenotype can be written as the sum of average allelic effects over all k loci plus a residual error. With a single diallelic locus, $z_i = b_1 x_{i1} + b_2 x_{i2} + e_i$, where b_j is the average effect of allele j and x_{ij} is the number of copies of allele j in individual i (values of 0, 1, or 2), so that (for a diploid) $\bar{x}_{\cdot j}/2 = p_j$, the frequency of allele j . The average of Equation 6.14 becomes

$$\bar{z} = \sum_j b_j \bar{x}_{\cdot j} = \sum_j 2b_j p_j \quad (6.15a)$$

At some time in the future, the values of both p_j (the allele frequency) and b_j (its average effect) may change to new values

$$p'_j = p_j + \Delta p_j \quad \text{and} \quad b'_j = b_j + \Delta b_j \quad (6.15b)$$

We write the new mean as

$$\bar{z}' = \sum_j 2b'_j p'_j \quad (6.15c)$$

and the same logic leading to Equation 6.4 allows us to decompose the total change as

$$\bar{z}' - \bar{z} = \sum_j 2b_j \Delta p_j + \sum_j 2p'_j \Delta b_j \quad (6.15d)$$

There are two sources for response: a change, $b_j \Delta p_j$, from the change in allele frequencies weighted by their original average effects, and a change, $p'_j \Delta b_j$, in the average effects weighted by the new allele frequencies. These two terms exactly correspond to the selection and transmission terms in Price's equation (compare this with Equation 6.4). The $b_j \Delta p_j$ terms correspond to partial evolutionary change caused by natural selection, while the transmission term represents the response due to changes, Δb_j , in the average effects themselves. These changes in turn influence the parent-offspring regression slope.

Example 6.3. The setting in which the breeder's equation is expected to be least accurate involves a trait entirely determined by a single dominant locus. This results in both a nonlinear parent-offspring regression and the potential for significant allele-frequency change following even a single generation of selection. Suppose that, at such a locus, genotypes QQ and Qq have a phenotypic value of 1, while qq has a value of 0 (there is no environmental variance), and that qq individuals have a survival rate twice as high as the survival rate of QQ and Qq individuals.

We now contrast the exact response from single-locus models (Chapter 5) with that predicted by the breeder's equation. Starting with the exact population-genetic model, and letting p be the frequency of allele q

Genotype	QQ	Qq	qq
Trait value z	1	1	0
Frequency (before selection)	$(1-p)^2$	$2p(1-p)$	p^2
Fitness	1	1	2
Frequency (after selection)	$(1-p)^2/\bar{W}$	$2p(1-p)/\bar{W}$	$p^2(2/\bar{W})$

The trait mean before selection is $\mu(p) = 1 - p^2$, with a mean fitness of $\bar{W}(p) = 1 + p^2$. The new frequency, p' , of allele q after selection is half the frequency of Qq plus the frequency of qq (both after selection)

$$p' = \frac{(1/2)2p(1-p) + 2p^2}{1+p^2} = \frac{p(1+p)}{1+p^2} \quad (6.16a)$$

yielding an allele-frequency change of

$$\Delta p = p' - p = \frac{p(1+p)}{1+p^2} - p \frac{1+p^2}{1+p^2} = \frac{p^2(1-p)}{1+p^2}$$

which translates into a change in mean phenotype of

$$R_z = \mu(p') - \mu(p) = p^2 - (p')^2 = -2p^3 \left(\frac{1-p(1+p^2)/2}{(1+p^2)^2} \right) \quad (6.16b)$$

This exact single-generation response in the trait mean is plotted in Figure 6.4.

Now consider the response predicted from the breeder's equation. Applying the standard trait-value parameterization of $2a : a(1+k) : 0$ to the preceding trait values, we have $a = 1/2$ and $k = 1$, yielding (LW Chapter 4) the additive and dominance variances of the trait

$$\sigma_A^2 = 2p(1-p)a^2[1+k(2p-1)]^2 = 2p(1-p)(1/4)(2p)^2 = 2p^3(1-p)$$

$$\sigma_D^2 = [2p(1-p)ak]^2 = p^2(1-p)^2$$

Because σ_E^2 is assumed to be zero, the heritability becomes

$$h^2 = \frac{\sigma_A^2}{\sigma_A^2 + \sigma_D^2} = \frac{2p^3(1-p)}{2p^3(1-p) + p^2(1-p)^2} = \frac{2p}{1+p} \quad (6.16c)$$

Following selection (but before reproduction), only QQ and Qq survive, each with a trait value of one, yielding the fitness-weighted mean

$$\mu^* = 1 \cdot \frac{1}{\bar{W}} (1-p^2) + 0 \cdot \frac{2}{\bar{W}} p^2 = \frac{1-p^2}{\bar{W}} = \frac{1-p^2}{1+p^2} \quad (6.16d)$$

yielding the selectional differential

$$S = \mu^* - \mu = \frac{1-p^2}{1+p^2} - (1-p^2) = -p^2 \frac{1-p^2}{1+p^2} \quad (6.16e)$$

Equations 6.16c and 6.16e give the predicted response from the breeder's equation as

$$R_z = h^2 S = \left(\frac{2p}{1+p} \right) \left(-p^2 \frac{1-p^2}{1+p^2} \right) = -\frac{2p^3(1-p)}{1+p^2} \quad (6.16f)$$

As shown in Figure 6.1, we see that the approximation given by the breeder's equation (Equation 6.16f) generally does well but slightly underestimates the exact response (Equation 6.16b), predicting (in the worst case) only about 90% of the actual response when $p \simeq 0.4$. For this simple one-locus model, two factors account for this discrepancy. First, owing to dominance, the parent-offspring regression is *not* linear. Second, the change in allele frequency in the selected parents results in changes in the parent-offspring covariance, and hence the parent-offspring regression slope.

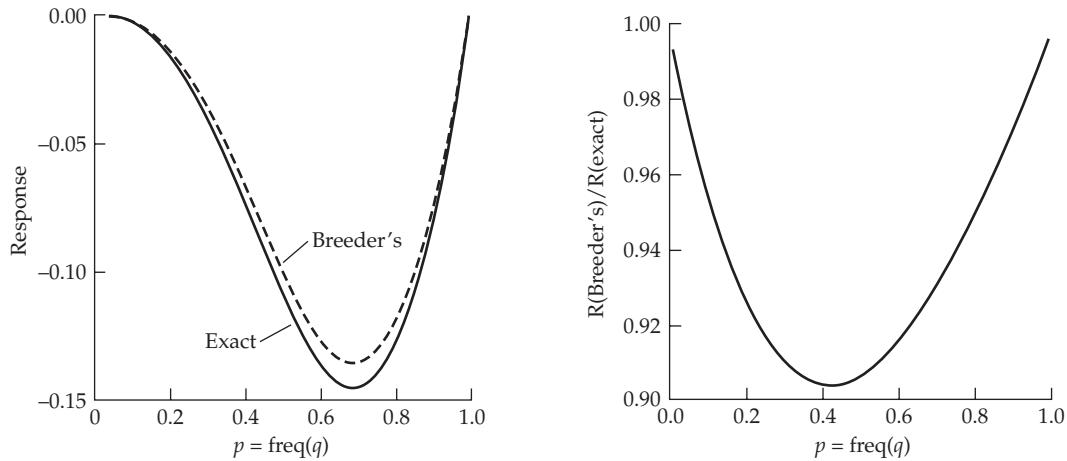

Figure 6.1 Analysis of the model from Example 6.3. (Left) Graph of the exact (using one-locus theory; Equation 6.16b) and predicted (via the breeder’s equation; Equation 6.16f) response as a function of allele-frequency p , for a trait under selection determined by a single dominant locus. (Right) The relative accuracies of the breeder’s equation as a function of p .

FISHER’S FUNDAMENTAL THEOREM OF NATURAL SELECTION

The rate of increase in fitness of any organism at any time is equal to its genetic variance in fitness at that time. Fisher (1930, p. 35)

This simple statement from Fisher’s (1930) book (which was dictated to his wife as he paced about their living room) has generated a tremendous amount of work, discussion, and sometimes heated arguments. Fisher claimed his result was exact, a true theorem. Historically, the **classical** (and seemingly obvious) interpretation of this quote is that the rate of increase in mean fitness equals the additive variance in fitness, $R_w = \sigma^2(A_w)$. Because variances are nonnegative, this interpretation implies that mean population fitness never decreases in a constant environment. However, we already know from Chapter 5 that this statement is incorrect, as mean fitness can decline even under simple models of selection. As a result, the mathematician Sam Karlin referred to this interpretation as “neither fundamental nor a theorem” as it requires rather special conditions to hold, especially when multiple loci influence fitness. As is discussed below, the classical interpretation of Fisher’s theorem only holds *exactly* under restricted conditions, but is often a good approximate descriptor. We first review the classical interpretation, and then discuss what it appears that Fisher actually meant.

The Classical Interpretation of Fisher’s Fundamental Theorem, $R_w = \sigma_A^2(w)$

One way to demystify the classical version of Fisher’s theorem is to suppose that fitness is just a trait, and use the breeder’s equation, $R = h^2S$, to predict the response to selection on that trait. Letting $z = W$, and recalling that $w = W/\bar{W}$, the Robertson-Price identity (Equation 6.10) yields the selection differential

$$S_W = \sigma(z, w) = \sigma(W, w) = \frac{\sigma(W, W)}{\bar{W}} = \frac{\sigma^2(W)}{\bar{W}} \quad (6.17a)$$

Substituting into the breeder’s equation shows

$$R_W = h_W^2 S_W = \frac{\sigma_A^2(W)}{\sigma^2(W)} \frac{\sigma^2(W)}{\bar{W}} = \frac{\sigma_A^2(W)}{\bar{W}} \quad (6.17b)$$

Expressed in terms of *relative fitnesses*,

$$R_w = \Delta \bar{w} = \frac{R_W}{\bar{W}} = \frac{\sigma_A^2(W)}{\bar{W}^2} = \sigma_A^2(w) \quad (6.17c)$$

recovering the classical view of Fisher's theorem.

One can also use a population-genetics framework to motivate Fisher's theorem in terms of allele-frequency change. Consider a diallelic locus with constant fitnesses under random mating, and define $\bar{W}(p)$ to be the mean population fitness at allele frequency p (Equation 5.1a). The change in mean fitness is a function of the allele-frequency change, Δp ,

$$R_W = \bar{W}(p + \Delta p) - \bar{W}(p) \quad (6.18a)$$

If the allele-frequency change is small, a first-order Taylor-series approximation yields

$$\bar{W}(p + \Delta p) \simeq \bar{W}(p) + \frac{d\bar{W}}{dp} \Delta p \quad (6.18b)$$

so

$$R_W = \bar{W}(p + \Delta p) - \bar{W}(p) \simeq \frac{d\bar{W}}{dp} \Delta p \quad (6.18c)$$

From Equation 5.5a

$$\begin{aligned} \frac{d\bar{W}}{dp} &= 2pW_{AA} + 2(1-2p)W_{Aa} + 2(p-1)W_{aa} \\ &= 2[p(W_{AA} - W_{Aa}) + (1-p)(W_{Aa} - W_{aa})] = 2(\alpha_A - \alpha_a) \end{aligned} \quad (6.18d)$$

where the last equality follows from the definition of the average effects (under random mating; see LW Chapter 4) of alleles A and a on fitness, namely,

$$\alpha_A = pW_{AA} + (1-p)W_{Aa} - \bar{W} \quad \text{and} \quad \alpha_a = pW_{Aa} + (1-p)W_{aa} - \bar{W} \quad (6.18e)$$

Recall that the quantity $\alpha = \alpha_A - \alpha_a$ is the average effect of an allelic substitution (LW Equation 4.6), as the difference in the average effects of these two alleles yields the mean effect on fitness from replacing a randomly chosen a allele with an A allele.

Applying Wright's formula (Equation 5.5b) together with Equation 6.18d returns

$$\Delta p = \frac{p(1-p)}{2\bar{W}} \frac{d\bar{W}}{dp} = \frac{p(1-p)}{2\bar{W}} (2\alpha) \quad (6.18f)$$

and substitution into Equation 6.18c then yields

$$R_W \simeq \frac{p(1-p)(2\alpha)^2}{2\bar{W}} = \frac{\sigma_A^2(W)}{\bar{W}} \quad (6.18g)$$

The last step follows from the fact that the additive genetic variance is related to α by $\sigma_A^2 = 2p(1-p)\alpha^2$ (LW Equation 4.12a). Thus, under this approximation of small allele-frequency change (in which terms of order $(\Delta p)^2$ can be ignored), the change in mean fitness is indeed proportional to the additive genetic variance in fitness.

As Example 6.4 (below) highlights, Equation 6.18g, and thus the classical view of Fisher's theorem, is only approximate. Under what conditions does this expression actually hold? While Equation 6.18g is correct for multiple additive loci (i.e., no dominance or epistasis) under both random and nonrandom mating (Kempthorne 1957; Ewens 1969), it is generally compromised by departures from additivity. Even when the theorem does not hold exactly, does it still remain a good approximation? Nagylaki (1976a, 1977a, 1977b, 1991, 1992b, 1993) examined ever more general models of fitness under the assumption of

weak selection (i.e., the fitness of genotypes being approximately $1 + bs$ with s small and $|b| \ll 1$) and random mating. Selection is further assumed to be much weaker than the recombination frequency c_{min} for the closest pair of loci under selection ($s \ll c_{min}$). Under these conditions, the evolution of mean fitness falls into three distinct stages. During the first phase (roughly $t < 2 \ln s / \ln[1 - c_{min}]$ generations), any initial disequilibrium has a transient impact on the dynamics until the point where disequilibrium reaches a steady-state value. At this point, we enter the central phase, with the change in mean fitness becoming

$$R_W = \frac{\sigma_A^2(W)}{W} + O(s^3) \quad (6.19)$$

where $O(s^3)$ means that terms on the order of s^3 have been ignored. Because additive genetic variance is expected to be of order s^2 , Fisher's theorem is expected to hold to a good approximation during this period. The central phase of evolution lasts roughly $1/s$ generations. However, as gametic frequencies approach their equilibrium values, we reach the third phase, where the additive variance in fitness can be much smaller than order s^2 , in which case terms of order s^3 can be important. During the first and third phases, mean fitness can decrease, but the fundamental theorem holds during the central phase of evolution. Because we expect the bulk of evolution (the majority of change in \bar{W}) to occur during this middle phase, Fisher's theorem approximately holds over the major part of evolutionary change. While Nagylaki's results are weak-selection approximations, we often expect weak selection to be the norm for quantitative traits, as even strong selection on a trait translates into weak selection on the underlying loci if each of these has a small effect (Equation 5.21).

Unlike Fisher's theorem, because Price's theorem is exact, we can go further and apply Price's results to make an exact statement about the evolution of mean fitness. Letting $z_i = A_i$ denote the breeding value for the fitness of the i th midparent, the mean breeding value in their offspring becomes

$$\bar{z}_i = A_i + \bar{\delta}_i \quad (6.20a)$$

where (as above) $\bar{\delta}_i$ is the difference between the trait value in the ancestor (the breeding value of the midparent) and the mean value in its offspring. The phenotypic value of fitness for this midparent (the average of the two parental fitnesses) can be written as $W_i = A_i + \epsilon_i$. Substituting these results into Equation 6.7c gives the between-generation change in the mean breeding value ($\Delta \bar{A}_W$) for fitness as

$$\begin{aligned} R_{A_W} &= \sigma(w_i, A_i + \bar{\delta}_i) + E(\bar{\delta}_i) \\ &= \sigma(w_i, A_i) + \sigma(w_i, \bar{\delta}_i) + E(\bar{\delta}_i) \\ &= \frac{1}{\bar{W}} \sigma(A_i + \epsilon_i, A_i) + \sigma(w_i, \bar{\delta}_i) + E(\bar{\delta}_i) \\ &= \frac{\sigma_A^2(W)}{W} + \sigma(w_i, \bar{\delta}_i) + E(\bar{\delta}_i) \end{aligned} \quad (6.20b)$$

where the last expression follows because $\sigma(A_i, \epsilon_i) = 0$ by construction. When $E(\bar{\delta}_i) = \sigma(w_i, \bar{\delta}_i) = 0$, we recover the classic version of Fisher's fundamental theorem. If the mean breeding value for offspring is the average of their parent's breeding values, then $\bar{\delta}_i = 0$ and these conditions hold. Even if not exactly true, often $\bar{\delta}_i$ is very close to zero and the leading term (and hence Fisher's theorem) dominates.

Example 6.4. The accuracy of the first-order Taylor-series approximation used in Equation 6.18b was examined by Li (1967). Because \bar{W} is a quadratic polynomial of p , the second-order Taylor series is exact,

$$\Delta \bar{W} = \frac{d \bar{W}}{dp} \Delta p + \frac{1}{2} \frac{d^2 \bar{W}}{dp^2} (\Delta p)^2$$

As shown by Equations 6.18c and 6.18f, the first term recovers Fisher's theorem, while the second term is the error resulting from this approximation.

Taking the derivative of Equation 6.18d yields

$$\frac{d^2 \bar{W}}{dp^2} = 2(W_{AA} - 2W_{Aa} + W_{aa})$$

and recalling Equation 6.18f, the residual term becomes

$$\frac{1}{2} \frac{d^2 \bar{W}}{dp^2} \Delta p^2 = (W_{AA} - 2W_{Aa} + W_{aa}) \left(\frac{p(1-p)}{\bar{W}} \alpha \right)^2$$

Thus, if fitnesses are additive, meaning that $[W_{AA} + W_{aa}]/2 = W_{Aa}$, the residual term is zero, and Fisher's theorem holds. However, when dominance in fitness is present, Fisher's theorem fails even for a single locus under random mating.

What Did Fisher Really Mean?

Fisher (1930, p. 35) warned that his theorem “requires that the terms employed should be used strictly as defined,” and much of the confusion being referred to is concerned with what Fisher meant by “fitness.” Crow (2002) noted that in stating his theorem, “Fisher was indulging in his usual elegant obscurity.” Price (1972b) and Ewens (1989, 1992) argued that Fisher's theorem is always true because he had a very narrow interpretation of the change in mean fitness (also see Edwards 1990, 1994; Frank 1995; Lessard and Castilloux 1995; Lessard 1997; Plutynski 2006). They argued that rather than considering the *total* rate of change in fitness, Fisher was instead concerned only with the *partial* rate of change, that due only to changes in allele frequency, without considering any corresponding changes in the average excesses or effects of these alleles.

Placed in the framework of Price's theorem, this “partial increase” interpretation becomes clear. From Equation 6.15d (setting $b_j = \alpha_j$), the total response in fitness can be decomposed into two components

$$R_w = \sum_j 2\alpha_j \Delta p_j + \sum_j 2p'_j \Delta \alpha_j \quad (6.21a)$$

where α_j is the average effect of an allele on fitness. Recalling Equation 6.5a, the first sum is simply $\sigma(w_i, A_i) = \sigma(A_i + \epsilon_i, A_i) = \sigma_A^2(w)$, yielding

$$R_w = \sigma_A^2(w) + \sum_j 2p'_j \Delta \alpha_j \quad (6.21b)$$

Note that the first term in Equation 6.21a is the partial change due *solely* to changes in allele frequencies

$$\sum_j 2\alpha_j \Delta p_j$$

which we denote by ∂R_w to emphasize that only a *specific part* of the total change is being considered. Price argued that Fisher's interpretation of his theorem was that

$$\partial R_w = \sigma^2(A_w) \quad (6.21c)$$

Thus, the exact version of Fisher's theorem (Equation 6.21c) simply concerns the partial evolutionary response caused by natural selection, as Price argued that Fisher essentially regarded the second term as a change in the “environment” within which alleles find themselves after selection, with Fisher having a very broad interpretation of

“environment,” referring to both physical and genetic backgrounds. In the words of Price (1972b, p. 130), Fisher

regarded the natural selection effect on fitness as being limited to the additive or linear effects of changes in gene (allele) frequencies, while everything else—dominance, epistasis, population pressure, climate, and interactions with other species—he regarded as a matter of the environment.

A nice discussion of this point was offered by Frank and Slatkin (1992), who pointed out that the change in mean fitness over a generation is also influenced by the change in “environment,” E . Specifically,

$$R_W = (\overline{W}' | E') - (\overline{W} | E) \quad (6.22a)$$

where the prime denotes the fitness or environment in the next generation. Expanding the preceding expression, we can partition the contributions from the change in fitness and the change in the environment by writing

$$R_W = [(\overline{W}' | E) - (\overline{W} | E)] + [(\overline{W}' | E') - (\overline{W}' | E)] \quad (6.22b)$$

where the first term in brackets represents the change in mean fitness under the initial “environment,” while the second represents the change in mean fitness due to changes in the environmental conditions. This decomposition is simply another way of stating Equation 6.21a. The exact version of Fisher’s theorem relates solely to changes in the first component, $(\overline{W}' | E) - (\overline{W} | E)$, which he called the change in fitness due to natural selection. In considering this exact version of Fisher’s theorem, Ewens (1994, p. 187) stated

I believe that the often-made statement that the theorem concerns changes in mean fitness, assumes random-mating populations, is an approximation, and is not correct in the multi-locus setting, embodies four errors. The theorem relates the so-called partial increase in mean fitness, makes no assumption about random mating, is an exact statement containing no approximation, and finally is correct (as a theorem) no matter how many loci are involved.

Nagylaki (1993) suggested that the statement $R_W = \sigma_A^2(W)/\overline{W}$ be referred to as the **asymptotic fundamental theorem of natural selection**, while Fisher’s more narrow (and correct) interpretation based on partial change should be referred to as the **Fisher-Price-Ewens theorem of natural selection**. A clear distinction between these two very different interpretations seems quite reasonable given their considerable past history of confusion. Warren Ewens (personal communication, 2005) said it best by noting that

one should think of two totally different results, holding under totally different sets of circumstances, not intersecting with each other much, and which should not be put under the same umbrella.

Thus, the bold, sweeping classical interpretation of Fisher’s statement is replaced in the exact version by an unfortunately all-too common outcome of mathematics—a result that is absolutely correct, but not really useful. While the nature of the partial response is certainly elegant, our interest is in the total response.

IMPLICATIONS OF FISHER’S THEOREM FOR TRAIT VARIATION

While the classical view of Fisher’s theorem does not generally hold and the exact version has rather limited utility, Fisher’s theorem has still had an enormous impact on how quantitative geneticists view trait variation. This is because an important corollary holds under very general conditions in a constant environment (Kimura 1965b; Ewens 1976; Nagylaki 1976a, 1977b; Ewens and Thomson 1977; Charlesworth 1987): in the absence of new variation from mutation or other sources such as migration, *selection is expected to eventually remove all additive genetic variation in fitness*. This can be seen immediately for a single locus by considering Equation 5.8b—if the population is at equilibrium, all average excesses

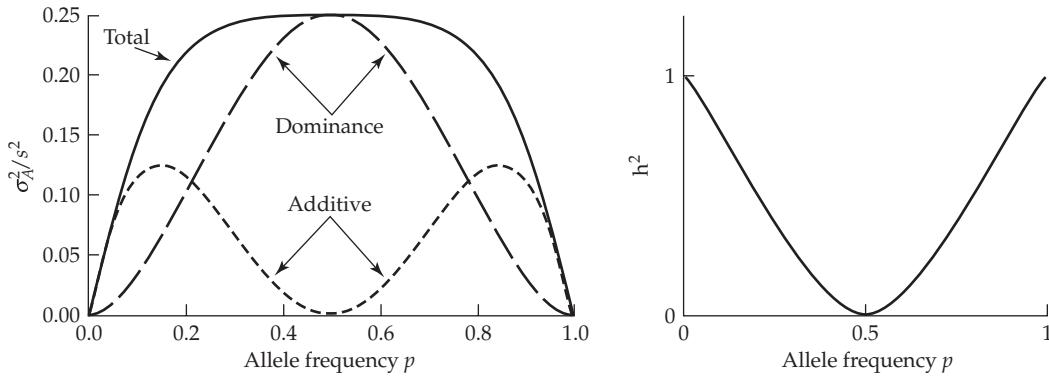

Figure 6.2 The behavior of genetic variance components and the heritability for fitness as a function of allele frequency p under the parameters given in Example 6.5. (**Left**) Note that total genetic variance is maximized at the value ($p = 1/2$), where the additive variance is zero. (**Right**) Assuming that there is no environmental variance, the heritability is simply the ratio of additive to total genetic variance, which is also zero when total variance is maximized.

are zero, as all segregating alleles have the same marginal fitness and hence no additive variation *in fitness* is present (Fisher 1941).

This corollary makes the general prediction that characters that are strongly genetically correlated with fitness should show reduced additive variance relative to characters that are less well correlated with fitness (Robertson 1955b), reflecting the removal of additive variance by selection (which is partly countered by new mutational input). As we now will review, there is indeed a loose trend for traits that are correlated with fitness to show reduced heritability, which is often interpreted as being due to a reduction in σ_A^2 for fitness-related traits. However, note that we can express heritability as $h^2 = \sigma_A^2 / (\sigma_A^2 + \sigma_e^2)$, where $\sigma_e^2 = \sigma_z^2 - \sigma_A^2$ is the residual variance (the non-additive genetic and environmental variances). While a reduction in σ_A^2 with σ_e^2 held constant results in a smaller h^2 , by sufficiently increasing σ_e^2 , one can still have a reduced h^2 , even when σ_A^2 has also increased. Indeed, as we will show, a closer look at the data shows that the additive variance is often *greater* for traits that are correlated with fitness, but that this increase is overwhelmed by an increased residual variance, resulting in a lower heritability.

Example 6.5. Consider a locus with two alleles (A_1 and A_2) and overdominance in fitness,

$$W_{11} = 1 - s \quad W_{12} = 1 \quad W_{22} = 1 - s$$

Letting $p = \text{freq}(A_1)$, from Equation 6.18e and the definition of the average effect of a substitution under random mating, we have

$$\alpha = \alpha_A - \alpha_a = p[(1-s) - 1] + (1-p)[1 - (1-s)] = s(1-2p)$$

giving the additive genetic variance in fitness as

$$\sigma_A^2(W) = 2p(1-p)\alpha^2 = 2p(1-p)s^2(1-2p)^2$$

The dominance variance is computed from LW Equation 4.12b to be $\sigma_D^2(W) = [2p(1-p)s]^2$. For simplicity, the plot of h^2 for fitness (Figure 6.2) assumes no environmental effects, so $h^2 = \sigma_A^2/\sigma_G^2 = \sigma_A^2/(\sigma_A^2 + \sigma_D^2)$. As illustrated in Figure 6.2, these variance components change dramatically with p . The maximum total genetic variance in fitness occurs at $p = 1/2$, but in this particular example none of this variance is additive, so the heritability in fitness is zero, as the corollary of Fisher's theorem predicts. Even though *total* genetic variation in

fitness is maximized at $p = 1/2$, no change in \bar{W} occurs at this frequency, as none of the variance is additive.

Traits Correlated With Fitness Have Lower Heritabilities

The corollary to Fisher's theorem, that additive genetic variance in fitness is driven toward zero by selection in a constant environment, suggests that traits that are correlated with fitness will have reduced levels of additive variance relative to characters under less direct selection. How well does this prediction hold up? Many authors have noticed that characters that are expected to be under selection (e.g., life-history traits, such as clutch size) tend, on average, to have lower heritabilities than morphological characters measured in the same population or species (reviewed by Robertson 1955b; Charlesworth 1987; Mousseau and Roff 1987; Roff and Mousseau 1987; also see LW Figure 7.10). However, some notable exceptions are also apparent (see Charlesworth 1987).

The difficulty with these general surveys is knowing whether a character is highly *genetically* correlated with *lifetime* fitness. Clutch size, for example, would seem to be highly correlated with total fitness, but if birds with large clutch sizes have poorer survivorship, the correlation with lifetime fitness may be weak. Negative genetic correlations between components of fitness allow for significant additive variance in each component at equilibrium, even when additive variance in *total* fitness is zero (Robertson 1955b; Rose 1982).

Unfortunately, estimates of lifetime fitness in natural populations and their correlation with components of fitness (such as clutch size) are rare. One example was given by Gustafsson (1986; see also Merilä and Sheldon 2000), who measured lifetime reproductive success as well as the heritabilities of fitness and other characters in a closed natural population of collared flycatcher birds (*Ficedula albicollis*) in the Baltic Sea. Lifetime reproductive success had an estimated heritability that was not significantly different from zero, as expected from the corollary to Fisher's theorem. Clutch size had a rather high heritability, 0.32 ± 0.15 , but the estimated phenotypic correlation between clutch size and total fitness was very low, $r^2 = 0.03$. In general, as the phenotypic correlation between a trait and total fitness decreased, its heritability increased (Figure 6.3).

McCleery et al. (2004) also found a negative relationship between trait heritability and trait-fitness phenotypic correlation in an English population of great tits (*Parus major*) that was followed for almost 40 years. Similar findings were seen by Teplitsky et al. (2009) in red-billed gulls (*Larus novaehollandiae*). Conversely, Schwaegerle and Levin (1991) found no significant association between the heritability of a character and its phenotypic correlation to fruit production (chosen as one measure of total fitness) in a wild population of the plant *Phlox dummondii* (Figure 6.3). While the evidence is mixed, these studies suggest a mild trend for characters that are phenotypically correlated with fitness to have reduced heritabilities relative to other characters. One important caveat is that this association is based on phenotypic, rather than genetic, correlations with fitness.

Under the classical view, if a trait is known to be under selection, one might be tempted to assume it is still far from its genotypic equilibrium value if it shows a modest to large heritability. This is false. As Example 6.6 highlights, a trait that is under selection can still have a high *trait* additive variance even when the additive genetic variance in *fitness* is near zero. This can happen if there is a nonlinear transformation of the trait value into fitness, such as occurs with stabilizing selection.

More generally, Price and Schlüter (1991) noted that even with a simple linear relationship between a trait and fitness, it is quite likely that there may be a modest heritability for the trait but a very low heritability for fitness. The following simple model makes most of their main points. Assume fitness is entirely determined by a metric character, with fitness being a linear function of the phenotypic value z plus a residual deviation e , $W(z) = a + \beta z + e$, making the total variance in fitness $\sigma^2[W(z)] = \beta^2\sigma_z^2 + \sigma_e^2$. Writing $z = A + E$, the additive genetic value A plus all other sources of variance (environmental and genetic), makes the

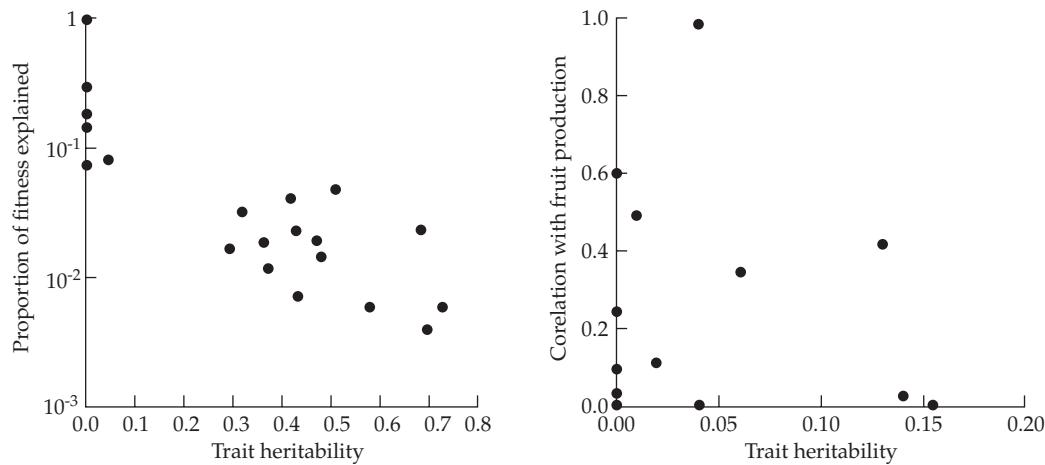

Figure 6.3 Two studies examining the association between a character's heritability and its total fitness, measured by r^2 , the squared phenotypic correlation between the character and lifetime fitness. (**Left**) Gustafsson's (1986) work on the collared flycatcher *Ficedula albicollis* on the island of Gotland in the Baltic Sea. (**Right**) Schwaegerle and Levin's (1991) study of *Phlox drummondii*, with fruit production used as a measure of total fitness.

additive variance in fitness $\beta^2 \sigma_A^2$. The heritability of fitness can be expressed in terms of the variance components for z as follows:

$$h_W^2 = \frac{\beta^2 \sigma_A^2}{\beta^2 (\sigma_A^2 + \sigma_E^2) + \sigma_e^2} = \frac{\sigma_A^2}{\sigma_A^2 + \sigma_E^2 + \sigma_e^2 / \beta^2} < h_z^2 = \frac{\sigma_A^2}{\sigma_A^2 + \sigma_E^2} \quad (6.23)$$

Thus, even when fitness is entirely determined by a single trait, the heritability of fitness is less than the heritability of the character under selection, due to the variation, σ_e^2 , in fitness about its expected value for a given trait value (which is expected to be considerable; see Chapter 29). If the heritability of fitness is found to be close to zero in this case, there still could be a significant heritability in the actual *character* under selection, implying that the trait mean can continue to change over time, albeit slowly.

Example 6.6. Even if Fisher's theorem holds exactly, its implication for character evolution can often be misinterpreted. Suppose that locus A in Example 6.5 completely determines a character under stabilizing selection. Let the genotypes AA , Aa , and aa have discrete phenotypic values of $z = -1$, 0, and 1, respectively (so that this locus is strictly additive with respect to the trait), and let the fitness function be $W(z) = 1 - sz^2$. If we assume no environmental variance, this generates the fitnesses for each genotype assumed in Example 6.5. The additive genetic variance for the trait z is $2(1)^2 p(1-p)$, which is maximized at $p = 1/2$, precisely the allele frequency at which the additive genetic variance in fitness, $\sigma_A^2(W)$, equals zero. This difference emphasizes that Fisher's theorem concerns additive genetic variance in *fitness*, not in the *character*. In this example, the nonlinear mapping of the phenotypic character value, z , into the trait fitness, W , results in a situation where a character that is correlated with fitness retains additive variance in the trait but *not* in fitness at its equilibrium value.

Table 6.2 Heritabilities and coefficients of additive genetic (CV_A) and residual (CV_R) variation for representative traits in *Drosophila melanogaster*. Both CV_A and CV_R values are multiplied by 100. Here n is the number of studies, and the median estimates are reported. (After Houle 1992.)

Trait	n	h^2	CV_A	CV_R
Sternopleural bristles	21	0.44	8.39	7.97
Wing length	31	0.36	1.56	2.09
Fecundity	12	0.06	11.90	39.02
Longevity	7	0.11	9.89	27.73

Traits Correlated With Fitness Have Higher Levels of Both Additive and Residual Variance

While a reduced h^2 value is often interpreted as resulting from a decrease in the additive variance, it can also result from an increase in the residual variance, and the argument made by Price and Schlüter raises the question of whether traits that are more closely associated with fitness have increased residual variances. If this is the case, a simple comparison of heritabilities can be misleading (Houle 1992).

When comparing additive variances across traits, a standardized measure is required, and a common approach is to compare coefficients of variation, the ratio of the standard deviation to the mean. This led Houle (1992; see also Charlesworth 1984a) to suggest that the **coefficient of additive genetic variance**, $CV_A = \sigma_A/\mu$ (where μ is the trait mean) is the appropriate scale-free measure for comparing the amount of additive genetic variation across traits. To distinguish this measure from the heritability, Houle coined the term **evolvability** for CV_A (a term that has unfortunately since been co-opted in a number of ill-defined ways by developmental biologists). As a representative sample of *Drosophila* traits illustrates (Table 6.2), traits with low h^2 values can have very high CV_A values. Indeed, in a recent meta-analysis, Hansen et al. (2011) found essentially no correlation between heritability and evolvability.

However, in a survey of over 800 estimates for CV_A from a variety of traits, Houle (1992) found that characters assumed to be closely related to fitness (such as life-history traits) have higher evolvabilities (larger CV_A values) than do traits that are more loosely associated with fitness. Thus, the pattern of trait heritabilities decreasing with their correlation with fitness is not due to smaller additive variances, but instead is caused by larger residual (nonadditive plus environmental) variances, as quantified by the coefficient of residual variation (CV_R).

A study by Kruuk et al. (2000) on Scottish red deer (*Cervus elaphus*) offers some additional insight. The authors estimated components of additive genetic, maternal, and residual variances from pedigree data for this wild population (on the Isle of Rum in Scotland) for five life-history and three morphological traits in addition to lifetime fitness. As shown in Figure 6.4, they also found heritabilities to be negatively correlated with fitness, whereas the coefficient of additive genetic variance CV_A , was *positively* correlated with fitness in males (but negatively correlated in females). Moreover, CV_A values were higher for life-history traits than for morphological traits, and the coefficient of residual variation CV_R was also positively correlated with fitness. Similar patterns of both CV_A and CV_R being positively correlated with fitness have been seen in the seed beetle *Callosobruchus maculatus* (Messina 1993), in an Alberta population of bighorn sheep (Coltman et al. 2006), in the perennial herb *Ipomopsis aggregata* (Campbell 1997), and in natural bird populations (collared flycatchers by Merilä and Sheldon 2000; great tits by McCleery et al. 2004). For these studies, high residual variance, not low σ_A^2 , accounts for the observed lower h^2 values for traits related to fitness. Conversely, while Teplitsky et al. (2009) also observed lower heritabilities for fitness-related traits in red-billed gulls, both higher residual variance *and* lower additive variance accounted for their trend.

What accounts for the higher coefficients of additive variance in traits associated with fitness? The prediction of lower additive variance in fitness-related traits is based on the notion that σ_A^2 is removed by selection. However, the loss of variation is partly countered

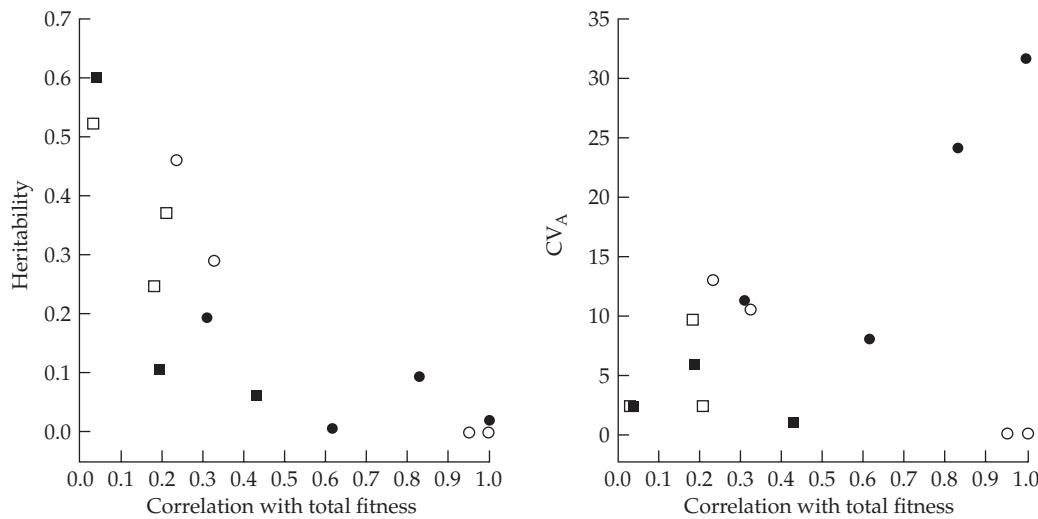

Figure 6.4 Kruuk et al.'s (2000) study of life-history and morphological traits in the Scottish red deer (*Cervus elaphus*). Circles denote life-history traits, squares morphological traits. Filled symbols are for males, open for females. **(Left)** The heritability of a trait is negatively associated with the correlation of that trait with fitness. **(Right)** The coefficient of additive genetic variation CV_A (the square root of the additive genetic variance of a trait divided by the trait mean, here multiplied by 100) is positively associated with fitness in males, and negatively associated with fitness in females.

by new mutational input, leaving some nonzero amount even in the face of strong selection (Chapter 28). If all traits have similar mutational variances, a faster removal of σ_A^2 by selection for the traits that are more closely related to fitness would indeed lead to lower equilibrium levels of additive genetic variance. However, it appears that traits that are more closely associated with fitness actually have *higher* mutational variances (Houle et al. 1996), most likely due to a larger number of loci influencing fitness (Houle 1992; Houle et al. 1996; Merilä and Sheldon 1999).

As with any summary metric, CV_A should be used with a little caution. Garcia-Gonzalez et al. (2012) found that roughly 45% of the studies they examined used incorrect methods in calculating CV_A (the most common being use of the sire variance $\sigma_A^2/4$ in place of σ_A^2 , which results in a two-fold lower estimate). A second issue is that coefficients of variation should only be compared among items with the same dimensions (Lande 1977c). CVs for linear measures tend to be less than those for volumetric measures. Hence, something like body mass might intrinsically have a higher CV_A than some linear morphological trait. These and other issues are discussed by Garcia-Gonzalez et al. (2012), who provide a delta-method approximation (LW Appendix 1) for the standard error of a CV estimate.

A final caveat with these studies is that they examined the correlation between fitness (either total fitness or one of its components) and additive variance of a trait, while Fisher was concerned with the additive genetic variance of *fitness itself*. Estimates of the additive variance in total fitness in natural populations are very rare, as these require estimates of lifetime fitness (not a trivial task; see Chapter 29), further compounded by the difficulty of having to obtain such estimates over a set of relatives. To date, estimates of the additive variation associated with lifetime reproductive success in natural populations are from vertebrates with extensive known pedigrees. Kruuk et al. (2000) found no evidence for a significant heritability of this trait in red deer. McCleery et al. (2004) found positive, but not significant, estimates in great tits. Merilä and Sheldon (2000) found a significant additive

variance for females and a positive (but not significant) variance for males in collared flycatchers. Teplitsky et al. (2009) found positive (but not significant) variance in females and no variance in males for red-billed gulls (*Larus novaehollandiae*). Blomquist (2010) obtained rather high (~0.4) estimates of heritability for lifetime reproductive success in a free-ranging population of rhesus macaques (*Macaca mulatta*) introduced in 1938 (from India) to a small island in Puerto Rico. Finally, Papaïx et al. (2010) obtained a very low estimate (a posterior mean of 0.02) for heritability of adult survival in the wild for a population of blue tits (*Cyanistes caeruleus*). One issue with all of these studies is the expected low power to detect small amounts of variances, so negative results should be viewed cautiously.

Nonadditive Genetic Variance for Traits Under Selection

As selection drives the additive variance in fitness toward zero, any remaining genetic variance is expected to be increasingly composed of nonadditive terms. As Example 6.5 highlights, this nonadditive genetic variance can be considerable. Thus, characters that are more closely associated with fitness are expected to have a higher fraction of nonadditive variance and hence a higher residual variance. This trend can be seen in results from chromosome substitution analysis (Example 6.7), which tend to show epistatic interactions for life-history characters but not for morphological characters (also see LW Table 5.1).

Crnokrak and Roff (1995) examined roughly 340 estimates of dominance variance in both life-history and morphological traits from 17 wild and 21 domestic species. In the wild species, traits assumed more closely connected with fitness (life-history traits) showed significantly higher dominance genetic variation (measured relative to total variance) than did morphological traits. In domesticated species, however, there were no significant differences in dominance genetic variance between life-history and morphological traits. The presumption is that many of the morphological traits examined in the domesticated species were themselves the result of strong recent selection during domestication (and thus, both groups of traits may have been under similar selection). This is supported by the observation that morphological traits in domesticated species showed significantly higher dominance variance than morphological traits in wild species. While certainly not conclusive, these results are consistent with the prediction of higher dominance genetic variance in traits more closely associated with fitness. Ideally, as above, the comparison of the amount of dominance variance should also be examined in terms of the coefficients of variation, as opposed to just the fraction of total variance.

Roff and Emerson (2006) presented a somewhat complementary analysis, using 90 estimates for life-history traits and over 140 estimates for morphological traits from line-cross data. Line-cross analysis examines the components (additive, dominance, etc.) contributing to the between-line divergence, rather than the variance segregating in any particular population (LW Chapter 9), and it is by no means clear if additive variance being driven to zero by selection within populations translates into significant nonadditive contributions to differences between line means. This important caveat aside, Roff and Emerson found that the magnitude of dominance effects (relative to additive effects) in line differences was much greater for life-history traits. Further, epistatic effects were more often detected for life-history traits, and the ratio of total nonadditive effects (dominance plus epistasis) relative to additive effects for life-history traits was roughly double that for morphological traits. Finally, DeRose and Roff (1999) showed that (in animals) inbreeding depression is greater for life-history than morphological traits, indicating higher amounts of directional dominance among segregating alleles for life-history traits (see also LW Chapter 10).

What accounts for the increase in residual variation for traits associated with fitness? One source, as suggested by Price and Schlüter (1991), is higher environmental variance associated with fitness. As we have just seen, a second source is an increase in nonadditive variance. While both factors likely play a role, their relative importance is unknown (Merilä and Sheldon 1999). Due to the difficulty of estimating nonadditive genetic variance components without special mating designs (LW Chapter 20), resolving this question for natural populations is likely to prove quite difficult.

Example 6.7. Mackay (1985b) examined total fitness (measured by competition against a marked balancer stock) of 41 third chromosomes extracted from a natural population of *Drosophila melanogaster*. Using these chromosomes, lines with an otherwise common background could be made homozygous for a particular extracted third chromosome, and likewise the performance of that chromosome as a heterozygote could also be assayed. If there is significant additive genetic variance in fitness, a correlation between homozygote and heterozygote fitness is expected. Such a correlation was found for viability, suggesting some additive genetic variance in this character. However, when total fitness was examined, no correlation was found, suggesting no significant additive variation in total fitness. Mackay observed strong inbreeding depression, consistent with the total genetic variation in fitness being caused by segregation of rare deleterious recessive alleles (LW Chapter 10). A very similar experiment using segregating third chromosomes within a *Drosophila* population selected for domestication, Fowler et al. (1997) and Gardner et al. (2005) found high homozygote-heterozygote correlations for total fitness, and thus significant additive variance in fitness.

ROBERTSON'S SECONDARY THEOREM OF NATURAL SELECTION

In two separate papers, Robertson (1966a, 1968) suggested that the expected response to selection of any trait is a function of the covariance between the breeding value for that trait and relative fitness. Robertson (1968) called this relationship the **secondary theorem of natural selection**. While these two papers are usually jointly cited as the source for this theorem, a more careful reading shows that Robertson proposed two *different* formulae, based on whether the covariance with trait breeding value A_z involves the phenotype (w) or the breeding value (A_w) of relative fitness. As a result, there is confusion in the literature as to the exact form of Robertson's secondary theorem.

1968 Version: $R_z = \sigma_A(w, z)$

We first consider Robertson's (1968) version, as it is widely used in the population-genetics literature (e.g., Crow and Nagylaki 1976; Nagylaki 1992b). Robertson's (1968, p. 13) paper does not contain either a proof or a formal expression, just the clear statement that "The secondary theorem of natural selection states that the change in any character produced by a selection process is equal to the additive covariance between fitness and the character itself." In equation form,

$$R_z = \sigma_A(w, z) = \sigma(A_w, A_z) \quad (6.24a)$$

The expression $\sigma_A(w, z)$, which is shorthand for the covariance between the breeding values for the trait and relative fitness $\sigma(A_w, A_z)$, is often called the **Robertson covariance**. The term *secondary theorem* is reasonable for this version, as it directly follows from Fisher's fundamental theorem, using a simple regression argument (Falconer 1985). The expected change in a trait is given by its change in mean breeding value, ΔA_z , which in turn is the change in the breeding value of relative fitness, $R_w = \Delta A_w$ times the regression of the trait breeding value A_z given A_w , or

$$R_z = \Delta A_z = \beta_{A_z|A_w} \Delta A_w \quad (6.24b)$$

From standard regression theory (LW Chapter 3), the slope of the regression of A_z on A_w is simply

$$\beta_{A_z|A_w} = \frac{\sigma(A_w, A_z)}{\sigma^2(A_w)} \quad (6.24c)$$

Likewise, under the fundamental theorem (Equation 6.17c), $\Delta A_w = \sigma^2(A_w)$. Substituting

these two results into Equation 6.24b recovers Robertson's 1968 version of his theorem,

$$R_z = \left(\frac{\sigma(A_w, A_z)}{\sigma^2(A_w)} \right) \sigma^2(A_w) = \sigma(A_w, A_z)$$

1966 Version: $R_z = \sigma(w, A_z)$

Although Robertson coined the term “secondary theorem” in his 1968 paper, a careful reading of Robertson’s rather opaque 1966 paper suggests that his original result arose as a natural extension of the Robertson-Price identity, with

$$R_z = \sigma(w, A_z) \quad (6.25a)$$

Equation 6.10 shows that the within-generation change in the mean of a trait z is simply $\sigma(w, z) = S$. If one takes z as the breeding value of the trait, the Robertson-Price identity yields Equation 6.25a as the within-generation change in the breeding value of the trait caused by selection, and hence the expected response in the next generation when the average parental breeding value predicts the mean of their offspring. Equation 6.25a is widely used in evolutionary quantitative genetics (e.g., Lande 1976; Frank 1997), and is closely connected with the breeder’s equation.

To see this connection, taking the regression of breeding value on phenotype as $A_z = h^2(z - \mu) + e_A$ and substituting into Equation 6.25a yields

$$R_z = \sigma[w, h^2(z - \mu) + e_A] = h^2\sigma(w, z) + \sigma(w, e_A) = h^2S + \sigma(w, e_A) \quad (6.25b)$$

and we recover the breeder’s equation when $\sigma(w, e_A) = 0$. Biologically, this last assumption implies that the relative fitness of an individual is uncorrelated with the residual error, e_A , when using their phenotype to predict their breeding value. The covariance, $\sigma(w, e_A)$, can be nonzero if an environmental factor influences both fitness and trait value, in which case the breeder’s equation can fail, while Robertson’s theorem (Equation 6.25a) may still hold. Indeed, as is detailed in Chapter 20, increased attention is being paid to Robertson’s theorem in ecological genetics, as a discrepancy between the predicted response using the breeder’s equation versus that using Robertson’s theorem suggests that the focal trait is not the only target of selection.

Finally, we can connect the two versions of Robertson’s theory by writing the phenotype, w , of relative fitness in terms of its breeding value, A_w , plus a residual, e_w (note that this is different from the residual e_A from Equation 6.25b, which is the error in predicting trait breeding value given trait phenotypic value). Substituting this expression for w in Equation 6.25a yields

$$R_z = \sigma(w, A_z) = \sigma(A_w + e_w, A_z) = \sigma(A_w, A_z) + \sigma(e_w, A_z) \quad (6.25c)$$

showing that while the 1966 version is more general, the two versions (Equations 6.24a and 6.25a) are equal when $\sigma(e_w, A_z) = 0$.

Accuracy of the Secondary Theorem

Formal population-genetic analysis of the secondary theorem is based on the 1968 version, and is very closely related to work on the accuracy of the classical interpretation of Fisher’s theorem. Recall Equation 5.22, which showed the contribution to the selection response in trait z from the k th locus (in the absence of epistasis) as

$$R_{z,k} = 2 \sum_j \alpha_j s_j p_j + \sum_{i,j} \delta_{ij} p_i s_i p_j s_j$$

where α_j is the average effect of allele i , δ_{ij} the dominance deviation associated with alleles i and j , and all terms relate to the values for locus k . The first sum is the expected product of

the average effect, α_j , of an allele on character value and the average excess, s_i , of that allele on relative fitness. Recall that the definition of a covariance is $\sigma(x, y) = E(xy) - E(x)E(y)$, and note that the first term above is simply $2E(\alpha_j s_j)$. Because (by definition), $E(\alpha_j) = 0$, the first sum is thus the covariance between α_j and s_j , in other words, the additive genetic covariance between relative fitness and the focal trait. Summing over all loci, we can express Equation 5.22 as

$$R_z = \sigma_A(z, w) + B \quad (6.26)$$

If the character has no dominance (all $\delta_{ij} = 0$), the correction term, B , vanishes, recovering Robertson's original suggestion. Even if dominance is present, in the absence of epistatic variance, the error in the secondary theorem becomes increasingly small as the number of loci increases (Example 5.12).

The most general statement on the validity of Robertson's 1968 version, which is from Nagylaki (1992b, 1993), assumes weak selection on the underlying loci and random mating but allows for arbitrary epistasis and linkage disequilibrium. Similar to his weak selection analysis of Fisher's theorem discussed above, Nagylaki showed that after a sufficient time, the change in mean trait value is given by

$$R_z = \sigma_A(z, w) + O(s^2) \quad (6.27)$$

As with the fundamental theorem, when gametic frequencies approach their equilibrium values, terms of order s^2 may become significant and the mean response may differ significantly from Robertson's prediction, but again, the bulk of evolutionary change likely occurs before the equilibrium value is approached too closely. Consequently, the amount of change during the final approach to the equilibrium is generally expected to be quite small, so (as with the fundamental theorem), Robertson's theorem holds for the bulk of evolutionary change under weak selection on the underlying loci.

Connecting Robertson's Results With Those of Price, Fisher, and Lush

As we have shown, Robertson's 1968 version directly follows from the classical version of Fisher's theorem, while his 1966 version easily recovers the breeder's equation. Recall that we also showed that the breeder's equation (introduced by Lush 1937) recovers the classical version of Fisher's theorem (Equation 6.17b). All that remains is to consider how Robertson's results fit with Price's theorem.

If we let z in Equation 6.7b denote the breeding value of the trait of interest, the between-generation change in the mean breeding value for our focal trait is

$$\begin{aligned} \Delta \bar{A}_z &= \sigma(w, A_z + \bar{\delta}) + E(\bar{\delta}) \\ &= \sigma(w, A_z) + \sigma(w, \bar{\delta}) + E(\bar{\delta}) \end{aligned} \quad (6.28)$$

Since we are following breeding values, $\bar{\delta}$ represents the difference between parent and offspring breeding values. As with our analysis of Fisher's theorem within the Price equation framework, if parental breeding values exactly predict mean offspring breeding values ($\bar{\delta} = 0$), Equation 6.28 reduces to $R_z = \sigma(w, A_z)$. In this setting, Robertson's (1966a) version (Equation 6.25a) naturally follows from Price's theorem, and holds exactly. When parental breeding values are good predictors of mean offspring breeding value, meaning that $\bar{\delta}$ is not zero but is still small, then Roberston's (1966a) theorem is a good approximation for the response to selection. If we write $w = A_w + e_w$, Equation 6.28 becomes

$$\begin{aligned} \Delta \bar{A}_z &= \sigma(A_w + e_w, A_z) + \sigma(w, \bar{\delta}) + E(\bar{\delta}) \\ &= \sigma(A_w, A_z) + \sigma(e_w, A_z) + \sigma(w, \bar{\delta}) + E(\bar{\delta}) \end{aligned} \quad (6.29)$$

which recovers Robertson's 1968 version (Equation 6.25a), provided that the last three terms are zero (or else are very small relative to the first term).

THE BREEDER'S EQUATION FRAMED WITHIN THE PRICE EQUATION

The breeder's equation forms the backbone for much of the theory of selection response in quantitative genetics (Chapters 13–20). Almost all of the theory of breeding is framed around it, as is much of evolutionary quantitative genetics, although Robertson's secondary theorem has been gaining some recent traction in studies in natural populations (reviewed in Chapter 20). As these results show, the breeder's equation is an approximation, with a linear parent-offspring regression as a necessary, but not sufficient, condition (Example 6.1). When viewed in a population-genetic framework, Example 5.12 showed that the breeder's equation is generally a fairly good approximation under weak selection on each of the loci underlying a trait. Conversely, as highlighted in Example 6.3, the performance of the breeder's equation can be compromised if there are major genes, especially if they display dominance. Here we conclude our discussion on theorems of selection by expanding upon our earlier discussion (Equations 6.12 and 6.13) to fully place the breeder's equation into the exact Price equation framework.

Equation 6.12 shows that when the parent-offspring regression is linear, the expression for selection response reduces to the breeder's equation plus two correction terms. What can be said if we make no assumptions about the functional form of this regression? The most general solution is **Heywood's decomposition** (2005), which we build up to after introducing the partial covariance and the effect of the reference population on the parent-offspring regression. Based on the Price equation, Heywood's decomposition yields components with biologically meaningful interpretations that go beyond simply being mathematically convenient correction terms. A key point from this decomposition was foreshadowed in Example 6.3—it is the parent-offspring regression *after*, as opposed to before, selection that is more appropriate for predicting the response to selection.

Partial Covariance and the Spurious Response to Selection

To express the selection response in terms of the Price equation, as done above, let z_i denote the phenotypic value of the i th parent whose relative fitness is w_i and whose offspring have mean value \bar{z}_i and, hence, a parent-offspring deviation $\bar{\delta}_i = \bar{z}_i - z_i$. Equation 6.7c shows the general expression for response as

$$R_z = \sigma(w_i, \bar{z}_i) + E(\bar{\delta}_i) \quad (6.30a)$$

Heywood's key insight is that Equation 6.30a can be decomposed into contributions from two biologically interpretable linear regressions and their corresponding residuals. The first regression involves offspring (\bar{z}_i) and parental (z_i) values

$$\bar{z}_i = \mu + \beta_{\bar{z}|z} z_i + e_{\bar{z},i}, \quad \text{where } \beta_{\bar{z}|z} = \frac{\sigma(\bar{z}_i, z_i)}{\sigma_z^2} \quad (6.30b)$$

The second is the regression of relative fitness w_i of a parent i on its phenotypic value z_i

$$w_i = 1 + \beta_{w|z} z_i + e_{w,i}, \quad \text{where } \beta_{w|z} = \frac{\sigma(w_i, z_i)}{\sigma_z^2} = \frac{S}{\sigma_z^2} \quad (6.30c)$$

It is important to stress that we are *not* assuming that the *true* relationship between either the mean offspring value \bar{z}_i or paternal fitness w_i and paternal phenotype value z_i is linear, but rather simply considering the best linear regression for these relationships and the resulting residuals.

A key feature of Heywood's decomposition concerns the covariance $\sigma(e_w, e_{\bar{z}})$ between the residuals of these two regressions. As developed in Example 6.8, the covariance among the residuals for two variables regressed on a third is as known as the **partial covariance** between two variables (here w_i and \bar{z}_i) given a third (here z_i), which is denoted as

$$\sigma(e_w, e_{\bar{z}}) = \sigma(w, \bar{z} || z) \quad (6.31a)$$

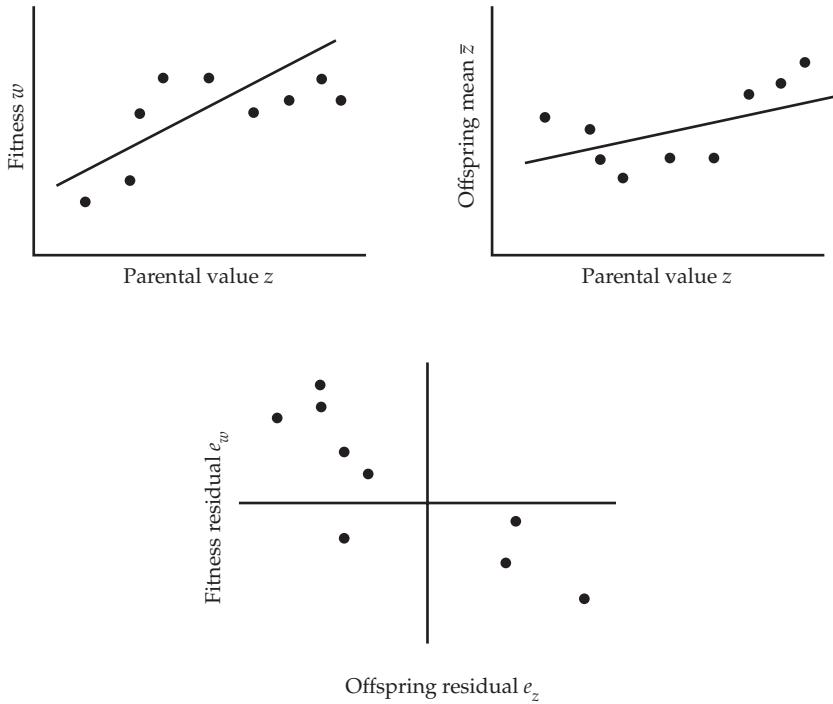

Figure 6.5 The partial covariance, $\sigma(w, \bar{z} || z)$, is the covariance $\sigma(e_w, e_{\bar{z}})$ between the residuals ($e_{\bar{z}}$) of the linear regression of \bar{z}_i on z_i (the parent-offspring regression; Equation 6.30b) and the residuals (e_w) of the linear regression of w_i on z_i (fitness-phenotype regression; Equation 6.20c). In this example, both of these relationships are nonlinear, resulting in the distribution of residuals for the best fitting linear regression being nonrandomly distributed. A plot of these residuals against each other shows a strong negative covariance, so while $\sigma(w, z)$, $\sigma(\bar{z}, z)$, and $\sigma(w, \bar{z})$, are all positive, $\sigma(w, \bar{z} || z)$ is negative.

As shown in Example 6.8 (Equation 6.33f), we can write

$$\begin{aligned}\sigma(w, \bar{z}) &= \sigma(w, \bar{z} || z) + \beta_{\bar{z}|z} \sigma(w, z) \\ &= \sigma(w, \bar{z} || z) + \beta_{\bar{z}|z} S\end{aligned}\quad (6.31b)$$

Substitution of this expression into Equation 6.30a yields

$$R_z = \beta_{\bar{z}|z} S + \sigma(w, \bar{z} || z) + E(\bar{\delta}) \quad (6.32)$$

Thus, even when the parent-offspring regression is nonlinear, we can express the selection response in trait z as a linear response (breeder's equation) term $\beta_{\bar{z}|z} S$ plus a correction $\sigma(w, \bar{z} || z) = \sigma(e_w, e_{\bar{z}})$ accounting for (among other things) nonlinearity and an additional correction $E(\bar{\delta})$ for transmission. Because $\sigma(w, \bar{z} || z)$ removes the (linear) effect of parental value z_i , on both its offspring mean \bar{z}_i and its own relative fitness, w_i , any residual association between w_i and \bar{z}_i is uncorrelated with z_i and hence uncorrelated with selection on the parent. Thus, the response from this component need not be adaptive, leading Heywood to denote $\sigma(w, \bar{z} || z)$ as the **spurious response to selection**.

There are two ways to generate a nonzero $\sigma(w, \bar{z} || z)$. First, both regressions (w_i on z_i and \bar{z}_i on z_i) may be nonlinear, and, as a result, their residuals may be correlated, generating a spurious response (e.g., Figure 6.5). Second, even if one (or both) of these regressions is linear, if both w_i and \bar{z}_i are correlated through an unmeasured variable (such as an environmental

effect), their residuals, after being regressed on z_i , can still be correlated, again generating a potentially spurious response (Chapter 20 examines this process in more detail).

Example 6.8. One can imagine several measures of the residual dependency between two variables (say x and y) once the effects of a third (z) is removed. One is **conditional covariance**, $\sigma(x, y | z)$, defined as the covariance conditioned on the value of z :

$$\sigma(x, y | z) = E \left[(x - E(x|z)) (y - E(y|z)) \mid z \right] \quad (6.33a)$$

Heywood's decomposition uses an alternative measure of dependency, the **partial covariance**

$$\sigma(x, y || z) = \sigma(e_x, e_y) \quad (6.33b)$$

where e_x and e_y are the *residuals* for the linear regression of x on z and of y on z . We use the notation $||z$ in place of $|z$ to distinguish between partial and conditional covariances. If the three variables are multivariate normal, the conditional and partial covariances are equal, but generally they differ (Lawrence 1976; Baba et al. 2006).

The partial covariance can be expressed in terms of the various pairwise covariances between the three variables, as follows. The linear regression of x on z can be written as

$$x = \mu_x + \beta_{x|z} z + e_x = \mu_x + \left(\frac{\sigma(x, z)}{\sigma_z^2} \right) z + e_x$$

implying that

$$e_x = x - (\mu_x + \beta_{x|z} z) = x - \mu_x - \left(\frac{\sigma(x, z)}{\sigma_z^2} \right) z \quad (6.33c)$$

with a similar expression for e_y . Substituting these into Equation 6.33b and ignoring the mean terms (which, as constants, do not factor in the covariance) yields

$$\sigma(x, y || z) = \sigma(e_x, e_y) = \sigma \left[x - \left(\frac{\sigma(x, z)}{\sigma_z^2} \right) z, y - \left(\frac{\sigma(y, z)}{\sigma_z^2} \right) z \right]$$

which, by expansion, leads to

$$\begin{aligned} \sigma(x, y || z) &= \sigma(x, y) - \left(\frac{\sigma(x, z)}{\sigma_z^2} \right) \sigma(y, z) - \left(\frac{\sigma(y, z)}{\sigma_z^2} \right) \sigma(x, z) + \left(\frac{\sigma(y, z)}{\sigma_z^2} \right) \left(\frac{\sigma(x, z)}{\sigma_z^2} \right) \sigma_z^2 \\ &= \sigma(x, y) - \frac{\sigma(x, z) \sigma(y, z)}{\sigma_z^2} \end{aligned} \quad (6.33d)$$

The last term can be expressed as either $\beta_{x|z} \sigma(y, z)$ or $\beta_{y|z} \sigma(x, z)$. Applying Equation 6.33d by taking $x = w$ and $y = \bar{z}$ yields

$$\sigma(w, \bar{z} || z) = \sigma(w, \bar{z}) - \frac{\sigma(\bar{z}, z)}{\sigma_z^2} \sigma(w, z) = \sigma(w, \bar{z}) - \beta_{\bar{z}|z} \sigma(w, z) \quad (6.33e)$$

Rearranging this last expression yields

$$\begin{aligned} \sigma(w, \bar{z}) &= \sigma(w, \bar{z} || z) + \beta_{\bar{z}|z} \sigma(w, z) \\ &= \sigma(w, \bar{z} || z) + \beta_{\bar{z}|z} S \end{aligned} \quad (6.33f)$$

which is used to obtain Equation 6.32.

Parent-Offspring Regressions Before and After Selection

The second feature leading to Heywood's decomposition concerns the reference population for the parent-offspring regression. A subtle but important point to stress about Equation 6.32 is that $\beta_{\bar{z}|z}$ is the slope of the regression of offspring mean on parental phenotypes *following* selection. This slope may be different from the regression based upon unselected parents. In particular, when considering a *single* parent-offspring (as opposed to a midparent-offspring) regression, selection can change the mean of the offspring by changing the distribution of genotypes for the other parent with which the parent mates.

To see this point, suppose a single locus determines the trait of interest, and the selected parent chosen has genotype Aa . If the frequency of A before selection was $1/4$, then the expected offspring frequencies when this parent is randomly mated to an unselected random parent (and hence a $1/4$ chance of an A and a $3/4$ chance of an a) are $(1/8)$ AA , $(1/2)$ Aa , and $(3/8)$ aa , and these frequencies determine the trait value in the offspring from this parent. Now suppose that selection changes the frequency of A to 0.35 . The resulting offspring frequencies when our Aa parent is now crossed to a random parent from the selected population become 0.175 AA , 0.5 Aa , and 0.325 aa , resulting in a different mean offspring value for this parent versus that when crossed to an unselected parent. When the allele-frequency change is very small (as would occur with weak selection on each underlying locus), these two regressions are very similar. However, when a gene of large effect is under selection, the regression using selected versus unselected parents can be different (Example 6.3).

Thus, the single-parent-offspring regression can change between selected and unselected populations, as the mate is not specified. This is *not* the case when we take the unit to be the midparent, because, given the genotypes of both parents, their distribution of offspring is fully determined, independent of the frequency of other genotypes in the population. The same is true for parents that asexually reproduce or that self.

Thus, when considering single parents, Equation 6.32 needs to be modified to account for the possibility that the mean offspring from this parent is influenced by the distribution of other parents after selection. To do so, let \bar{z}_i and \bar{z}_i° denote the offspring mean from parent i when mated to parents from selected and unselected populations, respectively. Given that Equation 6.32 is expressed in terms of \bar{z}_i , following Heywood, we wish to translate this equation into an expression involving \bar{z}_i° (the offspring means of the parents in the absence of selection). To do so, we define $\delta_i^\circ = \bar{z}_i - \bar{z}_i^\circ$ as the difference in the offspring means for parent i when crossed to selected versus unselected parents. Because $\bar{z}_i = \bar{z}_i^\circ + \delta_i^\circ$

$$\sigma(\bar{z}_i, z_i) = \sigma(\bar{z}_i^\circ + \delta_i^\circ, z_i) = \sigma(\bar{z}_i^\circ, z_i) + \sigma(\delta_i^\circ, z_i) \quad (6.34)$$

Thus

$$\beta_{\bar{z}|z} = \frac{\sigma(\bar{z}, z)}{\sigma_z^2} = \frac{\sigma(\bar{z}^\circ, z) + \sigma(\delta^\circ, z)}{\sigma_z^2} = \beta_{\bar{z}^\circ|z} + \frac{\sigma(\delta^\circ, z)}{\sigma_z^2} \quad (6.35)$$

Equation 6.35 relates the parent-offspring regressions using unselected ($\beta_{\bar{z}^\circ|z}$) versus selected ($\beta_{\bar{z}|z}$) parents.

The same logic leading to Equation 6.33f (Example 6.8) can be used to obtain two useful identities:

$$\sigma(w, \bar{z}^\circ) = \sigma(w, \bar{z}^\circ || z) + \beta_{\bar{z}^\circ|z} \sigma(w, z) \quad (6.36a)$$

and

$$\sigma(w, \bar{z} || z) = \sigma(w, \bar{z}^\circ || z) + \sigma(w, \delta^\circ) - \frac{\sigma(\delta^\circ, z) \sigma(w, z)}{\sigma_z^2} \quad (6.36b)$$

Finally, while $\bar{\delta}_i$ is often considered to be the change from parent to offspring in the absence of selection, this is not strictly correct. Formally, it has two components,

$$\bar{\delta}_i = \bar{z}_i - z_i = (\bar{z}_i^\circ + \delta_i^\circ) - z_i = \delta_i^\circ + (\bar{z}_i^\circ - z_i) \quad (6.37)$$

Table 6.3 Terms in Heywood's (2005) decomposition of response and their biological interpretations. See the text for further details.

Term	Heywood's Interpretation
βS	Linear response to selection. Breeder's equation analog.
$\sigma(w, \bar{z}^\circ \parallel z)$	Spurious response to selection. Nonadaptive response to selection (i.e., uncorrelated with selection on the parent).
$E(\delta^\circ)$	General induced transmission bias. Difference between offspring mean when the selected parent is crossed to a selected vs. unselected individual.
$\sigma(w, \delta^\circ), \sigma(w, \delta^\circ \parallel z)$	Special induced transmission bias. Covariance between parental fitness and difference in offspring mean when a parent is crossed to a selected vs. unselected individual. Which version is used depends on whether regression is based on selected (Equation 6.40) or unselected (Equation 6.39) parents.
$E(\bar{z}^\circ - z)$	Constitutive transmission bias. Change in offspring mean in unselected individuals.

Hence

$$E(\bar{\delta}_i) = E(\delta_i^\circ) + E(\bar{z}_i^\circ - z_i) \quad (6.38)$$

where $E(\bar{z}_i^\circ - z_i)$, which Heywood calls the **constitutive transmission bias**, is the change from parent to offspring using *unselected* parents. Inbreeding, the decay of linkage disequilibrium, and randomization of correlated environmental effects are all examples of situations with the potential for a nonzero constitutive transmission bias (Chapters 15 and 23). The first component, $E(\delta_i^\circ)$, Heywood's **general induced transmission bias**, is the difference between the offspring mean when the parent is crossed to the selected population and the offspring mean when crossed to the unselected population. If the change in genotypic frequencies in the selected population is small relative to the unselected population, then the general induced transmission bias will be low. This is expected to be the case when the trait is determined by loosely linked loci, each with a small (to very small) effect.

Heywood's Decomposition of Response

We now have all of the components in place for Heywood's decomposition of the selection response. Expressed in terms of a regression using parents before selection ($\beta_{\bar{z}^\circ|z}$), substituting Equations 6.35–6.38 into Equation 6.32 yields

$$R = \beta_{\bar{z}^\circ|z} S + \sigma(w, \bar{z}^\circ \parallel z) + \sigma(w, \delta^\circ) + E(\delta^\circ) + E(\bar{z}^\circ - z) \quad (6.39)$$

Conversely, when expressed in terms of the regression after selection ($\beta_{\bar{z}|z}$), the response is

$$R = \beta_{\bar{z}|z} S + \sigma(w, \bar{z}^\circ \parallel z) + \sigma(w, \delta^\circ \parallel z) + E(\delta^\circ) + E(\bar{z}^\circ - z). \quad (6.40)$$

This is obtained from Equation 6.39, using Equation 6.35 and the identity

$$\sigma(w, \delta^\circ) - \frac{\sigma(\delta^\circ, z) \sigma(w, z)}{\sigma_z^2} = \sigma(w, \delta^\circ \parallel z) \quad (6.41)$$

Equation 6.41 follows, using the same logic leading to Equation 6.31f. Beside the different regression coefficients ($\beta_{\bar{z}^\circ|z}$ vs. $\beta_{\bar{z}|z}$), Equations 6.39 and 6.40 differ in that $\sigma(w, \delta^\circ)$ in Equation 6.39 is replaced by $\sigma(w, \delta^\circ \parallel z)$ when we use the regression on selected parents.

Heywood noted that the last four terms in Equations 6.39 and 6.40 arise because of imperfect transmission of parental to offspring phenotype. If transmission is perfect, then $z_i = \bar{z}_i^\circ = \bar{z}_i$ and $\delta_i^\circ = 0$, and these last four terms are all zero. Heywood pointed out that although all four terms are due to imperfect transmission, they have different causes and can be thought of as logically distinct processes, as is summarized in Table 6.3. In the decomposition given by Equation 6.39, the linear response to selection (βS) is exactly the breeder's equation (assuming that $\beta_{\bar{z}^\circ|z} = h^2$), as the regression coefficient is based on unselected parents. In the version given by Equation 6.32, β is the parent-offspring regression following selection. This regression may change as the fitness scheme changes, while the before-selection regression remains unchanged under any fitness scheme (assuming an unselected base population). Once selection has occurred, the genotypic frequencies in the offspring from selected parents will depart from those in the unselected base population. Hence, the regression based on unselected individuals starting from this new population will likely be different (although perhaps only trivially so) from that in the founding, unselected base population. These issues are examined in Chapters 15, 16, and especially 24–26. See Heywood (2005) for several worked examples using this decomposition.

7

Interaction of Selection, Mutation, and Drift

In recent years, there has been some tendency to revert to more or less mystical conceptions revolving about such phrases as “emergent evolution” and “creative evolution.” The writer must confess to a certain sympathy with such viewpoints philosophically but feels that they can have no place in an attempt at scientific analysis of the problem. Wright (1931)

In the previous chapters, we treated the response to selection as an effectively deterministic process, making the assumption that the stochastic force of random genetic drift is negligible relative to the power of selection, and also ignoring the origin of new variation by mutation. Such an approach often works well when the focus is on short-term evolutionary issues. However, on longer time scales, interactions between selection, mutation, and drift can influence patterns of variation within and among populations in significant and sometimes counterintuitive ways. As all populations are finite in size and all genomes are subject to mutation, such factors must be incorporated into any general theory of evolution. Although the material in this chapter is confined to one- and two-locus systems, the resultant principles provide the basic building blocks for more complex models for the evolution of quantitative traits, which are presented in subsequent chapters.

Generally, mutation and drift, respectively, introduce and remove variation from populations, but selection can have either effect, depending on whether it is directional, stabilizing, or purifying in nature. Of special interest is the degree to which all three forces interact to define the distribution of allele frequencies in an equilibrium population (or more precisely, in a **quasi-equilibrium** population, as with drift there is always some stochastic wandering of allele frequencies around a long-term expectation). One of the key issues considered in the following pages concerns the amount of variation maintained in the face of opposing pressures. We initially address this matter by retaining the assumption of an effectively infinite population size, considering the issue of selection-mutation balance and the fitness load that recurrent mutation always imposes upon a population. We then evaluate the situation in which drift is sufficiently strong to compete with, or even overpower, the effects of selection. The latter issue is of special interest when we consider selection on a quantitative trait, as strong selection at the phenotypic level does not necessarily translate into strong selection on any particular underlying locus (Equation 5.21). We also show that even when they are completely penetrant, only a small fraction of advantageous mutations will be successfully fixed in a population owing to the overwhelming influence of stochastic forces when alleles are rare.

Because the ways in which genes evolve often depend on the background context, we also use this chapter to introduce some key issues regarding the evolution of multilocus systems. First, drawing on results outlined in Chapter 3 for the effects of linkage on the effective population size for a chromosomal region, we explore how this translates into a reduction in the efficiency of selection for advantageous alleles. Second, using compensatory mutations as an entrée into the matter of epistasis, we evaluate the extent to which such pairwise changes are promoted in small vs. large populations. Third, we evaluate the situation in which two or more key mutations are required for a new adaptation, showing that some relatively simple scalings apply to the time to establishment with respect to population sizes and mutation rates.

SELECTION AND MUTATION AT SINGLE LOCI

As discussed in Chapter 5, many of the central questions in population and quantitative

genetics concern the mechanisms responsible for the maintenance of genetic variation in natural populations. Here, we introduce a few classical models for the balance between the opposing forces of mutation and directional selection. Our preliminary focus will be on the simple case of two alleles, as this serves as the foundation for more complex models for the maintenance of quantitative variation, which are covered in Chapter 28.

Consider a locus with an advantageous allele A and a deleterious allele a , which have respective frequencies of $1 - p$ and p . Let μ be the mutation rate from A to a , let v be the rate of back mutation to A , and assume there is selection preceding mutation in each generation, followed by random mating in a population that is effectively infinite in size. From Chapter 5, the new frequency of a after a generation of viability selection is

$$p' = p \frac{W_a}{\bar{W}} \quad (7.1)$$

where W_a is the marginal fitness of a (Equation 5.7b), and \bar{W} is the mean fitness. Letting p'' be the allele frequency following mutation, we then have

$$p'' = (1 - v)p' + u(1 - p') = (1 - \mu - v)p' + \mu \quad (7.2)$$

This follows because $1 - v$ is the fraction of a that remains unchanged following mutation, while a fraction μ of all A alleles (with frequency $1 - p'$) mutate to a . Thus, one generation of the joint action of selection and mutation leads to the new frequency of a

$$p'' = (1 - \mu - v)p \frac{W_a}{\bar{W}} + \mu \quad (7.3)$$

Haldane (1927) was the first to consider the equilibrium allele frequencies that are eventually reached under this model of opposing mutation and selection pressures. If we let the fitnesses of genotypes AA , Aa , and aa be 1 , $1 - hs$, and $1 - s$, respectively, the equilibrium frequencies, \tilde{p} , satisfying $\Delta p = p'' - p = 0$ are given by the solutions of the rather complicated cubic equation

$$(1 - \tilde{p})^3 s(2h - 1) + (1 - \tilde{p})^2 [2 - 3h + \mu h + v(1 - h)] + (1 - \tilde{p})[-s(1 - h) + \mu(1 - hs) + v(1 - 2s + hs)] - v(1 - s) = 0 \quad (7.4)$$

(Bürger 2000). Provided $0 < s < 1$ and $h \leq 0.5$, this expression has a single stable equilibrium and considerable simplification is possible in a number of biologically realistic cases. For example, for the case of neutrality ($s = 0$), the equilibrium is simply defined by the opposing forces of mutation

$$\tilde{p} = \frac{\mu}{\mu + v} \quad (7.5)$$

A situation of special interest concerns the polymorphism maintained by a balance between selection and mutation when allele a is at a selective disadvantage. To simplify the solution, it is generally assumed that back mutation to the advantageous allele is a negligible force. There are several mathematical justifications and one biological justification for such an assumption. First, unless the selection coefficient is small relative to the mutation rate, the frequency of the mutant allele will generally be low enough that back mutation will be a second-order effect. Second, although functional genes may mutate to deleterious alleles through numerous mechanisms, precise back mutations to normal alleles will necessarily be much rarer events, i.e., we expect that $v \ll \mu$. Letting $v = 0$, Equation 7.4 can be reduced to a more manageable quadratic equation, with a solution of

$$\tilde{p} = \frac{(1 + \mu)hs - \sqrt{[hs(1 + \mu)]^2 - 4(1 - 2h)\mu s}}{2(2h - 1)s} \quad (7.6a)$$

assuming $s > \mu$. For the general case of intermediate dominance ($0 < h \leq 1$)

$$\tilde{p} \simeq \frac{\mu}{hs}, \quad \text{provided } h \gg \sqrt{\mu/s} \quad (7.6b)$$

For the extreme situation in which a is a completely dominant deleterious mutation ($h = 1$)

$$\tilde{p} = \frac{\mu}{s} \quad (7.6c)$$

whereas if A is recessive ($h = 0$)

$$\tilde{p} = \sqrt{\frac{\mu}{s}} \quad (7.6d)$$

A number of other special cases were presented in Nagylaki (1992a) and Bürger (2000); for example, $\tilde{p} \simeq 3\mu/s$ for sex-linked recessives.

The multiple-allele version of this model can be obtained in a straightforward manner. Suppose there are k alleles (A_1, \dots, A_k) and let μ_{ij} be the probability that allele A_i mutates to allele A_j . If we let $\mu_i = \sum_{j \neq i} \mu_{ij}$ be the total mutation rate from allele A_i to any other allele, and assuming constant viability selection followed by mutation and then random mating, the allele-frequency change equations become

$$p''_i = \frac{1}{\bar{W}} \left((1 - \mu_i) W_i p_i + \sum_{j \neq i} \mu_{ji} W_j p_j \right) \quad (7.7)$$

where W_i is the marginal fitness of allele A_i (Equation 5.7b). The equilibrium behavior of this system can be quite complex, and with sufficiently strong mutation there will be the possibility that stable cycles exists (Bürger 2000).

Clark (1998) examined a special case of the multiple-allele model in which there is one optimal allele, and all heterozygotes for single mutations have a fitness of $1 - hs$, while heterozygotes for two different mutant alleles have a fitness of $1 - ks$, where k is a measure of complementation between two deleterious alleles (with $k = 0$ implying that each allele compensates for the other allele's deficiencies). Under this model, multiple deleterious alleles are maintained by mutation pressure, and provided $k < 1$, the sum of their frequencies was higher than expected under the two-allele model. The latter result arises as interallelic complementation reduces the magnitude of selection operating on mutant alleles when they are jointly present in the same genotype.

Example 7.1. How much variation can mutation maintain when a mutant allele is lethal ($s = 1$)? The equilibrium frequency of a dominant lethal allele is

$$\tilde{p} = \mu$$

(Equation 7.6b), whereas for a recessive lethal

$$\tilde{p} = \sqrt{\mu}$$

(Equation 7.6c). Thus, because $\mu \ll 1$ (Chapter 3), recessive lethals are expected to be much more common than dominant lethals, a pattern that is seen for numerous human genetic disorders (Cavalli-Sforza and Bodmer 1971). Drawing from a tradition starting with Haldane (reviewed in Nachman 2004), these expressions are often used to estimate the lethal mutation rate for monogenic human diseases under the assumption that the observed allele frequencies are at mutation-selection equilibrium (e.g., Kondrashov 2003).

For a dominant lethal, the frequency of selected individuals in the equilibrium population is

$$\text{freq}(aa) + \text{freq}(Aa) = \mu^2 + 2\mu(1 - \mu) \simeq 2\mu$$

whereas for a recessive, the frequency of selected individuals is

$$\text{freq}(aa) = (\sqrt{\mu})^2 = \mu$$

Thus, despite the great disparity in allele frequencies for dominant and recessive lethals, when there are low mutation rates, there will only be a two-fold difference in the expected frequencies of affected individuals.

What about the equilibrium mean fitness of the population? With a dominant lethal

$$\overline{W} = \text{freq}(AA) = (1 - \mu)^2 \simeq 1 - 2\mu$$

while for a recessive lethal

$$\overline{W} = 1 - \text{freq}(aa) = 1 - \mu$$

owing to the two-fold lower incidence of affected individuals.

Example 7.2. Albinism in humans is caused by a recessive allele, with an estimated frequency of albinos of around 1/20,000 (Cavalli-Sforza and Bodmer 1971). If we assume that albinos are at a moderate selective disadvantage ($s = 0.1$) and at mutation-selection equilibrium, what is the estimated mutation rate to albino alleles? Assuming genotype frequencies in Hardy-Weinberg equilibrium, so that $\tilde{p}^2 = 1/20,000$, from Equation 7.6c,

$$\tilde{p}^2 = \frac{1}{20,000} = \left(\sqrt{\frac{\mu}{0.1}} \right)^2$$

which implies that $\mu = 5 \times 10^{-6}$. Conversely, if we were to assume a mutation rate of $\mu = 10^{-5}$, the strength of selection against albinism would be inferred from

$$\tilde{p}^2 = \frac{1}{20,000} = \left(\sqrt{\frac{10^{-5}}{s}} \right)^2$$

implying $s = 0.2$, i.e., a 20% reduction of fitness in albinos.

Example 7.3. Our treatment of mutation-selection balance has assumed that there is a single reoccurring allele. For many human diseases, however, a large number of different mutational events can have the same fitness effect, e.g., numerous kinds of mutations can inactivate a gene. In such cases, \tilde{p} is the equilibrium frequency of the entire set of such deleterious alleles. An important question in human genetics is the diversity (or **spectrum**) of alleles within this set—is the disease largely dominated by a single allele or is it a diverse collection of rare alleles?

Hartl and Campbell (1982) found that the probability that two random alleles in the disease class are identical by descent is

$$\varphi = \frac{1}{1 + 4N_e\mu(1 - \tilde{p})} = \frac{1}{1 + \theta(1 - \tilde{p})}$$

where $\theta = 4N_e\mu$, with μ being defined here as the total mutation rate to deleterious alleles. This expression is closely connected to the results on mutation-drift balance presented in Chapter 2, where we showed that $\theta/(1 + \theta)$ is the probability of a heterozygote, and hence $1/(1 + \theta)$

is the probability of a homozygote. To obtain the diversity within the set of disease alleles, here we restrict ourselves to the population of normal alleles, $2N_e(1 - \tilde{p})$, as these are the source of mutations to new disease alleles. At mutation-selection equilibrium, this flux of new mutations is countered by the selective removal of existing alleles. The reciprocal of φ , which asymptotically approaches 1.0 for $\theta \ll 1$, provides an estimate of the effective number of alleles.

Reich and Lander (2001) considered the implication of this result for two equilibrium frequencies of a monogenic disease, rare ($\tilde{p} = 0.001$) and common ($\tilde{p} = 0.2$). Assuming an ancestral human N_e of 10^4 and a total deleterious mutation rate of $\mu = 3 \times 10^{-6}$ (meaning that $\theta = 0.12$), they obtained the effective number of alleles as $\varphi^{-1} = 1 + 0.12 \cdot (1 - 0.001) = 1.12$ and $\varphi^{-1} = 1 + 0.12 \cdot (1 - 0.2) = 1.10$ for the rare and common disease, respectively. Thus, both diseases have a very simple and similar expected allelic spectrum under the historical effective population size. However, as the human population rapidly expanded to 6×10^9 individuals, meaning that currently $\theta = 72,000$, the expected numbers of alleles at equilibrium now become $\varphi^{-1} = 1 + 72,000 \cdot (1 - 0.001) \approx 72,000$, and $\varphi^{-1} \approx 58,000$ for the rare and common diseases, respectively. These spectra are clearly very complex.

Reich and Lander noted that, owing to the rapidity of human population-size expansion, we are still far from having these much higher equilibrium values, and that the transient dynamics of the two disease classes are significantly different en route to their new equilibrium values. The number of new disease alleles arising each generation is $2N\mu(1 - \tilde{p})$, the number of normal alleles times the mutation rate. Because the mutation-selection equilibrium frequency is not changed by the increase in population size, the per-generation turnover within the disease allele class must then scale as $2N\mu(1 - \tilde{p})/(2N\tilde{p}) = \mu(1 - \tilde{p})/\tilde{p}$, which is the fraction of the standing pool of disease alleles that arises on a per-generation basis. With this mutation rate, the turnover amounts to 0.3% per generation for the rare disease and 0.0012% for the common disease.

The fraction of the ancestral disease alleles that remains after t generations following the population expansion is $\exp[-t\mu(1 - \tilde{p})/\tilde{p}]$, which implies a half-life of $\ln(2)\tilde{p}/[\mu(1 - \tilde{p})]$ generations. Assuming a human generation time of 25 years, the ancestral spectrum half-life is $\sim 5,000$ years for the rare disease and $\sim 1.3 \times 10^6$ for the common disease. Hence, under the expected pattern of demographic change in the human population, a common disease should largely retain the ancestral spectrum (very few alleles), while a rare disease should have an increasingly complex one. Consistent with this prediction, Reich and Lander (2001) found a strong negative correlation between the observed frequency of a monogenic disease and its associated number of alleles.

SELECTION AND DRIFT AT SINGLE LOCI

In the preceding section, we assumed that we were examining a situation in which the forces of selection and mutation are powerful enough to ignore the stochastic consequences of random genetic drift, at least in the short term. This deterministic approach to population genetics yields explicit equilibrium solutions for allele frequencies, usually with no oscillatory behavior. In reality, however, drift plays a significant role in all long-term population-genetic contexts. For example, even when selection against deleterious mutations is strong, the defective alleles segregating in a population today will generally be descendants of entirely different mutations than those that segregated many millenia in the past.

All mutations eventually experience one of two alternative fates, complete loss or fixation, and our focus now becomes the latter, specifically the probability that by the spread of its descendants, an allele expands to a total frequency of 1.0. In general, drift reduces the efficiency of selection because the sampling of gametes to form each consecutive generation results in random deviations of allele frequencies from their deterministic expectations based on selection alone. If drift is strong relative to selection, a favored allele may stochastically decrease in frequency, and sometimes, eventually become lost. Throughout the following subsections, we ignore the effects of recurrent mutation, focusing instead on a single specific event—the fate of a preexisting allele or newly arisen mutation.

Most of the theory of the interaction between selection and drift was developed for a single diallelic locus under viability selection, which allows the change in allele frequency per generation to be treated as the sum of changes resulting from selection and drift,

$$\Delta p = \Delta p_s + \Delta p_d$$

where Δp_s is given by Equation 5.1b and 5.1c, and Δp_d (the per-generation change due to drift) is a random variable. Drift causes no directional tendency in the change in allele frequency, and hence $E(\Delta p_d) = 0$. Thus, the simplest measure of the strength of drift is the expected variance in allele-frequency change due to gamete sampling, which, under the standard Wright-Fisher model (Chapter 2), is defined by the binomial distribution

$$\sigma^2(\Delta p_d) = \frac{p(1-p)}{2N_e} \quad (7.8)$$

where p is the allele frequency prior to sampling, N_e is the variance effective population size, and the 2 accounts for diploidy (and is replaced by a 1 for a haploid population; Chapter 3). If $\sigma^2(\Delta p_d)$ is small relative to Δp_s , allele-frequency changes will not be dramatically different from their expectations under selection in an infinite population, but if $\sigma^2(\Delta p_d) > \Delta p_s$, drift can substantially obscure the deterministic force of selection.

Consider the situation in which alleles have additive fitness effects, with the genotypes AA , Aa , and aa having respective fitnesses of 1, $1+s$, and $1+2s$. Letting p be the frequency of allele a , then, from Equation 5.2, $\Delta p_s \simeq s p(1-p)$, assuming weak selection ($|s| \ll 1$). If we compare this result with Equation 7.8, it becomes clear that directional selection dominates drift when $2N_e|s| \gg 1$, whereas drift dominates directional selection when $2N_e|s| \ll 1$.

Because the intensity of drift scales with $1/(2N_e)$, a useful heuristic is that $2N_e s$ approximates the ratio of the power of selection to drift. This argument is not quite precise because the variance of allele-frequency change is only a rough indicator of the sampling properties of the allele-frequency distribution. However, **diffusion theory**, which gives an essentially complete description of the dynamics of a diallelic locus under drift and selection, upholds this general conclusion (Appendix 1). We will frequently encounter the composite parameter, $2N_e s$, in the following paragraphs.

Probability of Fixation Under Additive Selection

There is no possibility of having a perfectly stable polymorphism when drift and selection interact. Indeed, even in the case of overdominant selection (where there is a stable equilibrium in an infinite population; Chapter 5), one allele will eventually drift to fixation unless both homozygotes are lethal. Under this scenario, all new mutations ultimately become either lost or fixed at the population level, and those that become fixed will themselves be subject to replacement by subsequently arising mutations. Thus, when finite populations are considered, we need to think in terms of fixation probabilities and sojourn times of mutations. Even highly favorable alleles have fixation probabilities of less than 1.0 to a degree that depends on the initial frequency p_0 , the strength of selection, and the effective population size N_e .

Suppose we denote by $u_f(p_0)$ the probability that an allele starting at initial frequency p_0 will become fixed. As noted in Chapter 2, under neutrality, the probability of fixation depends only on an allele's initial frequency regardless of population size, so that

$$u_f(p_0) = p_0 \quad (7.9)$$

Depending on the magnitude and direction of selection, this probability will either increase or decrease. When allelic effects on fitness behave additively, such that each copy of allele a changes fitness by s (giving fitnesses of 1, $1+s$, and $1+2s$)

$$u_f(p_0) \simeq \frac{1 - e^{-4N_e sp_0}}{1 - e^{-4N_e s}} \quad (7.10a)$$

$$\simeq p_0 + 2N_e sp_0(1 - p_0) \quad \text{when } 2N_e|s| \leq 1 \quad (7.10b)$$

Equation 7.10a, due to Kimura (1957) with a slightly improved version given by Cash (1977), was derived using diffusion theory in Appendix 1. The simplified version, Equation 7.10b, was developed by Robertson (1960a) using the Taylor series approximation $e^{-x} \simeq 1 - x + x^2/2$ for $|x| \ll 1$, and an alternative derivation is given below. Although these approximations apply to both beneficial ($s > 0$) and deleterious ($s < 0$) alleles, and work especially well with favorable alleles (Carr and Nassar 1970), they can significantly *overestimate* the fixation probabilities of highly deleterious alleles ($N_e s \leq -1$), an issue examined in detail by Bürger and Ewens (1995).

It is critical to note that even when an allele is under strong selection, drift still plays a powerful role when allele frequencies are near zero. Starting with a single copy of an advantageous allele (with frequency $p_0 = 1/(2N)$, where N is the number of reproductive adults in the population), Equation 7.10a implies that the probability of fixation of a new mutation is approximately $2s(N_e/N)$ when $4N_e s \gg 1$. As we expect N_e to generally be $\ll N$ (Chapter 3) and s is typically $\ll 1$, this implies that a newly arisen favorable mutation will usually be lost by drift, no matter how beneficial. However, once the frequency of a strongly beneficial allele becomes sufficiently high, fixation is almost certain. For example, if $N_e s p_0 > 0.5$, the probability of fixation exceeds 0.70, while if $N_e s p_0 > 1$, the probability of fixation exceeds 0.93.

For mutations with a weak effect, it is informative to consider the probability of fixation of a newly arisen mutation relative to the neutral expectation of $1/(2N)$. Returning to Equation 7.10a, and approximating the numerator as $4N_e s p_0$, with $p_0 = 1/(2N)$, the scaled probability of fixation

$$u'_f(p_0) = \frac{u_f(p_0)}{1/(2N)} \simeq \frac{4N_e s}{1 - e^{-4N_e s}} = \frac{S}{1 - e^{-S}} \quad (7.11)$$

is found to be entirely a function of the composite parameter $S = 4N_e s$, which, as noted above, is a measure of the strength of selection (2s in favor of homozygotes) relative to that of drift, $1/(2N_e)$ (Figure 7.1). For positive selection with $S = 0.01, 0.1$, and 1.0 , respectively, $u'_f(p_0) \simeq 1.005, 1.05$, and 1.58 , respectively, whereas with negative selection with the same absolute values, $u'_f(p_0) \simeq 0.995, 0.95$, and 0.58 , respectively. This shows that the fixation probability of a mutant allele will be very close to the neutral expectation of $1/(2N)$ provided $|S| \ll 1$. This domain of **effectively neutrality** is potentially significant in a number of different contexts. For example, populations of sufficiently small size are unable to purge deleterious mutations or promote beneficial mutations with $|s| < 1/(4N_e)$.

A number of other useful approximations for alleles with additive effects on fitness have been derived from diffusion theory. For example, Kimura (1969) found that the average cumulative contribution of a new mutation to the population-level heterozygosity (summed over all generations until it is lost or fixed) is equal to

$$H_T = \left(\frac{4N_e}{N} \right) \left(\frac{S - 1 + e^{-S}}{S[1 - e^{-S}]} \right) \quad (7.12)$$

Although this measure may seem somewhat abstract, the product of H_T times the number of new mutations arising in the population per generation, $2N\mu$, is equal to the expected heterozygosity under selection-mutation-drift equilibrium. For neutral mutations ($S \rightarrow 0$), $H_T \rightarrow 2N_e/N$, implying an expected heterozygosity of $4N_e\mu$ (which, assuming $4N_e\mu \ll 1$, is consistent with results in Chapter 2 that were obtained by a different method). For large positive values of S (strongly beneficial mutations), H_T approaches a limiting value of $4N_e/N$, implying that on a per-mutation basis, such mutations make twice the contribution to the heterozygosity as neutral mutations. Finally, for deleterious mutations with sufficiently strong effects to be eliminated by selection, $H_T \simeq 2/(N|s|)$.

As in the case of the fixation probability, the expected heterozygosity at a locus scaled to the neutral expectation (dividing $2N\mu H_T$ by $4N_e\mu$) is a simple function of S (Figure 7.1). Viewed in this way, it can be seen that although both the relative fixation rate and the

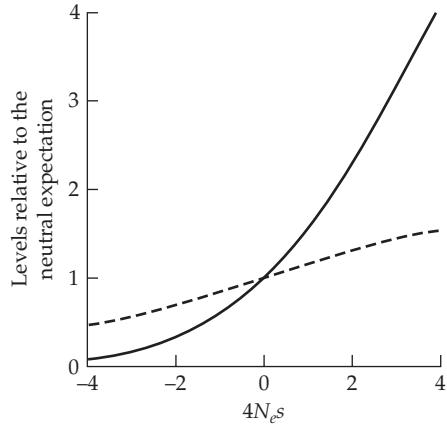

Figure 7.1 Probability of fixation (solid line) and lifetime contribution to heterozygosity (dashed line) of a new mutant allele with additive effects on fitness as a function of $4N_e S$ (using Equations 7.11 and 7.12), both relative to the neutral expectation.

contribution to heterozygosity increase with S , the former responds much more rapidly. This is because deleterious mutations that essentially never fix in a population nevertheless make transient contributions to the heterozygosity prior to their elimination by selection, whereas positively selected mutations that are driven through the population relatively rapidly contribute to heterozygosity for only a relatively short period of time.

A useful approximation for newly arisen mutations with additive effects is that, conditional upon fixation, the expected number of generations spent at frequency x will be

$$\Phi_f(x) = \frac{2N_e(1 - e^{-Sx})(1 - e^{-S(1-x)})}{SNx(1-x)(1 - e^{-S})} \quad (7.13a)$$

where $x = 1/(2N), \dots, (2N-1)/(2N)$ (from Equation 8.66 in Kimura 1983). There are two notable points with respect to this residence-time relationship (Figure 7.2). First, provided $|S| < 1.0$, conditional upon fixation, a new mutant allele will spend approximately $2N_e/N$ generations in each frequency class. Second, the residence-time features of a deleterious mutation en route to fixation are exactly the same as those for a beneficial mutation with the same absolute fitness effects, implying that both have the same mean time to fixation, even though the probability of fixation is lower in the former case. First pointed out by Maruyama and Kimura (1974), this counterintuitive behavior results from the fact that if a deleterious allele is to become fixed, it must do so as a consequence of some fortuitously rapid and extreme sampling errors.

It is also sometimes useful to know the expected residence times of mutations that eventually become lost, $\Phi_l(x)$. From Equation 8.70 in Kimura (1983), the unconditional mean residence time for mutations (regardless of being fixed or lost) is

$$\Phi(x) = \frac{2N_e(1 - e^{-S(1-x)})}{Nx(1-x)(1 - e^{-S})} \quad (7.13b)$$

and using the fact that

$$\Phi(x) = u_f(1/2N) \cdot \Phi_f(x) + [1 - u_f(1/2N)] \cdot \Phi_l(x) \quad (7.13c)$$

yields the residual times conditional upon eventual loss

$$\Phi_l(x) = \frac{N_e e^{Sx} (e^{S(1-x)} - 1)^2}{N^2 x (1-x) (e^S - 1) (e^{S[1-(1/2N)]} - 1)} \quad (7.13d)$$

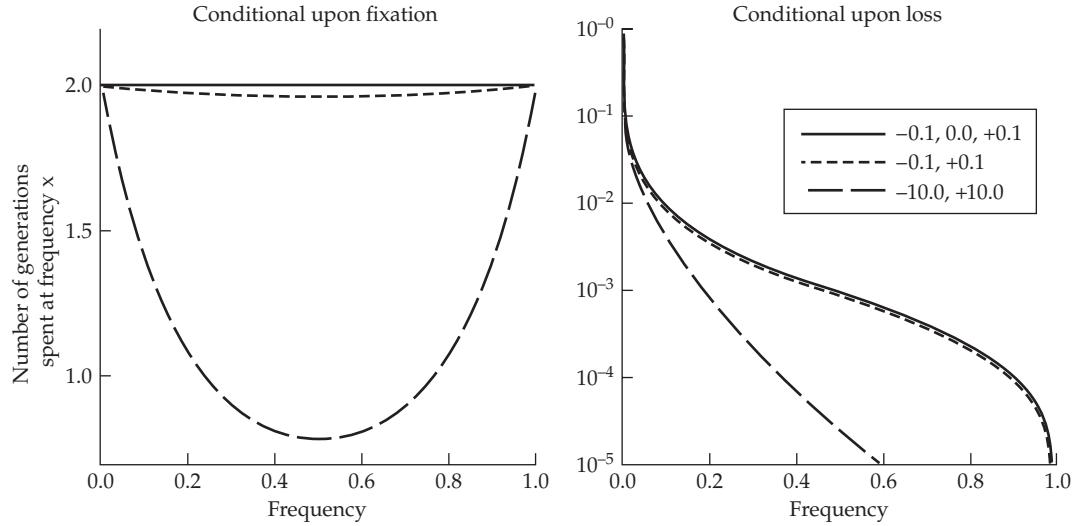

Figure 7.2 Average number of generations that a new mutation spends within different frequency classes, $x = 1/(2N), \dots, (2N-1)/(2N)$, conditional on going to fixation (**Left**) or conditional on being lost (**Right**), given as a function of the scaled selection parameter $S = 4N_e s$ (**inset values**), obtained using Equations 7.13a and 7.13d, with $N = N_e = 1000$. Note that in each case, the results are identical for beneficial and deleterious mutations with the same absolute values of s . With $N_e \neq N$, the results must be multiplied by N_e/N .

Again, we see that the residence times conditional upon loss are essentially the same for positive and negative selection coefficients of the same absolute magnitude (Figure 7.2). This is not true for the unconditional residence times, $\Phi(x)$, which are functions of $\Phi_f(x)$ and $\Phi_l(x)$ weighted by the probabilities of fixation and loss (Equation 7.13c).

For effectively neutral mutations destined to loss, $|S| < 1.0$,

$$\Phi_l(x) \simeq \frac{N_e(1-x)}{N\lambda x} \quad (7.14a)$$

where $\lambda = 1 - [1/(2N)]$, whereas the unconditional residence time is

$$\Phi(x) \simeq \frac{N_e}{Nx} \quad (7.14b)$$

i.e., the average time spent in frequency class x is inversely proportional to x .

The preceding expressions are useful in a number of applications. For example, the mean numbers of generations to fixation, loss, or either (removal of either allele) can be obtained, respectively, by summing Equations 7.13a, 7.13d, and 7.13c over all frequency classes in the interval $[1/(2N), 1 - 1/(2N)]$. Simplifications can be made possible in some cases. For example, as noted above, a neutral mutation that is destined for fixation spends an average of $2N_e/N$ generations in each frequency class, and because there are $2N - 1$ classes, the time to fixation of effectively neutral alleles is essentially $4N_e$ generations, an outcome obtained in Chapter 2 by different means. The conditional time to loss of a neutral mutation is

$$t_l = \frac{2N_e \ln(2N)}{N\lambda} \quad (7.15)$$

(derived in Example A1.8). The mean number of generations until the complete loss of a new mutation with a deleterious heterozygous effect of $s < 0$ is

$$t_l \simeq 2(N_e/N)[\ln(2N/|S|) + 0.423] \quad (7.16)$$

provided $|S| \gg 1$ (Kimura and Ohta 1969b; Nei 1971). More general expressions, which require some numerical integration, can be found in Kimura and Ohta (1969a).

Knowing the mean total number of copies descended from a mutation prior to its loss or fixation is useful in a number of contexts, e.g., determining the total number of individuals affected by a deleterious mutation. This is defined as

$$\bar{n} = \sum_{y=1}^{2N-1} \Phi(y/2N) \cdot y \quad (7.17a)$$

with a shift of the function Φ to Φ_l or Φ_f , leading to the expected numbers conditional on loss or fixation, respectively. For the case of neutral mutations

$$\bar{n} = 4N_e\lambda \quad (7.17b)$$

$$\bar{n}_f = 4N_e N \lambda \quad (7.17c)$$

$$\bar{n}_l = 2N_e\lambda \quad (7.17d)$$

The mean frequency prior to absorption is simply $\bar{n}/(2N)$ divided by the average absorption time.

Example 7.4. Although it is generally thought that selection will increase the determinism of a system, this is not necessarily the case. Cohan (1984b) showed that, starting with identical allele frequencies, the probability of divergence between replicate populations can *increase* relative to the situation under pure drift if the initial frequency of the advantageous allele is sufficiently small. We refer to this phenomenon as the **Cohan effect**. This point can easily be seen as follows. Supposing two replicate populations are segregating alleles A and a at a locus, with the frequency of A being $p = 0.25$, then under pure drift, the probability that one replicate will become fixed for A and the other for a is $2 \cdot 0.25 \cdot (1 - 0.25) = 0.375$. Now suppose that A is favored by selection, with $N_e s = 0.5$. Again assuming $p_0 = 0.25$, Equation 7.10a gives the fixation probability of A as 0.46, implying that the probability of fixing alternative alleles is $2 \cdot 0.46 \cdot 0.54 = 0.496$. Thus, in this case, divergence is substantially *increased* by the interaction between selection and drift.

In general, the probability of fixing alternative alleles in two replicates is $2u_f(p)[1 - u_f(p)]$, which is maximized when $u_f(p) = 1/2$. Thus, the probability of divergence is increased by selection if $u_f(p)$ under selection is closer to $1/2$ than $u_f(p) = p$ under drift; and because $u_f(p) > p$ for a selectively favored allele, a minimum requirement for increased divergence under pan-selection is that the starting frequency of the advantageous allele be $< 1/2$. Figure 7.3 shows that under additive selection, the conditions for the probability of divergence under drift plus selection to exceed that under drift alone are not very restrictive.

The Cohan effect has a number of practical implications. For example, an elevated level of population subdivision for a quantitative trait relative to the neutral expectation is often taken to imply that there are divergent selective regimes across subpopulations (Chapter 12). However, here we see that under identical directional selection pressures, populations that initiate with low-frequency, advantageous alleles can exhibit levels of divergence that are conventionally interpreted as being associated with diversifying selection. Whether allele frequencies, selection coefficients, and drift intensities commonly have the right mixes for uniform selection to enhance the magnitude of phenotypic divergence remains to be seen, but a wide range of conditions appears to yield divergence levels that would be difficult to discriminate from the neutral expectation (Lynch 1986).

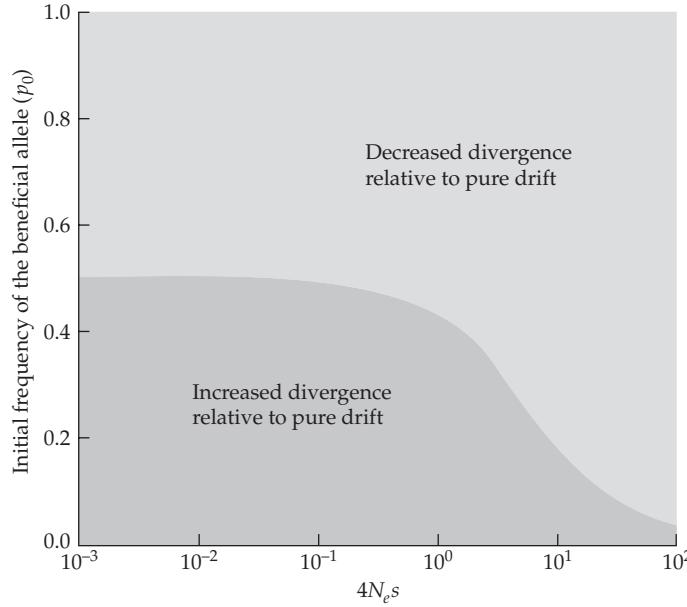

Figure 7.3 The influence of drift on the probability of fixation of alternative alleles in a pair of populations starting from an identical state. A diallelic locus under additive selection with fitnesses 1, $1 + s$, and $1 + 2s$ is considered. The slightly darker shaded area on the lower left is the region of p_0 (the initial frequency of A) and $4N_e s$ space where the probability that isolated populations are eventually fixed for alternative alleles under selection and drift is higher than under drift alone. In this region, parallel selection *increases* the amount of evolutionary indeterminism relative to drift alone.

Probability of Fixation Under Arbitrary Selection

We now consider the more general model, allowing for dominance, with the genotypes aa , Aa , and AA having fitnesses of 1, $1 + sh$, and $1 + 2s$, respectively. Diffusion theory (as developed in Appendix 1) then shows the fixation probability of allele A as

$$u_f(p_0 | s, h) \simeq \frac{\int_0^{p_0} e^{G(x)} dx}{\int_0^1 e^{G(x)} dx} \quad (7.18a)$$

where

$$G(x) = -4N_e s x(h - x) \quad (7.18b)$$

For a new mutant introduced as a single copy, $p_0 = 1/(2N)$, under random mating and at least partial dominance,

$$u_f \left(\frac{1}{2N} \right) \simeq \frac{2N_e sh}{N[1 - e^{-4N_e sh}]} \quad (7.19a)$$

This shows that the probability of fixation of a new mutation is largely determined by the heterozygous effect, as almost all copies of a mutation remain in this state until the allele frequency has achieved a moderately high level. For a complete recessive ($h = 0$), the approximation leading to Equation 7.19a breaks down, and higher-order terms in the approximation of Equation 7.18a are required. However, for strong positive selection on

homozygotes of a completely recessive allele ($4N_e s \gg 1$), a close approximation is given by

$$u_f \left(\frac{1}{2N} \right) \simeq \frac{\sqrt{4N_e s / \pi}}{N} \quad (7.19b)$$

(see Example A1.7 for details).

If there is direct inbreeding due to the mating of close relatives (beyond the amount of long-term inbreeding that is naturally generated by drift), Equation 7.18a will still hold, but now with

$$G(x) = -4N_e s x [2f + (1-f)(h-x)] \quad (7.20a)$$

where f is a measure of the departure of genotypes from Hardy-Weinberg expectations, defined (in Chapter 2) by the frequency of heterozygotes, $2p(1-p)(1-f)$ (Caballero and Hill 1992b). Using Equation 7.18a, the fixation probability now becomes

$$u_f \left(\frac{1}{2N} \right) \simeq \frac{2N_e s [2f + (1-f)h]}{N} \quad (7.20b)$$

(Caballero and Hill 1992b; Caballero 1996), which, for a complete recessive ($h = 0$), reduces to

$$u_f \left(\frac{1}{2N} \right) \simeq \frac{4N_e f s}{N} \quad (7.20c)$$

Thus, with even a small amount of inbreeding, the probability of fixation of a beneficial recessive allele is considerably higher than under random mating (Equation 7.19b) due to the elevated exposure in homozygotes (Caballero et al. 1991). In contrast, inbreeding has much more moderate effects on the fixation probabilities of alleles with additive ($h = 1$) or dominant ($h = 2$) fitness effects. Glémén (2012) showed that inbreeding also speeds up the loss and fixation times of a new allele relative to panmixia.

By indirectly causing localized inbreeding, population subdivision can also influence the probability of fixation. Whitlock (2003) found that, for a wide variety of population structures, the global probability of fixation of a new beneficial mutation is well approximated by

$$u_f \left(\frac{1}{2N} \right) = \frac{2N_e s h (1 - F_{ST})}{N} \quad (7.21)$$

where the effective and total population sizes (N_e and N) are defined at the metapopulation level and F_{ST} is an index of population subdivision (defined as the fraction of metapopulation variation for neutral alleles that is distributed among populations; see Chapter 2). Note that with complete population subdivision ($F_{ST} = 1$), fixation is impossible at the metapopulation level as mutations will be permanently confined to the demes in which they arise.

One cannot immediately infer from Equation 7.21 whether population subdivision will enhance or reduce the probability of fixation because subdivision influences both F_{ST} and N_e . Expressions for effective population sizes under a number of metapopulation structures were presented in Chapter 3, and parallel expressions for F_{ST} can be found in most of the literature cited there. In the case of the ideal island model with symmetric migration between demes and equal contributions of all demes to the entire metapopulation (Chapter 3), $N_e = N/(1 - F_{ST})$, and Equation 7.21 reduces to $2hs$, showing that in this particular case the probability of fixation is independent of the magnitude of population subdivision and simply equal to twice the selective advantage in heterozygotes (Maruyama 1970). Analyses of more complex population structures (Slatkin 1981b; Barton 1993) are all special cases of Whitlock's (2003) expression provided the assumption of equal deme productivity is met; and the modifications that are necessary when this condition is violated were developed by Whitlock (2003) as well. The more complex situation in which the strength of selection varies among demes was taken up by Whitlock and Gomulkiewicz (2005).

Otto and Whitlock (1997) provided results for fixation probabilities in populations of changing size, and showed that selection is more effective in growing populations (increasing the probabilities that favorable alleles will be fixed and that deleterious alleles will be lost) than in declining populations. This result has obvious implications for managed populations. Fortunately, the limiting expression for the fixation probability of alleles with additive effects (given above as $2sN_e/N$) applies to populations that are changing in size, provided appropriate modifications are made in the definition of N_e (Otto and Whitlock 1997). The much more complex issue of jointly varying population sizes and selection coefficients was taken up by Uecker and Hermisson (2011). Finally, a number of additional diffusion results are given for a diallelic locus in Appendix 1, but simple expressions are generally unavailable for multiple alleles.

Fixation of Overdominant and Underdominant Alleles

A case of special interest is the effect of drift on a locus experiencing selective overdominance, where the heterozygote has higher fitness than either homozygote. Whereas such balancing selection permanently maintains both alleles in an infinite population (Example 5.4), drift will ultimately fix one allele in a finite population provided that the homozygote has a nonzero fitness. Although it might seem that balancing selection will always magnify the longevity of a polymorphism, contrary to intuitive expectations, selection sometimes increases the rate of fixation at an overdominant locus in a finite population (Robertson 1962; Ewens and Thomson 1970; Chen et al. 2008).

If the equilibrium frequency expected in an infinite population is extreme (roughly $\tilde{p} < 0.2$ or $\tilde{p} > 0.8$), a polymorphism starting at \tilde{p} in a finite population will usually be lost *more rapidly* under balancing selection than under drift alone, thereby accelerating the removal of heterozygosity. Such behavior arises because selection keeps allele frequencies fairly close to their equilibrium values. If such values are near 0.0 or 1.0, the minor allele will be impeded from drifting to more protective states of moderate frequencies, thereby increasing the likelihood of loss by drift.

Nei and Roychoudhury (1973) evaluated this issue further with newly arisen overdominant alleles with an initial frequency of $1/(2N)$. In this case, the mutant allele is initially confined to the heterozygous state, so its early fate is largely independent of its own homozygous effect, but highly dependent on the magnitude of its heterozygous advantage over the ancestral homozygote. Fixation probabilities can only be obtained by numerical analysis in this case, but the results depend only on two parameters, $N_e(s_1 + s_2)$ and the infinite-population equilibrium frequency, $\tilde{p} = s_2/(s_1 + s_2)$, where s_1 and s_2 are, respectively, the selection coefficients against the homozygotes associated with the mutant and resident alleles. If \tilde{p} for the derived allele under consideration is much less than 0.5, the fixation probability is less than the neutral expectation, for the reasons already noted. However, if $\tilde{p} > 0.5$ (meaning that the fitness of the ancestral homozygote is lower than that of the mutant homozygote), the fixation probability will always be greater than the neutral expectation, even though fixation results in the loss of the optimal (heterozygous) genotype. Moreover, in this case, the fixation probability of the mutant allele is only slightly smaller than that predicted by Equation 7.10a when s_2 is used as a selection coefficient (Nei and Roychoudhury 1973). If $2N_e(s_1 + s_2) \ll 1$, selection will be uniformly overpowered by drift, and the system will behave in an effectively neutral fashion.

The fixation times for newly arisen overdominant mutations parallel the patterns of loss of variation that Robertson (1962) first noted (Nei and Roychoudhury 1973). When the equilibrium frequency is outside of the range of (0.2, 0.8), the mean fixation time will be lower than the neutral expectation of $4N_e$ generations, whereas for $0.2 < \tilde{p} < 0.8$, the time is elevated, with more extreme behaviors seen at high values of $N_e(s_1 + s_2)$ (Figure 7.4). Particularly intriguing is the fact that the fixation time of an overdominant mutation will be symmetrical around $\tilde{p} = 0.5$, i.e., for a given strength of selection $N_e(s_1 + s_2)$, the time to fixation is the same at equilibrium frequencies \tilde{p} and $1 - \tilde{p}$. This is consistent with the situation for mutants with additive effects that was already noted, and indicates that when an overdominant

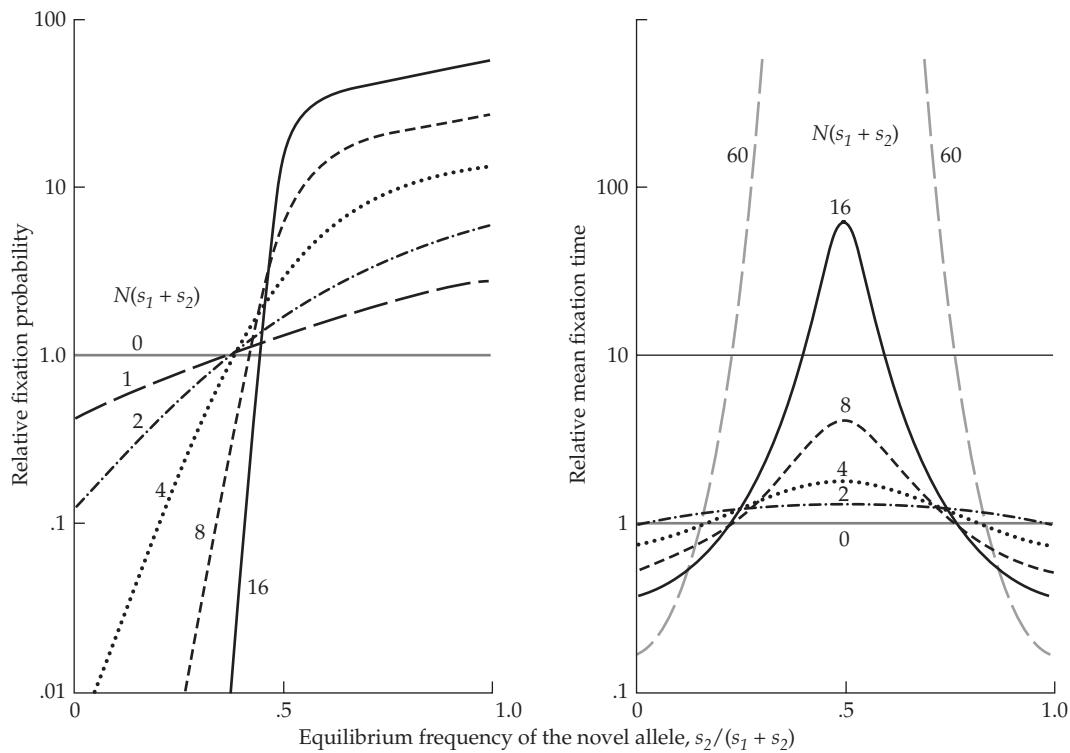

Figure 7.4 Ratios for the fixation probabilities and expected times to fixation for a newly arisen overdominant mutation relative to the expectation for a neutral mutation. These are given as a function of the equilibrium frequency expected in a population of infinite size, $\tilde{p} = s_2/(s_1 + s_2)$, where the fitnesses are $1 - s_1$, 1, and $1 - s_2$ (with the first value being the fitness for the mutant homozygote). Each curve gives results for a different value of $N_e(s_1 + s_2)$, a measure of the ratio of the overall power of selection to drift, where N_e is the effective population size. For any value of $N_e(s_1 + s_2)$, the probability of fixation increases with the magnitude of selection against the alternative homozygote, as this defines the selective advantage of the novel allele in the heterozygous state. (From Nei and Roychoudhury 1973.)

mutant allele is associated with the least fit homozygous type, for the rare occasions in which fixation occurs, it does so just as rapidly, on average, as when it is associated with the most fit homozygote (in which case it also fixes more frequently). Further considerations for the situation in which populations are subdivided were given in Nishino and Tajima (2004).

Important situations also exist in which a new mutation will be underdominant with respect to the ancestral allele, i.e., will have reduced fitness when in the heterozygous state, but equal or higher fitness as a homozygote. In an infinite population, such an allele will always be driven from the population if its marginal fitness at low frequency is less than that of the ancestral allele (Chapter 5). In a finite population, however, there is some chance that the mutant allele might drift to a high frequency, transiently taking the population through a reduction in mean fitness (during the period in which heterozygotes are common), but possibly eventually becoming fixed.

Such a scenario has generated considerable interest in the area of speciation biology, as the fixation of an underdominant mutation in a subpopulation will lead to a situation in which hybrids between subpopulations have reduced fitness. In principle, such a condition can constitute the first stage in the development of reproductive isolation.

For the situation in which the two homozygotes have equal fitness and heterozygotes experience a reduction in fitness of s , Lande (1979b) found that if $sN_e/N \ll 1$ (a condition

likely to be met based on empirical information on N_e/N ; Chapters 3 and 4), then

$$u_f(1/2N) \simeq \frac{\sqrt{N_e s / \pi}}{N \cdot e^{N_e s} \cdot \operatorname{erf}(\sqrt{N_e s})} \quad (7.22)$$

where the **error function**

$$\operatorname{erf}(x) = (2/\sqrt{\pi}) \int_0^x e^{-y^2} dy \quad (7.23)$$

is the cumulative frequency of a unit normal (Abramowitz and Stegun 1972). If the efficiency of selection is sufficiently low ($N_e s \ll 2$), then $u_f(1/2N) \simeq 1/(2N)$, as expected for an effectively neutral allele. However, if the efficiency of selection is high ($N_e s > 2$), so that $\operatorname{erf}(\sqrt{N_e s}) \simeq 1$, then

$$u_f(1/2N) \simeq \frac{\sqrt{N_e s / \pi}}{N e^{N_e s}} \quad (7.24)$$

Of special interest in the study of speciation are chromosomal rearrangements that cause problems during meiosis in chromosomal heterozygotes, with values of s as large as 0.5 being quite plausible (Lande 1979b, 1984b). With $N_e s = 2, 5$, and 10, Equation 7.24 predicts fixation rates that are, respectively, 0.22, 0.017, and 0.00016 times the neutral expectation. Such results imply that if heterozygote fitness is greatly reduced, transitions to alternative allelic states (with equivalent homozygous fitness) will only be possible if N_e is extremely small. However, when such fixations do occur, they proceed much more rapidly than the neutral expectation of $4N_e$ generations (Lande 1979b).

Walsh (1982) generalized these results to the situation in which the fitness in the novel homozygote is elevated to $1+t$, such that after passage through a fitness bottleneck, fixation of the underdominant allele leads to an increase in mean population fitness. Letting $\theta = N_e s$, and $\omega = 1 + (t/2s)$

$$u_f(1/2N) = \frac{\operatorname{erf}\{[(1/2N) - (0.5/\omega)]\sqrt{4\theta\omega}\} + \operatorname{erf}\{\sqrt{\theta/\omega}\}}{\operatorname{erf}\{[1 - (0.5/\omega)]\sqrt{4\theta\omega}\} + \operatorname{erf}\{\sqrt{\theta/\omega}\}} \quad (7.25)$$

For $t < 2s$, the fixation probability is close to that predicted by Equation 7.22, whereas for very large values of t , $u_f(1/2N)$ can moderately exceed the neutral fixation probability provided $N_e s$ is not so strong that the allele is incapable of drifting to a high enough frequency to be favored by selection (Figure 7.5).

The latter case is of special interest, as one can identify a critical effective population size (N_e^*) above which the efficiency of selection is so strong that there is essentially no possibility of the population passing through the fitness bottleneck imposed by heterozygotes. With heterozygotes having a fitness reduction of s , derived homozygotes having an advantage of t , and p being the frequency of the mutant allele, the mean population fitness is $\bar{W} = 1 - 2p(1-p)s + p^2t$, which reaches a minimum at $\hat{p} = s/(t+2s) = 0.5\omega$, so that $p < \hat{p}$ implies net selection against, and $p > \hat{p}$ net selection in favor of, the mutant allele. Thus, the key issue is whether the mutant allele can drift from an initial frequency of $1/(2N)$ to \hat{p} , at which point selection can pull it to fixation. When p is small, the frequency of mutant homozygotes is negligible, and the new allele effectively behaves like a deleterious mutation being removed from the population at rate s , and it can be shown that there is essentially no chance of the allele drifting to \hat{p} if

$$N_e^* > \frac{t+2s}{s^2} \quad (7.26)$$

(Lynch 2012a). For example, with a mutant allele with a disadvantage of $s = 0.01$ in the heterozygous state but an advantage of $t = 0.01$ in the homozygous state, an effective population size above 300 imposes a very strong barrier to its establishment. Lande (1979b, 1985)

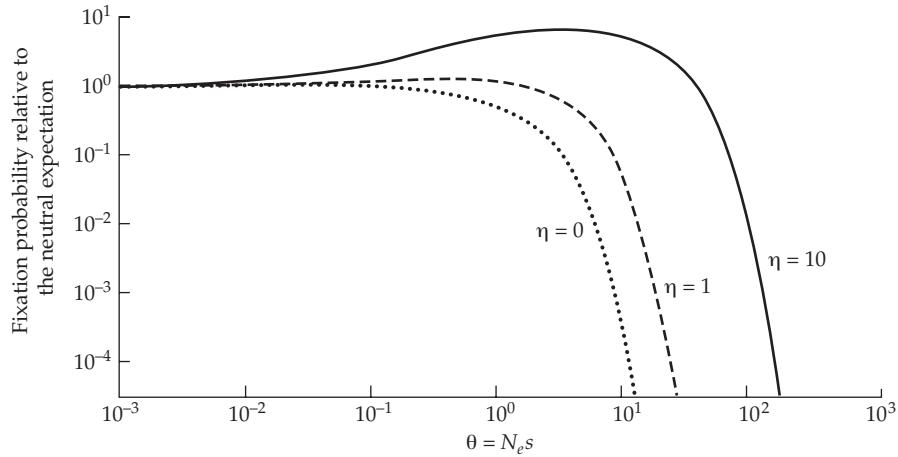

Figure 7.5 The probability of fixation of a newly arisen underdominant mutation, relative to the neutral expectation of $1/(2N)$, with a selective disadvantage of s in the heterozygous state and an advantage of t in the derived homozygous state, and $\eta = t/(2s)$. (After Walsh 1982.)

showed that such selective valleys are much more likely to be vaulted in subdivided populations, where local extinction and recolonization permit individual demes to make transitions to an alternative genotypic state and then export such a fixed change to a newly opened habitat.

Expected Allele Frequency in a Particular Generation

A number of applications, including attempts to predict the response to selection, arise for which it is useful to know the expected allele frequency at time t , $E(p_t)$. While exact results can be obtained from probability transition matrices (Hill 1969a; Carr and Nassar 1970) and good approximations can be derived from diffusion theory (Appendix 1; Maruyama 1977; Ewens 2004) and other approaches (Curnow and Baker 1968, 1969; Pike 1969), these methods tend to be numerically intensive. Fortunately, simple approximations have been developed for dealing with weak selection.

In a finite population, drift can reduce the selection response by progressively diminishing the expected heterozygosity in each succeeding generation. Consider a locus with additive selection, with the genotypes aa , Aa , and AA having fitnesses of 1 , $1+s$, and $1+2s$, respectively. If there is weak selection, such that changes in allele frequencies associated with selection are relatively minor compared to those induced by drift, we can use Equation 5.1b to show that the expected per-generation frequency change for an allele in the j th generation of additive selection can be described as

$$E(\Delta p_j) \simeq sE[p_j(1-p_j)] \simeq sp_0(1-p_0) \left(1 - \frac{1}{2N_e}\right)^j \quad (7.27)$$

where p_0 is the initial allele frequency. The last approximation follows directly from the expression for the expected heterozygosity for a neutral locus in a finite population after j generations with a starting allele frequency of p_0 (Equation 2.5). Summing over generations reveals that the expected frequency after t generations of selection and drift is

$$\begin{aligned} E(p_t) &= p_0 + \sum_{j=0}^t E(\Delta p_j) \simeq p_0 + sp_0(1-p_0) \sum_{j=0}^t \left(1 - \frac{1}{2N_e}\right)^j \\ &\simeq p_0 + 2N_e s p_0 (1-p_0) \left(1 - e^{-t/2N_e}\right) \end{aligned} \quad (7.28a)$$

where the last step follows from the useful approximation for large values of N_e

$$\sum_{j=0}^t \left(1 - \frac{1}{2N_e}\right)^j \simeq 2N_e \left(1 - e^{-t/2N_e}\right) \quad (7.28b)$$

More generally, if the genotypes aa , Aa , and AA have fitnesses of 1, $1 + hs$, and $1 + 2s$, respectively, then for small values of $N_e|s|$ and $N_e|sh|$, the expected frequency of A is

$$E(p_t) \simeq p_0 + 2N_e s p_0 (1 - p_0) \left[\left(1 - e^{-t/2N_e}\right) + \frac{(h-1)(1-2p_0)}{3} \left(1 - e^{-3t/2N_e}\right) \right] \quad (7.29)$$

These approximations provide a remarkably simple route to obtaining fixation probabilities under weak selection ($N_e s \ll 1$). Because an allele will ultimately be either fixed ($p_\infty = 1$) or lost ($p_\infty = 0$), the asymptotic mean frequency as $t \rightarrow \infty$ is equal to the fixation probability

$$E(p_\infty) = \{1 \cdot u_f(p_0)\} + \{0 \cdot [1 - u_f(p_0)]\} = u_f(p_0)$$

Thus, taking the limit of Equation 7.29 as $t \rightarrow \infty$ yields a useful expression for the probability of fixation under weak selection and arbitrary dominance

$$u_f(p_0) \simeq p_0 + 2N_e s p_0 (1 - p_0) \left(1 + \frac{(h-1)(1-2p_0)}{3}\right) \quad (7.30)$$

For additive fitness effects ($h = 1$), this expression is identical to Equation 7.10b. Hill (1969a, 1969b) found this approximation to be reasonable provided $N_e|s| < 1$. The more general versions (Equations 7.29 and 7.30) were produced by Silvela (1980).

JOINT INTERACTION OF SELECTION, DRIFT, AND MUTATION

We now turn to the situation in which selection, drift, and mutation operate simultaneously. Under these conditions, alleles are not simply permanently lost or fixed. Rather, the allele frequencies in a population of constant size eventually reach a stochastic equilibrium (or **stationary distribution**), $\phi(x)$, where x denotes the allele frequency. Recall from Chapter 2 that we can interpret such an equilibrium in two different ways. First, given a conceptually large number of replicate populations, $\phi(x)$ closely approximates the frequency histogram of the numbers of populations with specific allele frequencies at the locus. Conversely, if we were to follow a single population temporally and construct a histogram of the historical record of allele frequencies at the locus over a very large number of widely separated time points, under constant population conditions, we would again recover $\phi(x)$.

Diffusion theory provides a general solution to this problem (Appendix 1). For the simple biallelic case in which mutations from allele A to a occur at a rate of μ , and v is the reciprocal rate, Wright (1949) found that the equilibrium distribution for the advantageous A allele is given by

$$\phi(x) = C \bar{W}^{2N_e} x^{4N_e v - 1} (1 - x)^{4N_e \mu - 1} \quad \text{for } 0 < x < 1 \quad (7.31a)$$

where C is a normalization constant such that Equation 7.31a integrates to one, and hence is a proper probability density (Example A1.4 provides a derivation of this expression). Here, \bar{W} is the mean population fitness, which is itself a function of x and the selection coefficients associated with different gametic states. Note that when both mutation rates are substantially $< 1/(4N_e)$, conditions that may frequently be met for single nucleotide sites (Chapter 4), this simplifies to

$$\phi(x) \simeq \frac{C \bar{W}^{2N_e}}{x(1-x)} \quad (7.31b)$$

showing that with weak mutation pressure, the expected allele frequencies that are *conditioned on the population being polymorphic* are independent of both the mutation rate and the mutation bias.

This result, which represents yet another counterintuitive consequence of the influence of drift on gene frequencies, can be understood as follows. Suppose that allele A has a selective advantage s over allele a , and again let the rates of mutation from A to a and vice versa be μ and v , respectively. At a stationary state, the ratio of times that a population is completely fixed for optimal versus suboptimal alleles is

$$\frac{\tilde{P}_A}{\tilde{P}_a} = \left(\frac{v}{\mu} \right) e^S \quad (7.32)$$

where $S = 4N_e s$ (Wright 1931; Li 1987; Bulmer 1991; McVean and Charlesworth 1999). Note that (v/μ) and e^S are, respectively, the mutation and selection biases in favor of allele A , with the latter being equivalent to the ratio of fixation probabilities of newly arising beneficial and detrimental alleles with the same absolute s (obtainable from Equation 7.10a). Equation 7.32 demonstrates that although the distribution of allele frequencies that is conditional on polymorphism can be independent of mutational properties, the frequency of alternative fixed classes is not. In addition, it is apparent that the ratio at which the two monomorphic classes produce polymorphisms (μ/v) is perfectly compensated by the differential densities of the two classes, and provided the population is sufficiently small that each new mutation is either lost or fixed before another one is produced at the locus, this effect will not be influenced by secondary mutations. Equation 7.31b breaks down, however, when population sizes are large enough that the waiting times for new mutations are smaller than the sojourn times of mutant alleles.

Because Equation 7.31a treats allele frequencies as continuously distributed variables, they may behave aberrantly at the absorbing boundaries of the frequencies $x = 0$ and 1. However, an approximation for the absolute frequencies of the fixed classes can be obtained by noting that the equation

$$\tilde{P}_p \simeq 2N(\tilde{P}_A \mu \bar{t}_a + \tilde{P}_a v \bar{t}_A) \quad (7.33)$$

is the equilibrium proportion of time for which the sites are polymorphic, with \bar{t}_a and \bar{t}_A being, respectively, the mean sojourn times of mutations to alleles a and A . Using Equation 7.32 and the fact that $\tilde{P}_a + \tilde{P}_A + \tilde{P}_p = 1$, the solution can be obtained for all three components of this equation. By multiplying the values of Equation 7.31a by \tilde{P}_p over the range of $x = 1/(2N)$ to $1 - [1/(2N)]$, we then obtain the spectrum of alternative population states of polymorphism.

Figure 7.6 provides some examples of the form of the stationary distribution for biallelic loci experiencing bidirectional mutation. For neutral mutations, the distribution is highly U- or J-shaped (depending on the magnitude of mutation bias) at low population mutation rates ($4N\mu$ and $4Nv \ll 1$), as the population is almost always in a nearly fixed state, with the probability of the alternative fixed states being given by Equation 7.5. The distribution becomes flat with values of $4N\mu$ and $4Nv$ near 1.0, and then becomes more peaked as $4N\mu$ and $4Nv$ become progressively larger (with the mean centered on the infinite-population expectation given by Equation 7.5). Selection skews the distribution toward the more favorable allele, but even with an S as large as 10, a moderate frequency of the deleterious allele can be expected (even though fixation of the latter would essentially never occur).

Equation 7.31a is useful in a number of applications. Consider, for example, the case of a deleterious recessive allele maintained by mutation (with μ being the mutation rate to deleterious alleles, and s being the selective disadvantage of mutant homozygotes). If we let x be the frequency of the deleterious allele, the mean population fitness is $\bar{W} = 1 - sx^2$. Using the approximation $(1-y)^{2N_e} \simeq e^{-2N_e y}$ for small values of y , so that $\bar{W}^{2N_e} \simeq e^{-2N_e sx^2}$, and ignoring back mutation to the advantageous allele, yields the equilibrium distribution

$$\phi(x) = C e^{-2N_e sx^2} x^{4N_e \mu - 1} (1-x)^{-1} \quad \text{for } 0 < x < 1 \quad (7.34)$$

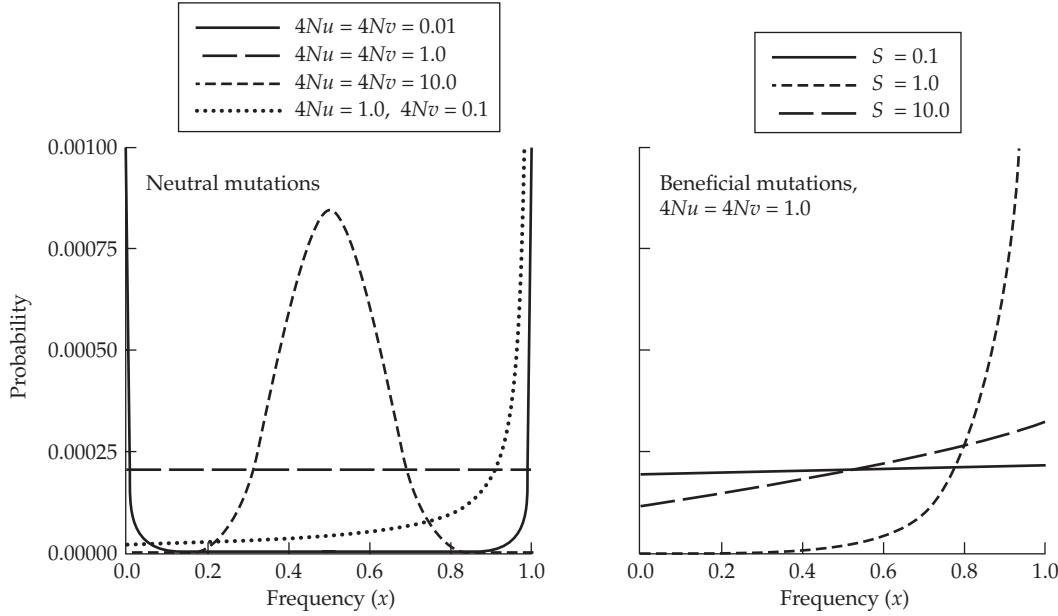

Figure 7.6 Stationary distributions of allele frequencies under the joint forces of mutation, selection, and random genetic drift (Equation 7.31a). An absolute population size of $N = 2000$ is assumed with $N_e = N$.

a result originally due to Wright (1938b).

Nei (1969) provided a broad overview of the allele-frequency spectrum for lethal mutations, including those that are entirely recessive or overdominant. As neither of these conditions are commonly observed (LW Chapter 10), we note only some of the results for partially recessive lethals. In this case, the average expected frequency at selection-mutation balance is given by Equation 7.6d, essentially independent of population size, and provided that $2N_e hs \gg 1$ (i.e., the power of selection against heterozygotes exceeds the power of drift), the variance in allele-frequency will be approximately

$$\sigma^2(p) = \tilde{p}/(4N_e hs) \quad (7.35)$$

Nei (1971) and Li and Nei (1972) gave expressions for the expected total number of individuals affected by a newly arisen deleterious mutation prior to its elimination by selection.

An area of special interest is the behavior of the four possible nucleotides at a particular site. If we denote the four frequencies as x_i (where $i = 1, \dots, 4$) and their selection coefficients as s_i (here assumed to be weak and additive), under the assumption that all nucleotides mutate to each other type at the same rate, μ , Equation 7.31a reduces to

$$\phi(x_1, x_2, x_3, x_4) = C\bar{W}^{2N_e} (x_1 x_2 x_3 x_4)^{4N_e \mu - 1} \quad (7.36)$$

where $\bar{W} = 1 + 2 \sum_{i=1}^4 x_i s_i$ is the mean population fitness. It is not surprising that the solution to this trivariate expression (x_4 being defined as $1 - x_1 - x_2 - x_3$) is quite cumbersome (Li 1987; Zeng et al. 1989; Bulmer 1991; McVean and Charlesworth 1999).

Consider, however, the situation in which there is one optimal nucleotide, the frequency of which is denoted by x , with the three others having an equal selective disadvantage, s , in the heterozygous state. If we scale the less-fit alleles to have a fitness of 1, the mean population fitness will then be $\bar{W} = 1 + 2xs$, which is closely approximated by e^{2xs} under the assumption of a small s . If we let the mutation rate of all nucleotides to the optimal state be v and the total mutation rate of the optimal nucleotide to the other states be μ , it follows from Equation 7.32 that the expected frequency of the optimal nucleotide is

$$\tilde{P}_{\text{opt}} \simeq \frac{(v/\mu)e^S}{1 + (v/\mu)e^S} \quad (7.37)$$

(Li 1987; Bulmer 1991; McVean and Charlesworth 1999). Strictly speaking, this expression applies to the weak-mutation limit (where $N(\mu + v) \ll 1$ ensures that polymorphisms are rare), so that \tilde{P}_{opt} denotes the fraction of time for which the site is fixed for the optimal nucleotide.

Equation 7.37 makes a simple, intuitive statement—the frequency of the optimal nucleotide at a site is a function of a single composite quantity, $(v/\mu)e^S$, which, as noted above, denotes the net pressure toward the optimal state. As $N_e s \rightarrow 0$, the expected frequency of the optimal allele approaches the expectation under pure mutation pressure, $v/(\mu + v)$. For populations that are sufficiently large to maintain substantial heterozygosity, Equation 7.37 will no longer serve as a strict definition of the probability of sampling an optimal allele, as prior to fixation the descendants of a new mutation will themselves have time to acquire secondary mutations. In this case, P_{opt} is more appropriately viewed as the probability that the most recent common ancestor of the alleles that are currently segregating in a population is an allele of the optimal type.

Sella and Hirsh (2005) and Lynch (2012b) expanded the model leading to Equation 7.37 to allow for multiple alleles with different fitness states. Both models assumed a stepwise-mutation model, with allele i mutating to $i - 1$ with a rate of μ and to $i + 1$ with a rate of v , and, again, are strictly valid as indicators of average allele frequency only in the weak-mutation limit, where the population is typically expected to be nearly monomorphic. Sella and Hirsh (2005) assigned a fitness of $W_i = 1 + s_i$ to allele i , and also assumed that there was symmetric mutation ($\mu = v$). If we let $S_i = 4N_e s_i$ (assuming diploidy), the equilibrium probability that i is the fixed (or nearly so) allele is completely independent of the mutation rate,

$$\tilde{p}_i = \frac{e^{S_i}}{T}, \quad \text{where } T = \sum_{i=1}^n e^{S_i} \quad (7.38)$$

and n is the number of alleles. Whereas the Sella-Hirsh model makes no assumptions about fitness ordering between alleles, Lynch's (2012b) model assumes there will be an ordered fitness increase in a series of alleles, such that $W_i = 1 - e^{-ki}$, with the constant k setting the granularity of fitness change between adjacent alleles, and a fitness of 1.0 being approached asymptotically as $i \rightarrow \infty$. In this case, the stationary distribution is

$$\tilde{p}_i = \frac{(v/\mu)^i e^{-S_i}}{T}, \quad \text{where } T = \sum_{i=1}^{\infty} (v/\mu)^i e^{-S_i} \quad (7.39)$$

and $S_i = 4N_e e^{-ki}$.

Formulae such as these can be readily modified into alternative fitness schemes. Among other things, they are useful for determining the extent to which drift limits the level of adaptation attainable by a population. For example, if we assume that there are higher mutation rates to unfavorable states ($\mu > v$), the advancement toward ever-higher (and fitter) allelic states will stall around a critical value in the allelic series, above which $s_i \simeq e^{-ki}$ is sufficiently small that drift (combined with mutation pressure) will overwhelm selection, thereby preventing any further adaptive progress (Lynch 2012b). Although alleles that are in a fitness state above this critical point can still arise by mutation, they will be unable to avoid being lowered by drift back down to the critical value. On the other hand, alleles with sufficiently large disadvantages will be incapable of proceeding to fixation and therefore will be purged by selection. Thus, as will be further discussed in the following section, under virtually all models of adaptation, a **drift barrier** will ultimately prevent a population from achieving a perfect state of adaptation, even in a constant environment.

HALDANE'S PRINCIPLE AND THE MUTATION LOAD

Having established the expected allele frequencies at a locus that is jointly influenced by mutation, selection, and drift, we will now consider in more detail the price that all organisms pay for the privilege of evolving. Because most mutations are deleterious, and many

are unconditionally so, for every beneficial allele created by mutation, many more detrimental mutations will be introduced to a population. In populations of sufficiently large size, the majority of such mutations will be kept at a low frequency and eventually purged, but the relentless flux of new mutations will nevertheless result in an equilibrium load on the mean fitness in the population (Muller 1950; Crow 1993). What is remarkable is that, under reasonably general conditions, this load is often essentially independent of the effects of individual mutations.

In an elegant display of population-genetic reasoning, Haldane (1937b) proposed that the reduction in fitness resulting from recurrent deleterious mutations is a function of the deleterious mutation rate alone, an observation that has come to be known as **Haldane's principle**. To illustrate, consider a deleterious recessive allele a , with a selective disadvantage, s , in homozygotes. Recalling Equation 7.6d reveals that the mean population fitness when this locus is in selection-mutation balance is

$$\overline{W} = 1 - s \cdot \text{freq}(aa) = 1 - s \left(\sqrt{\frac{\mu}{s}} \right)^2 = 1 - \mu \quad (7.40a)$$

Because the expected frequency of recessive homozygotes is inversely proportional to the selective disadvantage, the reduction in mean fitness (the **mutation load**) is independent of the strength of selection and simply equal to the deleterious mutation rate per allele.

Now consider an allele with partial to complete dominance and with heterozygote a fitness of $1 - hs$. If we recall from Equation 7.6d that the equilibrium allele frequency is $\tilde{p} = \mu/(hs)$, the mean population fitness is

$$\begin{aligned} \overline{W} &= 1 - 2hs\tilde{p}(1 - \tilde{p}) - s\tilde{p}^2 \\ &\simeq 1 - 2hs\tilde{p} = 1 - 2hs \left(\frac{\mu}{hs} \right) = 1 - 2\mu \end{aligned} \quad (7.40b)$$

The approximation, which assumes weak mutation, meaning that that $\tilde{p}^2 \ll 1$, shows that the expected mean fitness is independent of both h and s . Bürger (2000) explored these expressions in considerable detail and showed that the error in ignoring secondary terms in the preceding expressions is on the order of μ^2/s or smaller. With multiple deleterious alleles per locus, these same expressions apply if μ is interpreted as the total mutation rate of the most beneficial allele to all classes of deficient alleles at a locus (Crow and Kimura 1964; Clark 1998).

One potential caveat about these results is that the derivation assumes a situation in which there are negligible epistatic effects on fitness. To examine the robustness of this assumption, Kimura and Maruyama (1966) considered a quadratic fitness function of the form $w_i = 1 - h_1 i - h_2 i^2$, where i is the number of mutations carried by the individual. With $h_2 = 0$, the model of additive effects assumed above is closely approximated, and Haldane's principle continues to hold, with a mean fitness approximately equal to e^{-U} , where U is the deleterious mutation rate per diploid genome. However, at the opposite extreme, with $h_1 = 0$, fitness declines with the square of the number of mutations, and mean fitness is elevated to $\sim e^{-U/2}$ regardless of the magnitude of h_2 . A more general analysis, which allows for nonzero values of both h_1 and h_2 , was provided by Kimura and Maruyama (1966) and demonstrated that this type of **synergistic epistasis** always reduces the mutational load on a sexual population. In contrast, when there is **diminishing-returns epistasis**, where the decline in fitness with increasing numbers of deleterious mutations becomes progressively shallower, the mutation load will be elevated above the Haldane expectation.

Fitness functions involving epistasis have played a significant role in our attempt to understand the evolution of sexual reproduction, primarily because the behavior just noted does not extend to asexual genomes, as first shown by Kimura and Maruyama (1966) in a remarkably simple way. Consider an asexual population of mixed clones, with p_0 being the frequency of the clone with the minimum number of mutations in one generation and p'_0 being its frequency in the next generation. Then, accounting for selection and mutation,

$$p'_0 = \frac{p_0 W_0 e^{-U}}{\overline{W}} \quad (7.41)$$

where \overline{W} is the mean population fitness, $W_0 = 1$ is the fitness of the optimal genotype, and e^{-U} is the fraction of the members of this class that do not acquire mutations. Note that no assumptions have been made here with respect to the mode of gene action or on the form of the fitness distribution, and yet at equilibrium ($p'_0 = p_0$) we obtain the very general result that mean fitness, \overline{W} , equals e^{-U} . Thus, if synergistic epistasis among deleterious mutations is important, a matter on which there is little empirical consensus (Rice 2002b; Barton and Otto 2005; Kouyos et al. 2007; Keightley and Halligan 2009), a sexual population will have a long-term advantage in terms of mean fitness. Substantial additional work has been done on this subject (e.g., Kondrashov 1984, 1988; Charlesworth 1990; Agrawal and Chasnov 2001; Otto 2003; Haag and Roze 2007).

An additional issue with respect to Haldane's principle is that N_e must be several-fold greater than $1/(hs)$ for Haldane's principle to be closely approximated. If this is not the case, deleterious alleles will be capable of drifting to frequencies higher than what would be expected under selection-mutation balance alone. Although this observation led Kimura et al. (1963) to conclude that the mutational load due to segregating mutations will increase monotonically with decreasing N_e , their study invoked a relatively high level of back mutation in order to maintain a quasi-equilibrium allele frequency.

If, instead, one treats back mutation as a negligible force (for reasons stated above), it can be shown that the load associated with segregating mutations is nonmonotonic with respect to N_e . The segregational load actually reaches a maximum (in excess of the Haldane expectation) at the point where $1/(2N_e) \simeq hs$, as it is at this point that mutations have a maximum deleterious effect that is still consistent with being highly vulnerable to random genetic drift (Lynch et al. 1995a, 1995b). As N_e declines below this point, the segregational load approaches zero simply because drift becomes so strong that few segregating polymorphisms of any kind are maintained, and at this point permanent damage accrues via the fixation of deleterious alleles, i.e., there is a **fixation load** in addition to any **segregational load**. Indeed, once a population enters this small-population-size domain, the mutation load may no longer even be maintained at a quasi-equilibrium state as a continual flux of new rounds of weakly deleterious mutations will lead to further fixations. If unopposed for a sufficiently long time, such a condition can eventually reduce mean population fitness to the point at which the average individual will be incapable of replacing itself, leading to population extinction via a **mutational meltdown** (Lynch et al. 1995a, 1995b).

Even populations large enough to avoid extinction by a mutational meltdown must experience some fixation load, as they will often include mutationally derived alleles with small enough deleterious effects to be immune to selection (i.e., $|s| < 4N_e$). The issue has been explored with a variety of models for mutational passage between allelic classes (Hartl and Taubes 1998; Poon and Otto 2000; Sella and Hirsh 2005; Lynch 2012b). Although the exact results vary somewhat among studies, in every case the load resulting from the fixation of suboptimal alleles is inversely proportional to the effective population size, often with an upper bound on the order of $1/(4N_e)$.

One way to arrive at this result is to recall the additive two-allele model given above as Equation 7.37. Noting that the load associated with a fixed deleterious mutation is the homozygous effect, $2s$, multiplied by the expected fraction of time for which the deleterious allele is fixed, we then have

$$\begin{aligned} L &= 2s(1 - \tilde{P}_{\text{opt}}) = \frac{2s\mu/v}{e^S + (\mu/v)} \\ &\simeq \frac{2s\mu/v}{1 + 4N_e s + (\mu/v)} \end{aligned} \quad (7.42a)$$

The approximation applies when $S = 4N_e s < 1$, which must be the case for there to be a significant chance of fixation of a deleterious allele. Under the latter conditions, with symmetrical mutation rates ($\mu = v$),

$$L = \frac{1}{2N_e + (1/s)} < \frac{1}{4N_e} \quad (7.42b)$$

Mutational bias in the direction of deleterious alleles ($\mu/v > 1$) will elevate this load, but the point remains the same. Finite population size imposes an ultimate barrier to adaptive refinements that can be maintained in a population. Although this load may appear to be small, as noted in Chapter 4, in all known cases, $\mu < 1/(2N_e)$, suggesting that the drift load per locus is likely to be typically greater than Haldane's segregational load. In addition, the previous derivations apply to single loci, whereas the cumulative load over all n loci contributing to a trait will be roughly n times the single-locus load, assuming weak multiplicative fitness effects. Thus, drift appears to generally impose a nontrivial barrier to adaptive perfection.

There has been considerable debate about the meaning and consequences of the genetic load (Wallace 1991; Crow 1993; Kondrashov and Crow 1993; Reed and Aquadro 2006). As deleterious mutations impose differences in survival and/or reproduction, they must have some demographic consequences. Taken literally, if the deleterious mutation-free genotype is viewed as the standard ($W_0 = 1$), an equilibrium load, L , would imply approximately e^{-L} viability (not including mortality unassociated with genetic variation) provided its entire influence is on survivorship. This would then require an inflation of family sizes by a factor of e^L relative to the minimum value of two that is necessary to maintain population-size stability. Under this view, the load concept is paradoxical in that a low-fecundity organism such as a vertebrate would never be able to bear the demographic costs should the genome-wide deleterious mutation rate exceed ~ 1.0 , which is likely the case in vertebrates (Chapter 4). Lesecque et al. (2012) showed, however, that the magnitude of selective death is greatly diminished if the fitness of individuals is scaled relative to the actual mean fitness in the population rather than to the idealized $W_0 = 1$. Such a situation would be expected if selection operates mainly through competition of the actual members of the population, rather than by comparison to a nonexistent (idealized) genotype.

FIXATION ISSUES INVOLVING TWO LOCI

Populations and species diverge from each other through successive fixations of new mutations, which can be effectively neutral, advantageous, or even slightly deleterious. The relative contributions from these classes, especially the fraction of advantageous and hence adaptive substitutions, is of considerable interest (Kimura 1983; Gillespie 1994). Our goal here is to broaden the preceding outline of fixation theory by considering the influence of the genetic background on expected substitution rates.

There are a number of situations in which fixation probabilities of alleles are influenced by factors operating at other loci. For example, as discussed in Chapter 3, selection operating on any locus, either positive or negative, results in a reduction in the effective population size in the local chromosomal region, thereby reducing the efficiency of selection operating on all loci linked to the target of selection. Such effects will reduce the fixation probabilities for beneficial alleles, while enhancing the likelihood of fixation of deleterious alleles. In addition, for mutations with contextual (epistatic) effects, fixation probabilities depend critically on the genetic background, and hence on the frequencies of alternative alleles at interacting loci.

The Hill-Robertson Effect

We first consider the matter of selective interference associated with linked variation involving beneficial alleles. Suppose that the gamete with the highest fitness, AB , is initially absent and can only be generated by recombination in Ab/aB double heterozygotes. If we let x_2 and x_3 denote the frequencies of the Ab and aB gametes, and c be the recombination frequency between the two loci, then the probability of AB being generated in the population is related to the product of the expected frequency of Ab/aB heterozygotes and the probability that a random gamete from such individuals is AB , $(2x_2x_3)(c/2)$. Because $x_2x_3 \leq 1/4$ and a population with a stable size must produce $2N$ successful gametes, the upper bound to the

expected number of AB gametes generated in any generation is $(2N)(c/4)$. Thus, if $Nc < 2$, fewer than one AB gamete will be produced in each generation by recombination, so unless there is a strong advantage to AB , one of the intermediate gamete types will most likely become fixed before AB can reach a sufficiently high enough frequency to be deterministically promoted by selection. Such fixation of one of the intermediate types will then leave new mutation as the only mechanism for the generation of AB . For this special case, where the optimal gamete is initially absent, Latter (1966b) developed approximate expressions for the mean time to the first appearance of the AB gamete by recombination and for its subsequent fixation probability.

Although there is no general expression for the probability of fixation when alleles at two or more loci are competing for fixation, a number of important results were developed by Hill and Robertson (1966). Most notably, they obtained a weak-selection approximation for the probability of fixation for the following case. Let two diallelic loci (with designated alleles of A/a and B/b) have a recombination frequency of c , p_0 be the initial frequency of A , and D_0 be the initial gametic-phase disequilibrium (as defined in Chapter 2). Assuming completely additive selection (no dominance or epistasis), with each copy of A adding s_1 and each copy of B adding s_2 to total fitness, the probability that A becomes fixed is

$$u_f(p_0) \simeq p_0 + 2N_e s_1 p_0 (1 - p_0) + \frac{2N_e s_2}{2N_e c + 1} D_0 \quad (7.43)$$

provided that $2N_e|s_1|$ and $2N_e|s_2| < 1$. A comparison of this two-locus approximation to the single-locus result (Equation 7.10b) shows that the probability of fixation can be increased or decreased depending on the sign of the initial gametic-phase disequilibrium, D_0 .

Computer simulations show that when selection is strong ($N_e|s_1|$ and/or $N_e|s_2| \gg 1$), linkage (i.e., $c < 0.5$) generally *decreases* the probability of fixation of an advantageous allele relative to the single-locus result (Hill and Robertson 1966). If A and B are favored alleles, linkage will have little effect on the probability of fixation of the ab gamete, but the probabilities of fixation of the Ab and aB gametes increase at the expense of the optimal AB gamete (Latter 1965b; Hill and Robertson 1966). This decrease is maximized when $N_e c$ is small and both loci have the same effect (e.g., $s_1 = s_2$), as then there is no selective distinction between the two intermediate gametes, rendering them neutral with respect to each other. This is a significant point, as most theoretical investigations on the effects of linkage on the selection response have assumed loci with equal effects (e.g., Fraser 1957; Latter 1965b, 1966a, 1966b; Gill 1965a, 1965b, 1965c; Qureshi 1968; Qureshi and Kempthorne 1968; Qureshi et al. 1968), thereby inflating the perceived importance of linkage.

The general phenomenon of selective interference between linked loci was subsequently nicknamed the **Hill-Robertson effect** by Felsenstein (1974). As discussed in Chapter 3, the primary implication of the Hill-Robertson effect is that selection renders the behavior of linked loci closer to that expected under neutrality by reducing the effective population size for the chromosomal region (Birky and Walsh 1988; Charlesworth 1994b; Peck 1994). This effect applies to the efficiency of selection on all nonneutral alleles, both advantageous and deleterious. For example, sometimes a moderately beneficial mutation will arise in tight linkage to a highly detrimental allele at another locus, which will result in the former's rapid elimination from the population if the net fitness of the chromosomal region remains lower than that of the population mean. In addition, the average substitution rate at a locus generating deleterious alleles will be *increased* if that locus is linked to another locus generating either deleterious or beneficial alleles (Birky and Walsh 1988). In other words, the net effect of linkage is to reduce the overall efficiency of selection for fitness-enhancing mutations, magnifying the accumulation of mildly deleterious mutations at the expense of fixing more advantageous alleles.

This realization, that the majority of Hill-Robertson effects have the functional consequence of reducing N_e , greatly facilitates the estimation of fixation probabilities of new mutations subject to background selection. Indeed, in most contexts that have been examined thus far, the standard fixation expressions given above still apply provided the

appropriate modifications are made to the definition of N_e (Stephan et al. 1999), as was also found for subdivided and growing or declining populations. These redefinitions, which were already outlined at the end of Chapter 3, again point to the great technical utility of the concept of effective population size. Nonetheless, as detailed in the next chapter, interference among tightly linked loci can influence the dynamics of beyond the expectation with a simple reduction in N_e .

Mutations with Contextual Effects

To this point, we have generally been assuming that the magnitude of selection operating directly on an allele is independent of the genetic background (other than effects associated with linkage disequilibrium) on which it resides. However, there are numerous situations in which this will not be the case. Most notable is the broad category of **compensatory mutations**, wherein specific single mutations at either of two loci cause a reduction in fitness, while their joint appearance restores fitness or even elevates it beyond the ancestral state. Such epistatic interactions play a prominent role in Wright's (1931, 1932) **shifting balance theory** for adaptive evolution, under which an adaptive valley between two fitness peaks is traversed in a local subpopulation, with the locally fixed advantageous genotype then being exported to surrounding demes by migration. Compensatory mutations appear to play a number of important roles in protein-sequence evolution and in the composition of nucleotides in the stems of RNA molecules (Stephan and Kirby 1993; Kondrashov et al. 2002; Kulathinal et al. 2004; Azevedo et al. 2006; Breen et al. 2012).

Ascertaining the conditions under which evolution by compensatory mutation is most likely to occur is challenging because unlike the situation in which a single mutation fixes at a rate depending only on its own initial frequency, the success of a mutation involved in an interlocus interaction depends on the frequency of alleles at the interacting locus, on the fitnesses associated with the nine possible two-locus genotypes, and on the recombination rate between the two loci. Consequently, no general theory for the long-term evolution of interacting loci has yet been developed, although considerable progress has been made in a number of special cases.

Because the matter of fixation probability becomes less clear in the case of adaptations involving more than one mutation, in this final section, we will shift our focus slightly to the rate and mean time to **establishment** of an adaptation. The latter is defined to be the expected arrival time of the final multisite adaptation destined to be fixed in the population, starting from a state in which all participating mutations are absent. This excludes the additional time required for fixation, which can generally be obtained from the expressions given above, and will often be considerably smaller than the first-arrival time. When considering the response to a long-term regular regime of selection, the steady-state rate of evolution is expected to be close to the rate of establishment, as the extra time to fixation simply elongates each individual event, leaving the intervals between events the same. Assuming a constant influx of adaptive mutations, the steady-state rate of adaptation is then simply the inverse of the time to establishment.

As a benchmark for the following theoretical results, we start with the rate of establishment of a single-site adaptation, with mutations having additive fitness effects. Given a per-site mutation rate of μ , $2N\mu$ new mutations are expected to arise in each generation, each at frequency $1/(2N)$. As noted above, if the population size is sufficiently large that $4N_e s \gg 1$, the fixation probability $u_f(1/2N) \simeq 2sN_e/N$, and the rate of establishment becomes

$$r_e = (2N\mu)(2sN_e/N) = 4N_e\mu s \quad (7.44)$$

which is directly proportional to the effective population size, the mutation rate to adaptive changes, and the selective advantage. This approach, of course, assumes that the response to selection is limited by the appearance of new adaptive alleles, and in subsequent chapters we will consider in detail the situation in which part or all of the selection response is a consequence of preexisting variation. It also ignores the point made in the previous section, that if $2N\mu > 1$ (more than one favorable mutation arises per generation), the simultaneous

presence of multiple segregating mutations will reduce the effectiveness of selection, lowering the expected substitution rate (Chapters 8 and 10). The waiting time for establishment follows a geometric distribution with success parameter r_e , and hence the expected waiting time is $\bar{t}_e = 1/r_e$ generations, with a variance of $\sigma^2(t_e) = (1 - r_e)/r_e^2 \simeq 1/r_e^2$.

As the simplest possible model for the rate of adaptation by new mutations, Equation 7.44 relies on the assumption that fixations have no bearing on subsequent events. However, this assumption can be violated for at least two reasons. First, the fixation of a mutation can alter the selection coefficients of future mutations by, for example, moving the mean phenotype closer to the optimal state, and consequently reducing the magnitude of selection for further change. This point is implicit in the drift barrier to adaptation noted above, and it relates to the idea of Hartl et al. (1995) that the ultimate consequence of the relentless improvement of traits by natural selection is the evolution of effective neutrality among the remaining pool of segregating alleles. Second, when mutations have epistatic effects on fitness, i.e., when they depend on the genetic background, the possibility exists that neutral or even deleterious mutations may become beneficial in certain genetic contexts. We refer to multisite traits exhibiting the latter types of genetic behavior as **complex adaptations** because the paths for their evolution are much less obvious than under conditions of additive fitness effects.

Stochastic Tunneling

How do adaptations depending on the joint presence of more than one mutation become established? One possibility is simply that double mutations, while extremely rare, will still arise, with one eventually being carried to fixation by selection. If, however, the mutation rate at a nucleotide site is 10^{-9} (Chapter 4), a population size in excess of 10^{18} is required to routinely see such double mutations, making this route unlikely for all but enormous populations. On the other hand, in very small populations, the path toward adaptation must involve successive fixations via drift, which is also likely to be a very long process. In contrast, moderately large populations offer a dual problem in that the fixation of key intermediate mutations can be problematic if they are neutral (owing to the very long time to drift to fixation) and highly unlikely if they are deleterious.

Starting with Gillespie (1984b), it became clear that another pathway, often referred to as **stochastic tunneling** (Komarova et al. 2003; Iwasa et al. 2004), offers a route for the establishment of complex adaptations in large populations even when the intermediate states are deleterious. Under this scenario, secondary mutations arise within the small pool of segregating deleterious first-step mutations, resulting in fixation of the double mutant without either single mutation becoming common, and hence without a bottleneck in mean population fitness.

The power of stochastic tunneling is that it allows selection to explore (and exploit) the fitness surface more broadly than is possible by single-step mutations, and there is a growing, technical body of work on the subject (Carter and Wagner 2002; Komarova et al. 2003; Iwasa et al. 2004; Weinreich and Chao 2005; Gokhale et al. 2009; Weissman et al. 2009, 2010; Lynch 2010; Lynch and Abegg 2010). Drawing from this literature, our goal is to provide approximate answers to three basic questions regarding complex adaptations. First, what is the critical population size below which sequential fixation dominates tunneling as a mechanism for adaptation? Second, what is the expected rate of establishment of pairs of mutations? Third, how does recombination influence these processes?

To put the first question in context, we note that there must be a critical population size, N^* , below which adaptations are essentially only acquired via sequential fixations, owing to the extreme rarity of occasions in which multiple mutations simultaneously segregate at key sites. Below this threshold value, selection is restricted to exploring the fitness landscape by single mutational steps from the currently fixed genotype. While a single chance fixation can place a population one step closer to a distant adaptive peak, it can also move it even further away. Conversely, for population sizes exceeding N^* , stochastic tunneling allows selection to explore the consequences of genotypes that are two (and in that are large populations,

even more) mutational steps away from the currently most common state. This argument suggests that adaptation in small populations will typically occur by simple, single-step hill climbing, occasionally supplemented by fortuitous drift across a sufficiently shallow adaptive valley (with a reduction in fitness incurred during such a phase). In contrast, large populations should experience episodes in which adaptive events involve the simultaneous fixation of two (or more) mutations, without any intervening period of fitness loss at the population level.

A simple statement on the critical population size, N^* , can be made for the situation in which first-step mutations are neutral (Walsh 1995; Lynch and Abegg 2010). Consider a complex adaptation requiring two mutations, with the two sites completely linked, and suppose that an A mutation that is destined to fix has arisen. How likely is it that a B mutation will arise within a member of this lineage on its way to fixation? Because the first-step mutation is neutral, on average, the second mutation will have a window of $4N_e$ generations (the mean fixation time for a neutral mutation) within which it can arise on an A background. During this period, the average frequency of A will be 0.5, so the expected number of A -bearing alleles acquiring the second-site mutation will be $4N_e \cdot (2N\mu) \cdot (1/2) = 4N_e N\mu$, where μ is the site-specific mutation rate. Hence, when $N_e \simeq N$, there is essentially no chance of a two-mutation haplotype even arising during the fixation of a one-step mutation if the population size is much smaller than $1/(2\sqrt{\mu})$. Obviously, if the first-step lineage is destined to become lost, even fewer copies of the double mutation will be produced. Now suppose that the double mutation has a selective advantage, s , so that the fixation probability of the AB haplotype is $\simeq 2s$. Again assuming $N_e \simeq N$, the adaptation will almost certainly arise by stochastic tunneling rather than by sequential fixation if the population size exceeds

$$N^* \simeq \frac{1}{2\sqrt{2\mu s}} \quad (7.45)$$

Note that this is not a terribly stringent condition, as with $\mu = 10^{-9}$ and $s = 0.01$, $N^* \simeq 112,000$. The critical population size will be larger by a factor of $1/\sqrt{x}$ if $N_e = xN$ (recall from Chapter 3 that x is usually $\ll 1$). When the intermediate step is strongly deleterious (with an effect of s_d), then provided $4N_e s_d \gg 1$, first-step mutations will almost be never fixed, with tunneling dominating over sequential fixation.

We now turn to the matter of rates of establishment, focusing again on the situation in which two loci are fixed for alleles A and B , respectively, and inquiring as to the time to reach an alternative state of fixation at both loci, with respective alleles a and b . We will assume equivalent mutation rates of μ from A to a and B to b . The simplest selection scenario in this case, which was first explored by Kimura (1985), assumes that the gametes Ab and aB have equivalent fitnesses of $1 - s$ and the gametes AB and ab have equivalent fitnesses of 1.0. In this case, although transitions between pure population states of AB and ab may occur, nothing is gained in terms of fitness. Within the sequential fixation domain, the degree of linkage can be ignored (as only one locus is polymorphic at a time), and the mean time to establish the novel ab type from AB (or vice versa) is the sum of the waiting times for the two mutational steps,

$$\bar{t}_e = \frac{1}{2N\mu} \left(\frac{1}{2u_{fd}} + \frac{1}{u_{fb}} \right) \quad (7.46)$$

where u_{fd} and u_{fb} are, respectively, the probabilities of fixation of deleterious (first-step) and beneficial (second-step) alleles (obtained by applying the selection coefficients $-s$ and s to Equation 7.10a). Transitions to states Ab or aB (from the higher-fitness states ab or AB) occur at a rate of $(4N\mu)(u_{fd})$, which is the product of the population mutation rate and twice the rate of first-step fixation (because there are two ways to produce first-step mutations); and then, conditional on the first change, the second change occurs at a rate of $2N\mu u_{fb}$. Because the probability of fixation of a deleterious allele is $e^{-4N_e s}$ that of a beneficial allele (above), the establishment time in this case is expected to be primarily determined by the time required for the fixation of first-step alleles, so that the rate of establishment (the

reciprocal of the time to establishment)

$$r_e \simeq 4N\mu u_{fd} \quad (7.47)$$

If, on the other hand, selection against the intermediate haplotypes is much stronger than drift so that fixation of the intermediate state is unlikely (the stochastic-tunneling domain), the most likely scenario for a transition from the *AB* type to *ab* type is a population that is initially residing in a state of selection-mutation balance at both loci. If we assume complete linkage, and a selection coefficient of $-s$ associated with the *a* and *b* alleles when not appearing alone, the *Ab* and *aB* gametes, each with initial frequency $\tilde{p} = \mu/s \ll 1$ (from Equation 7.6d), would then serve as staging grounds for mutations to the *ab* type. Mutant *ab* gametes arise at a rate of μ from each of the $4N\mu/s$ intermediate types ($2N$ times the frequency of each heterozygote, $\simeq 2\tilde{p}$), and fix in an essentially neutral fashion with a probability of $1/(2N)$ (as most resident gametes are of the type *AB*, with equivalent fitness to *ab* as noted above). Thus, the rate of establishment of the *ab* type by stochastic tunneling to an equivalent fitness state is

$$r_e \simeq (2\mu/s)(\mu) = \frac{2\mu^2}{s} \quad (7.48)$$

(Gillespie 1984b; Stephan 1996), which is essentially independent of population size.

When mutations are reversible, the question also arises as to the long-term stationary distribution of alternative states. Adhering to the reasoning that *Ab* and *aB* gametes will generally be maintained at low levels by selection-mutation balance, and assuming equal back and forward mutation rates, Higgs (1998) elegantly showed that the stationary distribution for the frequency (x_0) of the *AB* gamete is

$$\phi(x_0) = \frac{1}{(1-z)^{2\alpha-1}} \frac{\Gamma(2\alpha)}{\Gamma(\alpha)^2} [x_0(1-z-x_0)]^{\alpha-1} \quad (7.49)$$

where $\alpha = 8N\mu^2/s$ is the population rate of mutational production of *ab* gametes, $z = 2\mu/s$ is the summed frequency of the *Ab* and *aB* gametes, and Γ denotes the gamma function (Equation 2.25b). The frequency of the *ab* gamete is simply $1 - x_0 - z$. With $\alpha < 1$, the distribution of x_0 is highly U-shaped, with the probabilities of the population being fixed for alternative *AB* and *ab* states being nearly equal. A more general analysis, which allows for weaker efficiency of selection ($4N_e s < 1$) and for differential selection and mutation operating on the intermediate states was presented by Innan and Stephan (2001).

Now suppose that the secondary mutation has an advantage of s_b , and we denote the disadvantage of first-step mutations as s_d . The general Equation 7.46 still applies in the sequential-fixation domain, and we again expect the rate of establishment to be approximated closely by Equation 7.47 owing to the long waiting time for the fixation of a first-step mutation. For the stochastic-tunneling domain, however, Equation 7.48 must be modified to account for the fact that the fixation probability of the double mutant is $\sim 2s_b(N_e/N)$

$$r_e \simeq (2\mu/s_d)(2N\mu)[2s_b(N_e/N)] = \frac{8N_e\mu^2 s_b}{s_d} \quad (7.50)$$

The key observations here are that the rate of establishment now depends on the effective population size, while also scaling linearly with the square of the mutation rate and the ratio of selection coefficients associated with first- and second-step mutations.

Finally, we consider the special situation in which first-step mutations are effectively neutral. Again, Equation 7.46 provides an accurate description for the sequential-fixation domain, and with substitution of the appropriate fixation probabilities, it reduces to

$$\bar{t}_e = \frac{1}{2N\mu} \left(\frac{1}{2[1/2N]} + \frac{1}{u_{fb}} \right) \simeq \frac{1}{2\mu} \left(1 + \frac{1}{2N_e s} \right) \quad (7.51)$$

with the last approximation obtained by using $u_{fb} \simeq 2sN_e/N$. Thus, provided $2N_e s \gg 1$, when the intermediate mutation is effectively neutral, the expected rate of establishment will be $\simeq 2\mu$ and will only be weakly dependent on the size of the population in the sequential-fixation domain.

To obtain the expected rate of tunneling for the case of neutral intermediates, we require the probability that tunneling occur within a descendant lineage of a first-step mutation before it becomes lost from the population. By various methods, and again assuming complete linkage, this probability has been found to be approximately $\sqrt{2\mu s N_e / N}$ in large populations (Komarova et al. 2003; Iwasa et al. 2004; Weissman et al. 2009, 2010; Lynch and Abegg 2010). With $4N\mu$ first-step mutations arising per generation, the rate of establishment via tunneling is then

$$r_e \simeq 4N\mu \sqrt{2\mu s N_e / N} = 4\mu \sqrt{2\mu s N_e N} \quad (7.52)$$

If the mutation rates at the two steps are different, μ inside and outside of the square-root expression should designate mutation rates at the first and second steps, respectively. The key observation here is that when the intermediate stages are neutral, tunneling occurs at a *higher rate* in larger populations, contrary to the situation with deleterious intermediates. Moreover, although two mutations are required for the final adaptation, the rate of establishment depends on the $3/2$ power of the mutation rate, unlike the square scaling with deleterious intermediates.

While these analyses assume an evolutionary path to a final adaptation through just a single intermediate step, actual fitness surfaces are likely to be more complex, with a variety of potential pathways through any number of mutations. The rates of establishment of complex adaptations under these alternative scenarios have been examined by Gokhale et al. (2009), Weissman et al. (2009), and Lynch and Abegg (2010). Simple analytical expressions were found in only a few cases, two of which we now summarize. As complex adaptations involving more than two mutations are unlikely to evolve by sequential fixation, owing to the long time necessary for cumulative fixations, we restrict our attention to the stochastic-tunneling domain, focusing on how the establishment rate r_e scales with the underlying features of population size, mutation rate, and selection intensity.

For the case of neutral intermediates with increasing numbers (d) of mutations required for the final adaptation (and the order of events assumed to be irrelevant), the rate of establishment can be viewed as a series of nested tunneling events. For example, for the case of $d = 3$ (two neutral mutations required before the final adaptation is assembled with a third mutation), Equation 7.52 expands to

$$r_e = 6N\mu \sqrt{2\mu \sqrt{2\mu s N_e / N}} \quad (7.53a)$$

Note that the first term is now $6N\mu$ because first-step mutations can arise at three sites. The next step then starts at either of the two remaining sites, with the final stage being initiated at the one remaining site and involving tunneling within the sublineage containing the first two mutations. For an arbitrary d , this expression generalizes to

$$r_e = d\lambda\mu(2N\mu)^{1-0.5^{d-1}} S^{0.5^{d-1}} \quad (7.53b)$$

where $S = 4N_e s$, and

$$\lambda = \prod_{i=1}^{d-1} (d-i)^{0.5^i} \quad (7.53c)$$

This result shows that, with neutral intermediates, the rate of establishment by tunneling scales with no more than the square of the mutation rate and with no less than linearly with the absolute population size, these extremes being approached at high d . Thus, the rate of establishment of complex adaptations can be much more rapid than expected under the naive assumption that independently arising mutations would lead to a scaling with the d th power of the mutation rate.

For the case of deleterious intermediates, suppose that all haplotypes involving one to $d - 1$ mutations are equally deleterious (with a fitness of $1 - s_d$), with the final mutation conferring an advantage, s_b . First-step mutations then arise at rate $2Nd\mu$, but owing to selection, they have an expected survivorship time of $1/s_d$ generations, during which period $d - 2$ additional intermediate-step mutations must be acquired, followed by the appearance of a final-step mutation destined to fixation. This leads to a rate of establishment via tunneling of

$$r_e \simeq 4N_e d! (\mu/s_d)^d s_d s_b \quad (7.54)$$

which reduces to Equation 7.50 when $d = 2$. Here we see that r_e scales with the d th power of the mutation rate owing to the limited opportunities for mutation during the short sojourn times of deleterious mutations, whereas there is a linear scaling with the effective population size. One cautionary note with respect to all of these scaling features is that mutation rates appear to generally evolve to be inversely related to the effective size of a population, which will tend to reduce the dependence of rates of establishment on μ and measures of population size, as these two factors often enter as products of each other (Lynch 2010b).

Finally, we note that all of these analyses assume an absence of recombination. This is a matter of significance, as it is often surmised that recombination facilitates the evolution of complex adaptations. In the sequential-fixation regime, recombination can be ignored simply because multiple polymorphic sites are never present simultaneously. However, in the stochastic-tunneling domain, opportunities will exist for both the creation and breakdown of optimal haplotypes. For the case of deleterious intermediates but selectively equivalent end states (above), Higgs (1998) provided general expressions, allowing for arbitrary levels of recombination. Strong linkage substantially accelerates the rate of peak shifts with this fitness landscape because the frequencies of the low-fitness intermediates remain nearly unchanged during transitions to alternative high-fitness states, ensuring that the population does not pass through a phase of reduced mean fitness (Kimura 1985; Michalakis and Slatkin 1996; Stephan 1996; Innan and Stephan 2001). In contrast, recombination between the high-fitness AB and ab gametes during a peak shift produces low-fitness intermediates, imposing a bottleneck on mean population fitness, and thereby inhibiting the movement from one state to the other.

Lynch (2010b) and Weissman et al. (2010) examined this problem with a broad class of models, and reached the conclusion that recombination is most likely to have either a minor or an inhibitory effect on the establishment of a complex adaptation. Consider, for example, the case of a two-site adaptation, starting with a population fixed for the suboptimal ab haplotype. The overall influence of recombination on the rate of establishment of the AB haplotype is a function of two opposing effects—the rate of origin of AB gametes by recombination within doubly heterozygous (aB/Ab) parents is proportional to the rate of recombination between the sites (c), whereas the net selective advantage of the resultant AB haplotypes is discounted from s to $s - c$ by subsequent recombinational breakdown (as in the early stages, ab haplotypes still predominate and are the primary partners in recombination events with AB). Thus, because the product $c(s - c)$ is maximized at $c = s/2$, two-site adaptations are expected to emerge most rapidly in chromosomal settings where the recombination rate is half the selective advantage of the final adaptation.

For the case of neutral intermediates, details in Lynch (2010b) suggest that even at the optimal recombination rate, the rate of establishment is generally enhanced by much less than an order of magnitude relative to the situation with complete linkage, whereas $c > (s/2)$ is not greatly inhibitory. In contrast, when first-step mutations are deleterious, if the rate of recombination exceeds the selective advantage of the AB haplotype, recombination will present an extremely strong barrier to establishment of the AB haplotype (Lynch 2010b). The latter result arises because almost all recombinational events involving a newly arisen AB haplotype will involve an ab participant, thus generating the maladaptive Ab and aB products.

Taken together, these results suggest that only a narrow range of recombination rates (in the neighborhood of $s/2$) can enhance the rate of establishment of a complex adaptation

from de novo mutations. Moreover, because the role that recombination plays in the origin of specific adaptations depends on both the selective advantage of the final product and the physical distance between the genomic sites of the underlying sites, the issue cannot be reduced to a simple generalization. With a highly context-dependent optimal recombination rate (per nucleotide site), it becomes unclear whether selection is likely to have any general influence on the promotion of recombination-rate modifiers (Chapter 4).

These kinds of observations, in which a two-locus system stochastically shifts from one semistable state to another through evolutionary time, appear to be closely related (albeit not transparently) to the features of a number of models of quantitative traits. For example, diallelic models of quantitative traits under stabilizing selection often exhibit multiple equilibria for allele frequencies (including alternative monomorphic and polymorphic states), depending on the effects of alleles and the ways of assembling a multilocus phenotype that is closest to the optimum (Bulmer 1972; Barton 1986, 1989; Bürger 1989; Gavrilets and Hastings 1994a). One can easily imagine that finite populations would wander from one local equilibrium to another through time, depending on the history of mutation and drift, although no formal theory on the rate of such internal shifts has been worked out.

8

Hitchhiking and Selective Sweeps

When a mutation B without much selective advantage occurs in the proximity of another mutant gene A with a high selective advantage, the survival chance of gene B is enhanced, and the degree of such enhancement is a function of the recombination fraction between the two loci.

Gene B under this situation resembles a hitch-hiker riding along with a host driver.

Kojima and Schaffer (1967)

As first noted by Kojima and Schaffer (1967) and Maynard Smith and Haigh (1974), the dynamics of a neutral allele are strongly influenced by selection at a linked locus. Almost 50 years later, we are still trying to fully understand all of the ramifications of this idea. Chapter 3 provided a brief introduction to two rather different linked-selection scenarios: selective sweeps (the fixation of newly beneficial mutations) and background selection (the removal of deleterious new mutations). In this chapter we further unpack these concepts, presenting a much richer theoretical treatment and a more detailed account of some of their potential consequences. The results presented here also underpin many of the tests for detecting currently ongoing, or very recent, selection developed in Chapter 9.

Our treatment is structured as follows. We start with a review of the basic terminology for different scenarios, all loosely referred to as **sweeps**. Next, we review the population genetics of hard sweeps (those arising from a single mutation that is immediately favorable), detailing how neutral variation is perturbed by positive selection at linked sites. We then turn to soft sweeps, wherein a preexisting allele is suddenly placed under selection, generating a different pattern of background neutral variation relative to a hard sweep. This naturally leads to a discussion as to whether adaptation to a new challenge occurs via existing variation or by waiting for a new favorable mutation, as well as to the notion of a polygenic sweep (small allele-frequency changes at a number of loci). Another scenario for a soft sweep to occur involves multiple favorable mutations arising *during* a sweep, which may be more likely than intuition might suggest. Next, we examine the consequences of repeated bouts of selection at linked sites (be they recurrent sweeps or background selection) for levels of nucleotide diversity, substitution rates, and codon usage bias. We conclude with a discussion on whether the current data warrant a paradigm shift away from Kimura's (1983) classical neutral theory of molecular evolution (Chapter 2).

SWEEPS: A BRIEF OVERVIEW

Given that our treatment of the mathematics of sweeps will be rather technical in places, we first start with a brief overview of the basic terminology and key ideas about sweeps. Casual readers may find this section sufficient for their needs, while it will serve to orient more diligent readers before proceeding onward.

Hitchhiking, Sweeps, and Partial Sweeps

Although usually attributed to Maynard Smith and Haigh (1974), the term **hitchhiking** was introduced by Kojima and Schaffer (1967) to describe the increase in frequency of a neutral allele linked to an allele under directional selection. Plant breeders were also aware of this phenomenon, in the context of **linkage drag** (Brinkman and Frey 1977), wherein an introgressed favorable region may drag with it unfavorable linked genes. The term **selective sweep** (Berry et al. 1991), which is often treated as synonymous with hitchhiking, originally

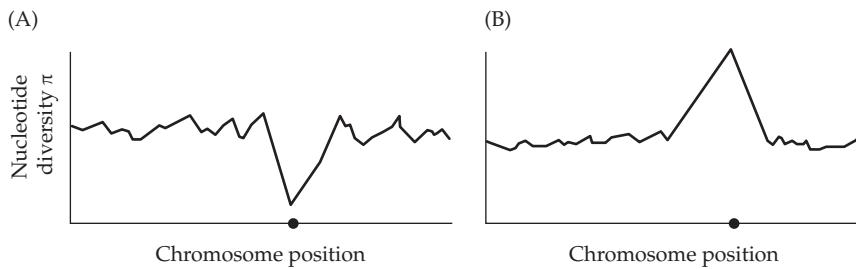

Figure 8.1 (A) The signature of positive directional selection (a selective sweep) around a selected site (the solid circle). The background levels of linked neutral variation (measured as the average nucleotide diversity, π , in a sliding window of markers) show a significant decrease around the selected site, reflecting the decreased effective population size (and hence a shorter time to the most recent common ancestor, TMRCA) for regions linked to this site. (B) By contrast, balancing selection generates an *increase* in nucleotide diversity at linked neutral markers, reflecting a longer TMRCA, and hence more opportunities for mutation to generate variation.

referred to the sweeping away of variation around a selected site following the fixation of a favorable allele (Figure 8.1A). This cleansing effect occurs because selection reduces the effective population size at linked regions, shortening the coalescence times for surviving neutral alleles relative to pure drift, and thus reducing the time for new variation to accumulate (Figure 8.3).

A **partial sweep** refers to the setting in which the favored allele is currently increasing in frequency, as would occur during an ongoing sweep. A partial sweep signal is also generated during **balancing selection** (Chapter 5), again when an allele is increasing in frequency toward some internal equilibrium value (as opposed to fixation). Indeed, any initially rapid increase in frequency by selection generates some type of transient sweep-related signal (albeit potentially quite small), even if the nature of selection changes before fixation (Coop and Ralph 2012).

Just as a specific signal for an ongoing selection event transitions into a different signal following the conclusion of the sweep, so too does the signal for a site under balancing selection. As shown in Figures 8.1 and 8.2, a region held under long-term balancing selection (meaning that the allele frequencies have been near their equilibrium values for a sufficient time) will show an *increase* in the amount of variation at linked neutral sites (Strobeck 1983; Hudson and Kaplan 1988; Kaplan et al. 1988). This occurs because selection holds alternate alleles at intermediate frequencies for a much longer time than expected under drift, resulting in an older common ancestor relative to the neutral expectation (Figure 8.3), and hence more time for variation to accumulate. Over time, however, recombination will constantly shrink the size of the region around the selected site with an elevated coalescence time, continually shrinking this signal of long-term balancing selection (Wiuf et al. 2004; Pavlidis et al. 2012).

Selection Alters the Coalescent Structure at Linked Neutral Sites

The underpinning for many tests of selection using polymorphism data (Chapter 9) is that selection changes the coalescent structure at linked neutral sites. If we view the structure of genealogical relationships among the alleles in a sample as a **tree** (Figure 8.3), recent positive selection shortens the **total branch length** (the sum of the lengths of all the branches, representing the coalescent times), thus decreasing the amount of variation. Conversely, long-term balancing selection generates longer times to common ancestors (as alleles are retained in the population longer than expected under drift), thus increasing the amount of variation. This effect is equivalent to a change in the effective population size, with a sweep reducing the effective population size in a linked region (Chapter 2), generating shorter coalescence times, and balancing selection increasing N_e and coalescent times.

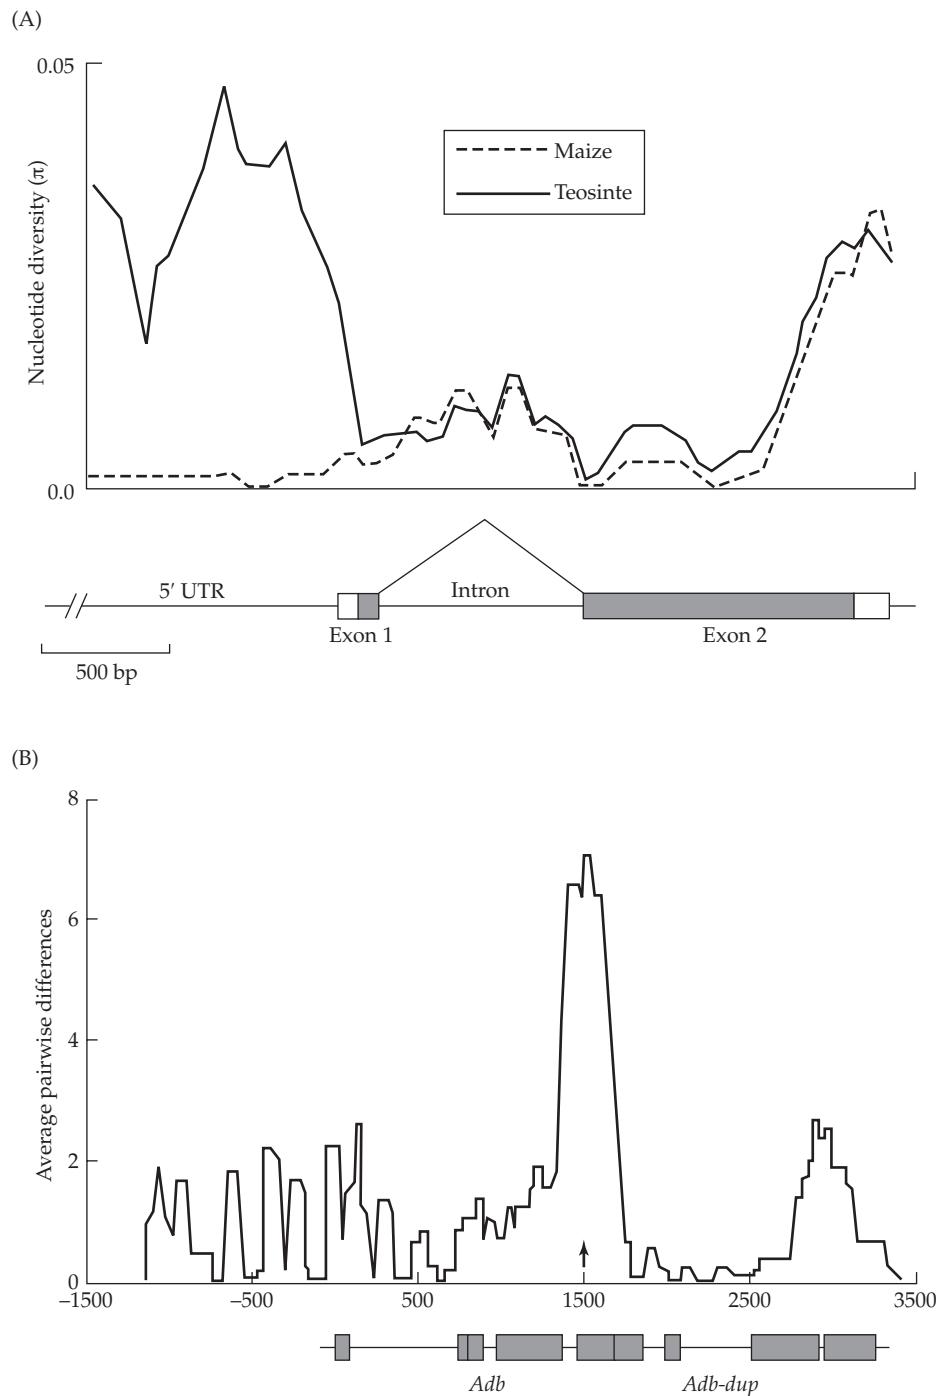

Figure 8.2 Examples of selection influencing levels of variation at linked neutral sites. (A) A sliding-window plot of levels of nucleotide diversity, π , around the *tb1* gene in maize (corn) and teosinte, a candidate gene for the domestication of teosinte into corn. Relative to teosinte, maize variation is dramatically reduced in the 5' UTR region of *tb1*, suggesting a sweep linked to this region. (After Wang et al. 1999.) (B) Inflated levels of variation are seen around a site that results in an amino acid change (arrow), generating two allelic classes, *fast* and *slow*, at the *Adh* gene in *Drosophila melanogaster*. These alternative alleles have long been thought to be under balancing selection, which is consistent with the increased variation observed around this site. However, the nature of selection on this gene is still an open issue, as Begun et al. (1999) showed that the excess variation is *within slow* haplotypes, *not* between *fast* and *slow* haplotypes as would be expected if these two alleles were under balancing selection. (After Kreitman and Hudson 1991.)

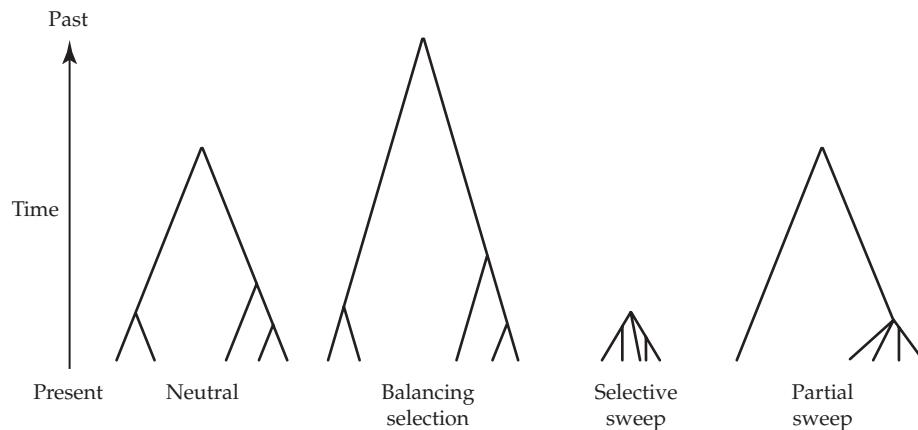

Figure 8.3 Example coalescent (or genealogical) structures (Chapter 2) for loci from the same population under pure drift, balancing selection, a selective sweep, and a partial sweep (ongoing selection in which an allele is still increasing in frequency). The tips of the tree at the bottom of the graph represent five sampled alleles, which eventually coalesce into a single lineage as we go back in time (the top of the graph). This final coalescent point represents the most recent common ancestor (MRCA) for the sampled alleles. For balancing selection, the time to the MRCA (TMRCA) is greater than for neutral genes, which in turn is greater than a region undergoing a sweep. The shape (measured by the relative distances between nodes) of the coalescent is also influenced by selection. Individual coalescent times for a sweep are much more compressed (the nodes are closer together) as one moves back in time, while under a neutral drift process, coalescent times *increase* as we approach the MRCA (Equation 2.40). A partial sweep represents a mixture, with a sweep-like structure in one part of the genealogy (here, the right branch) and a drift-like structure in the other (the left-branch).

Equally important, selection at a linked site does more than simply shorten or lengthen the coalescent structure. It *alters its shape* as well, namely, the expected distances between nodes conditioned on the total length of the tree (Figure 8.3). For a neutral coalescent, trees generated with different values of N_e have the same expected shape when scaled to the same total length (Chapter 2). Under a selective sweep, the **nodes** of the tree (the coalescent points of the genealogies in the sample) are compressed as one moves back in time. In the extreme, positive directional selection can be approximated by a **star** (or **palmetto**) **genealogy**, with all lineages coalescing at a single point. In contrast, under pure drift, the expected longest branch lengths are those that coalesce the final two lineages into a single ancestral lineage (Equation 2.40, Figure 2.10). While differences in the total length of the coalescent influence the total *amount* of neutral variation, changes in its *shape* alter the *pattern* of variation from that expected from a simple change in N_e (such as generating an excess number of rare alleles). The consequences of this change in tree shape are manifested through changes in the site and allele-frequency spectra (Chapter 2) and in the pattern of linkage disequilibrium, differences that underpin a number of tests of selection (Chapter 9). Unfortunately, recovery from a sharp population bottleneck (a crash in population size) also generates a very similar, although not quite identical, compression of the nodes (Barton 1998).

The precise coalescent structure generated by positive selection depends on when the process is being captured. The structure for a just-completed sweep is different from that generated during the initial phase of selection when a favorable allele is increasing in frequency (Figure 8.3). This latter setting is called a partial sweep and could represent either an allele ultimately on its way to fixation or an allele increasing to some equilibrium frequency under balancing selection. In either case, the resulting tree during the partial sweep phase can be rather unbalanced, with one branch displaying a sweep-like pattern (compressed nodal distances reflecting those lineages influenced by the selected

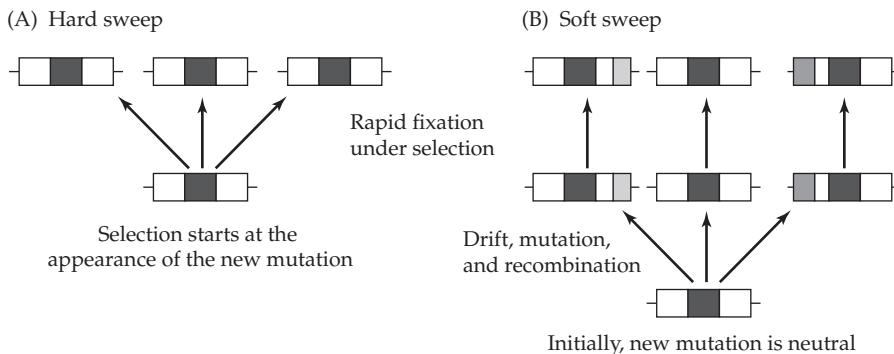

Figure 8.4 Types of sweeps and their corresponding collection of haplotypes. (A) A hard sweep. A new mutation is immediately favored, resulting in only a single haplotype sweeping to high frequency. (B) A single-origin soft sweep. Here a single mutation is initially neutral or even slightly deleterious. It drifts around the population, appearing in new haplotypes through recombination. At some point, an environmental change places this site under strong selection, which sweeps it to fixation, carrying along a sample of its existing collection of linked haplotypes.

allele) and the other a more drift-life pattern (those lineages that have yet to be affected). This partial-sweep coalescent structure is *transient*, and with time it may resolve to a sweep (if fixed by selection) or a balancing-selection structure.

Alternatively, the nature of selection may shift before fixation/equilibrium is reached. In such settings, an allele is driven to a certain frequency by selection, and then may subsequently be fixed by drift or by much weaker selection. Any initial rapid (relative to drift) change in allele frequency generates a signal, even if strong selection stops before fixation, as it modifies the coalescent structure of linked neutral alleles relative to that expected under pure drift (Coop and Ralph 2012).

Hard vs. Soft Sweeps

Not all sweeps, even those involving strong selection, are expected to leave a detectable signal. A **hard sweep** refers to a single favorable new mutation arising and immediately coming under selection (Perlitz and Stephan [1997] also refer to this as a **catastrophic sweep**). The fixation of this mutation drags the haplotype on which it arose to a high frequency, leaving a strong signal (Figure 8.4A). In contrast, under a **soft sweep** (Hermisson and Pennings 2005, 2017; Messer and Petrov 2013a) multiple haplotypes initially carry the favorable allele. The realization that there are different types of sweeps resolved one of the earlier criticisms of the Maynard Smith and Haigh model. Their analysis suggested a major impact on the amount of heterozygosity at linked neutral sites (detailed below), while Ohta and Kimura (1975) showed that recurrent hitchhiking had only a minor effect on heterozygosity. The resolution of these apparently contradictory results was that Maynard Smith and Haigh assumed a hard sweep, while Ohta and Kimura made what amounted to an assumption of a soft-sweep.

Soft sweeps can occur under two scenarios, which have different consequences for the nature and strength of the signal left by the sweep. Under a **single-origin soft sweep**, the eventually favorable mutation predates the start of selection, being either initially neutral or even slightly deleterious. It drifts around the population, potentially spreading to different haplotype backgrounds via recombination, until eventually a change in the environment results in it being favored. This has the effect of selection acting on a more diverse initial collection of haplotypes, giving off a much weaker signal than under a hard sweep. If p is the frequency of an allele at the start of selection, a soft sweep starts with $2pN$ copies of the favorable allele. Within this collection of haplotypes containing the eventually favored allele, the mean coalescence time for a completely linked site in two random individuals

is $t = 2pN_e$, where N_e is the effective population size at the start of selection (Innan and Tajima 1997; Berg and Coop 2015). Thus, there is the potential for substantial variation ($2t\mu = 4pN_e\mu = p\theta$ per site, where $\theta = 4N_e\mu$) at neutral sites among those haplotypes carrying the favorable allele at the start of selection.

Under a **multiple-origin soft sweep**, the fixed favorable allele does not descend from a *single* mutation, but rather from a *collection* of multiple independent events, a scenario that is more likely in larger populations (Pennings and Hermisson 2006). Each recurrent mutation to the favorable allele is associated with an independently chosen haplotype, potentially resulting in even more diversity at fixation than a soft sweep involving a single preexisting mutation. Such multiple mutations may either be present at the start of selection or arise during the sweep itself. The term **standing sweep** is used to distinguish sweeps that start with preexisting variation, in contrast to settings where sweeps are driven by new mutations that arise following the selective change in the environment.

While the difference between hard and soft sweeps is often framed as being rather sharp, this distinction is largely a function of the population sample (Messer and Petrov 2013a). If the coalescence time for the haplotypes in a sample is more recent than the start of selection, we will see a hard sweep. If the coalescence time for sampled haplotypes carrying favorable alleles predates the start of selection, we will see a soft sweep. As we detail below, demography and population structure further influence how we perceive a given sweep. For example, a population bottleneck may **harden** a soft sweep by allowing only a single favorable haplotype to pass through.

THE BEHAVIOR OF A NEUTRAL LOCUS LINKED TO A SELECTED SITE

We start our discussion of the population-genetic theory of sweeps by first considering hard sweeps and their effects on linked neutral loci. Parts of this discussion are rather technical, but the main theoretical results are summarized in Table 8.1, with the expected signatures from a hard sweep summarized in Table 8.2. Throughout, we assume that there is strong selection on the favorable allele ($4N_e s \gg 1$, where, unless otherwise specified, s is the heterozygote fitness advantage). We also assume that no new mutations (either at neutral sites or for the favorable allele) occur during the sweep. This negligible mutation approximation, which reflects a rapid sweep through the population of a new favorable allele and hence reduced time for new mutations to arise, is relaxed later in this chapter.

Allele-frequency Change

To quantify the impact of a sweep, we need to determine how selection influences the frequency of a neutral allele, m , at a linked locus. The ultimate variable of interest is $q(t)$, the frequency of m in generation t of the sweep, with $q(\infty)$ denoting its frequency at the sweep's completion. In the absence of any recombination during the sweep, $q(\infty) = 1$, as the initial haplotype bearing the new favorable mutation (and m) is swept to fixation. The degree to which $q(\infty)$ actually approaches one depends on the relative strengths of recombination, c (between the selected site and the neutral marker), and the strength of selection, s , on the favored site. In Chapter 5 we showed that the time to fixation from selection scales with $1/s$, so it is reasonable to expect that $q(\infty)$ is some function of c/s .

In order to obtain $q(t)$, we need to follow the frequencies of m on the two different chromosomal backgrounds, those with selected allele A and those carrying the alternative allele, a . If we let $q_A(t)$ and $q_a(t)$ denote the frequencies of allele m on A - and a -bearing chromosomes, conditional probability gives the population frequency of m as

$$q(t) = q_A(t) \cdot p(t) + q_a(t) \cdot [1 - p(t)] \quad (8.1a)$$

where $p(t)$ is the frequency of A in generation t of the sweep. When A becomes fixed, $q(\infty) = q_A(\infty)$, the fraction of A -bearing chromosomes that still contain m .

A related quantity is the difference, δ_q , in the frequency of m on these two backgrounds

(A versus a), whose initial value is

$$\delta_q(0) = q_A(0) - q_a(0) \quad (8.1b)$$

Nonzero values of δ_q imply linkage disequilibrium between A and m , with the frequency of m on A -bearing chromosomes differing from its unconditional frequency in the general population. Hitchhiking is basically a race between the rate of recombination reducing the initial disequilibrium (and hence δ_q) and the rate of selection fixing A , eliminating any further recombination. Smaller values of c (slower rates of recombination) and/or larger values of s (faster time to fixation) increase the impact of a sweep. When A is introduced as just one or a few copies, then $q_a(0) \approx q(0)$, as essentially all of the copies of m are on a chromosomes. If A arises as a single copy on an m -bearing chromosome, then $q_A(0) = 1$ (as the only A -bearing chromosome contains m), yielding $\delta_q(0) = 1 - q(0)$. Finally, let

$$\Delta_q = q(\infty) - q(0) \quad (8.1c)$$

denote the final change in the frequency of the linked neutral allele m after A has swept to fixation. Summarizing our notation to this point, we have

$q(t)$	Unconditional frequency of m in generation t
$q_A(t)$	Conditional frequency of m on A -bearing chromosomes
$q_a(t)$	Conditional frequency of m on a -bearing chromosomes
$\delta_q(t) = q_A(t) - q_a(t)$	Difference in frequency of m on A - versus a -bearing chromosomes
$\Delta_q = q(\infty) - q(0)$	Change in frequency of m after a sweep

In particular, note that $\delta_q(\infty)$ and Δ_q , while related, are still distinct.

To proceed, we define the critical measure of the strength of a hitchhiking event,

$$f_s = \frac{\Delta_q}{\delta_q(0)} = \frac{q(\infty) - q(0)}{q_A(0) - q_a(0)} \approx \frac{q(\infty) - q(0)}{1 - q(0)} \quad \text{when } p(0) \ll q(0) \quad (8.1d)$$

which is the fraction of the initial excess association of m with A , $\delta_q(0)$, that persists when A is fixed (Δ_q). If the sweep is started with a single lineage, f_s is the probability of identity-by-descent at the m locus among fixed A chromosomes (Gillespie 2000; Kim and Nielsen 2004). In the absence of recombination, $f_s = 1$, resulting in an allele-frequency change of $\Delta_q = \delta_q(0)$, which is $1 - q(0)$ at the point where A arose as a single copy. With recombination, $f_s < 1$, and our task is to evaluate how the relative values of selection (s) and recombination (c) determine the magnitude of this effect. An important result in sweep theory is that the final allele frequency of m for the case of A arising as a single copy can be expressed as

$$q(\infty) = q(0) + \Delta_q = q(0) + f_s \delta_q(0) = q(0) + f_s [1 - q(0)] = f_s + q(0)(1 - f_s) \quad (8.1e)$$

The derivation of the standard deterministic approximation for Δ_q (given in Example 8.2) requires a few tricks, and the basic biology can get somewhat lost during its development. Hence, we first sketch a rough approximation of how selection and recombination compete before presenting more accurate results. As noted by Maynard Smith and Haigh (1974) and Barton (2002), because m is neutral, its frequency on either background only changes through recombination, with

$$\delta_q(t) = q_A(t) - q_a(t) = (1 - c)^t [q_A(0) - q_a(0)] \approx \delta_q(0) e^{-ct} \quad (8.2a)$$

A rapid increase of A reduces the opportunity for recombination between A - and a -bearing chromosomes, which becomes nonexistent when A is fixed. Assuming A is under additive selection with fitness s , then as shown in Example 8.1, if A is introduced into the population as a single copy and is destined to become fixed, its approximate time to fixation is $\tau \approx 2 \ln(4N_e s)/s$. Substituting this time into Equation 8.2a yields

$$\delta_q(\infty) = \delta_q(0) e^{-c\tau} \approx \delta_q(0) \exp[-(2c/s) \ln(4N_e s)] = \delta_q(0) (4N_e s)^{-2c/s} \quad (8.2b)$$

so that

$$\frac{\delta_q(\infty)}{\delta_q(0)} = \left(\frac{1}{4N_e s} \right)^{2c/s} \quad (8.2c)$$

This shows that the fraction of initial association that persists following the sweep is a function of c/s , which is the key parameter for determining the strength of hitchhiking. When $c/s \ll 1$, most of the initial association remains at the conclusion of the sweep, while as ever-more-distant sites are considered (so that c/s increases), any initial association decay toward zero.

While Equation 8.2c conveys the general notion of competition between recombination and selection, this is a rather crude analysis, as it only considers the time to fixation for A (and hence the end of any opportunity for further recombination) and uses $\delta_q(\infty)$ in place of the real quantity of interest, Δ_q . As presented in Example 8.2, an improved analysis accounts for how the actual change in the frequency of A influences the opportunity for recombination. This problem has received considerable attention, starting with a strictly deterministic analysis by Maynard Smith and Haigh (1974; also see Stephan et al. 2006), followed by analyses allowing for finite population size by Kaplan et al. (1989), Stephan et al. (1992), Barton (1995a, 1998, 2000), Otto and Barton (1997), Durrett and Schweinsberg (2004), Etheridge et al. (2006), Pfaffelhuber et al. (2006), Pfaffelhuber and Studeny (2007), Ewing et al. (2011), and Coop and Ralph (2012).

The details for a deterministic analysis accounting for the change in A are given in Example 8.2. Under this analysis, if $p(0)$ is the starting frequency of A at the time of selection, then for $c/s \ll 1$, the change in q at the fixation of A is

$$\Delta_q \simeq \delta_q(0) p(0)^{c/s} \quad (8.3a)$$

so as a result, from Equation 8.1d,

$$f_s = \frac{\Delta_q}{\delta_q(0)} = p(0)^{c/s} \quad (8.3b)$$

This result shows that our approximate analysis leading to Equation 8.2c underestimated the effect of a sweep, as it scaled as the power $2c/s$, inflating the importance of recombination (Example 8.2 details why this occurs). Recalling that

$$x^a = e^{a \ln(x)} \simeq 1 + a \ln(x) \quad \text{for } |a \ln(x)| \ll 1 \quad (8.3c)$$

and applying this approximation to Equation 8.3b recovers the original result of Maynard Smith and Haigh (1974),

$$f_s \simeq 1 + \frac{c}{s} \ln [p(0)] \quad (8.3d)$$

$$\simeq 1 - \frac{c}{s} \ln(2N) \quad \text{for } p(0) = \frac{1}{2N} \quad (8.3e)$$

This approximation can fail if $(c/s) |\ln [p(0)]|$ is too large, although the more exact Equation 8.3b will still hold. If the favorable mutation is initially linked to deleterious alleles at nearby loci, this will result in a lower net selective advantage during the sweep (diminishing the effective value of s), and hence a diminished value of f_s (Hartfield and Otto 2011; Good and Desai 2014).

As Equation 8.3e shows, the hitchhiking effect for a favorable mutation introduced as a single copy diminishes with increasing population size, reflecting the longer time to reach fixation in larger populations and hence a greater reduction of any initial association by recombination. This effect, however, is rather modest, scaling as the log of population size.

When dominance is present, so that the fitnesses are $1 : 1 + 2hs : 2s$, then c/s in Equations 8.3a–8.3d is replaced by $c/(2hs)$ for $h \neq 0$. For the case of a completely recessive allele ($h = 0$), Maynard Smith and Haigh (1974) found that

$$f_s \simeq 1 - \left(\frac{c}{2s} \frac{1}{p(0)} \right) \quad (8.3f)$$

For example, with $p(0) = 1/(2N)$, Equation 8.3f becomes $1 - (c/s)N$ versus $1 - (c/s) \ln(2N)$ (Equation 8.3d). The much weaker hitchhiking effect (smaller value of f_s) reflects the much longer fixation time for a recessive mutation and hence the greater opportunity for recombination to decay any initial disequilibrium. Conversely, the decreased fixation time for a favorable dominant allele ($h = 1$) effectively doubles the strength of selection (with $c/[2s]$ replacing c/s in Equation 8.3a), resulting in a larger region influenced by the sweep (also see Teshima and Przeworski 2006; Ewing et al. 2011).

These results are for a deterministic analysis. When an analysis allowing for drift is performed, using the initial frequency $1/(2N)$ for a single copy *underestimates* the effects of hitchhiking, as those alleles that become fixed leave the drift-dominated boundary region of the allele-frequency space *faster* than would be predicted by a deterministic analysis (Example 8.1). As a reasonable approximation, this can be accommodated by replacing $p(0) = 1/(2N)$ with $p(0) = 1/(4N_e s)$ in all of the previous expressions (as already seen in Equation 8.2c), yielding

$$f_s \simeq 1 - \frac{c}{2hs} \ln(4N_e s) \quad \text{for } p(0) = 1/(2N) \quad (8.3g)$$

For those who wish a more refined analysis, there is a growing body of very technical literature focusing on the genealogical structure of a sample from a hard sweep (Kaplan et al. 1989; Barton 1998; Etheridge et al. 2006; Pfaffelhuber et al. 2006; Pfaffelhuber and Studeny 2007; Ewing et al. 2011).

Example 8.1. What is the expected time to fixation for an allele with additive fitness effects under strong selection ($4N_e s \gg 1$)? In a strictly deterministic analysis, the fixation time is infinite, as the allele frequency gets arbitrarily close to, but never actually reaches, one. However, in a finite population, once the allele frequency is driven sufficiently close to one by selection, it is rapidly fixed by drift. If the scaled strength of selection is large relative to drift ($4N_e s \gg 1$), we can approximate the change in $p(t)$ by a deterministic process, provided p is not too close to zero or one. Near these boundary values, drift determines the dynamics. Hence, a standard approach is to treat $p(t)$ as a deterministic process when it is in the range $\epsilon < p < 1 - \epsilon$, for $\epsilon \ll 1$ (Kurtz 1971; Norman 1974; Kaplan et al. 1989; Stephan et al. 1992). Once the allele reaches a frequency of $1 - \epsilon$, it is assumed to be quickly fixed by drift, and this additional time is assumed to be small and thus is ignored.

Let $p(t)$ denote the frequency of the favored allele A at time t . If s is small (but $4N_e s$ large), the deterministic allele-frequency dynamics are well approximated by Equation 5.3b, which can alternatively be expressed as

$$\frac{p(t)}{1 - p(t)} = \frac{p(0)}{1 - p(0)} e^{st} \quad (8.4a)$$

The time, τ , for the frequency of A to change from $p(0) = \epsilon$ to $p(\tau) = 1 - \epsilon$ is obtained by substituting these values into Equation 8.4a and rearranging to yield

$$\tau = -2 \ln(\epsilon)/s \quad (8.4b)$$

Taking $\epsilon = 1/(2N)$, the required time starting from a single copy to reach a frequency very close to one ($1 - 1/[2N]$) is

$$\tau \simeq -2 \ln(1/[2N])/s = 2 \ln(2N)/s \quad (8.4c)$$

While Equation 8.4c appears often in the literature, it actually *overestimates* the time to fixation in a finite population (and hence *underestimates* the strength of the sweep). A slightly better approximation follows if we first recall that only a fraction, $2sN_e/N$, of single introductions of A are expected to fix (Chapter 7). *Conditioned* upon those paths where A is fixed, its frequency must increase at a faster rate than would be predicted from the deterministic

analysis. Barton (1995a, 2000; Otto and Barton 1997) showed that, in such cases, the rate of increase in allele frequency is initially inflated (multiplied) by an amount of $1/(2sN_e/N)$, as the allele frequency moves more quickly into the region where deterministic dynamics, not drift, dominate. As a result, they showed that a more accurate estimate of the time for an allele to reach a high frequency (essentially becoming fixed), given it started as a single copy, is given by replacing $\epsilon = 1/(2N)$ by

$$\epsilon = \frac{1}{2N} \frac{N}{2sN_e} = \frac{1}{4N_e s}$$

which results in

$$\tau = 2 \ln(4N_e s)/s \quad (8.4d)$$

The standard finite-population-size correction for hitchhiking models starting with $p(0) = 1/(2N)$ is to replace $2N$ by $4N_e s$ (i.e., take $p[0] = 1/[4N_e s]$) to account for this effect.

Finally, the expected time, t_x , to reach a frequency of $x < 1$ appears in the analysis of partial sweeps (Coop and Ralph 2012). Again, starting at an initial frequency of $\epsilon \simeq 0$, Equation 8.4a yields

$$\frac{x}{1-x} = \epsilon e^{st_x}$$

which, upon rearranging (with $\epsilon = 1/[4N_e s]$), yields

$$t_x = \frac{1}{s} \ln \left(\frac{\epsilon^{-1}x}{1-x} \right) = \frac{1}{s} \ln \left(\frac{4N_e s x}{1-x} \right) \quad (8.4e)$$

Example 8.2. To obtain the final change, $\Delta_q = q(\infty) - q(0)$, in the frequency of a neutral linked allele under a deterministic model of hitchhiking, we follow Barton (2000). Letting $q'(t)$ and $p'(t)$ denote the frequencies of alleles m and A in generation t after selection, and recalling Equation 8.1a, we can express the change in q in generation t by selection (but before recombination). Letting $dp(t) = p'(t) - p(t)$, the change in the frequency of A resulting from selection in generation t ,

$$\begin{aligned} dq(t) &= q'(t) - q(t) = \{p'(t)q_A(t) + [1 - p'(t)]q_a(t)\} - \{p(t)q_A(t) + [1 - p(t)]q_a(t)\} \\ &= [p(t) + dp(t)]q_A(t) + [1 - p(t) - dp(t)]q_a(t) - \{p(t)q_A(t) + [1 - p(t)]q_a(t)\} \\ &= dp(t) [q_A(t) - q_a(t)] \end{aligned}$$

Using Equation 8.2a to substitute for $[q_A(t) - q_a(t)]$, we have

$$dq(t) = dp(t)\delta_q(0) e^{-ct}$$

The final frequency is just the sum of all these single-generation changes, which we approximate by an integral,

$$\Delta_q = q(\infty) - q(0) = \sum_{i=0}^{\infty} dq(i) \simeq \int_0^{\infty} dq(t) dt = \delta_q(0) \int_0^{\infty} dp(t) e^{-ct} dt$$

A more accurate result follows if we note that $dp(t) = \Delta p/\Delta t \simeq dp/dt$, yielding

$$\Delta_q = \delta_q(0) \int_0^{\infty} e^{-ct} \frac{dp}{dt} dt = \delta_q(0) \int_{p(0)}^1 e^{-ct} dp$$

where the final integral follows by a change of variables with $p(\infty) = 1$. The trick to evaluating this last integral is to recall Equation 8.4a for the behavior of a selected allele, and note that $1 - p(0) \simeq 1$ (because $p(0) \ll 1$), yielding

$$\frac{p(t)}{1-p(t)} = \frac{p(0)}{1-p(0)} e^{st} \simeq p(0) e^{st}$$

Rearranging yields

$$p(0) \frac{1 - p(t)}{p(t)} = e^{-st}$$

Noting that $e^{ab} = (e^a)^b$, we can write

$$e^{-ct} = (e^{-st})^{c/s} = \left(p(0) \frac{1 - p(t)}{p(t)} \right)^{c/s} = p(0)^{c/s} \left(\frac{1 - p(t)}{p(t)} \right)^{c/s}$$

which, upon substitution into the previous integral, yields

$$\Delta_q = \delta_q(0) \int_{p_o}^1 e^{-ct} dp = \delta_q(0) p(0)^{c/s} \int_{p_o}^1 \left(\frac{1 - p}{p} \right)^{c/s} dp$$

For $c/s < 0.1$, the integral is close to one, and we recover Equation 8.3a, $\Delta_q = \delta_q(0) p(0)^{c/s}$. Barton (Otto and Barton 1997; Barton 1998) showed that a more accurate result is given by

$$\Delta_q \simeq \delta_q(0) p(0)^{c/s} \{ \Gamma [1 + (c/s)] \}^2 \Gamma [1 - (c/s)] \quad (8.5a)$$

where Γ denotes the gamma function (Equation 2.25b). For $c/s < 0.1$, this reduces to

$$\Delta_q \simeq \delta_q(0) \left(1 + \frac{c}{s} [\ln[p(0)] + 0.5772] \right) \quad (8.5b)$$

which offers a slight improvement over Equation 8.3d, but only when $p(0)$ is not very small.

Reduction in Genetic Diversity Around a Sweep

By fixing any neutral alleles completely linked to the selected site (and usually on a faster time scale than the scale by which mutation can introduce new variation), a sweep removes any initial variation that is present over some region. Two central questions are how large a region is influenced by a recently completed sweep and how strong an effect is seen? To address these questions, we continue to assume that any effect from mutation occurring during the sweep can be ignored (a point that we will address shortly). The first treatment of this topic, and one of the more widely cited results on sweeps, is due to Kaplan et al. (1989). They showed that the expected coalescence time for two alleles at a neutral site that is linked (at recombination fraction c) to the site under selection differs significantly from $2N_e$ (the neutral value) when $c/s < 0.01$ and the sweep has been recent (fixation less than $0.2N_e$ generations ago, so that the effects of new mutations following fixation are negligible). This leads to their often-quoted approximation that *neutral sites within 0.01 s/c of a selected site will be significantly influenced by a recent sweep*.

To express this notion in terms of physical distances, let c_0 be the recombination rate per unit distance (for example, per Mb), so that sites separated by ℓ units have a recombination rate of $c = c_0\ell$. The expected total length L (scaled in our chosen units) of depressed variation associated with a recent sweep then becomes

$$L = 0.02 \frac{s}{c_0} \quad (8.6a)$$

where the factor of two arises because the influence extends on both sides of the sweep. If we suppose that c scales as 1 cM/Mb ($c_0 = 0.01$ for each 10^6 bases), then this approximation implies that a recent sweep with a selection coefficient of $s = 0.01$ is expected to influence variation in a region of size $0.02 \cdot (0.01/0.01) = 0.02$ Mb, or roughly 20 kb (Example 8.3 gives a more refined result). Likewise, a selection coefficient of $s = 0.1$ leaves an initial signature over a region of roughly 200 kb.

Rearrangement of Equation 8.6a can be used to obtain a rough estimate of s . Given a total length, L , of decreased variation and a value of c_0 for this interval,

$$s \simeq \frac{c_0 \cdot L}{0.02} \quad (8.6b)$$

For example, if a sweep roughly covers 50 kb (or $L = 0.05$ Mb) in a region where $c_0 = 0.02$ (2 cM/Mb), then an order-of-magnitude approximation for s is

$$s \simeq \frac{0.02 \cdot 0.05}{0.02} = 0.05$$

This is a crude approach, requiring a reasonable estimate of the size of the region influenced by a very recently completed sweep. Further, simulation studies have shown that *sweeps can be asymmetric around the site under selection* (Kim and Stephan 2002; Schrider et al. 2015), reflecting the random location of rare recombination events between markers and the selected site that occur early in a sweep. Simply taking the middle of a region of depressed variation can be a poor approach for localizing the site under selection.

A more accurate expression for the amount of variation remaining after a very recent sweep follows from the expected allele-frequency change (Equation 8.3a). Let $q(0)$ denote the initial frequency of allele m at a linked neutral marker, with $H_0 = 2q(0)[1 - q(0)]$ denoting the initial heterozygosity, which is typically measured as per-nucleotide diversity, π (Chapters 2 and 4). Hitchhiking during the fixation of a linked selected allele changes a marker allele frequency to $q(\infty) = q(0) + \Delta_q$, and hence the heterozygosity becomes

$$\begin{aligned} H &= 2q(\infty)[1 - q(\infty)] = 2[q(0) + \Delta_q][1 - (q(0) + \Delta_q)] \\ &= H_0 - 2[1 - 2q(0)]\Delta_q - 2(\Delta_q)^2 \end{aligned} \quad (8.7a)$$

The expected heterozygosity is the average of H over two scenarios. With a probability of $q(0)$, the favorable mutation arises on an m background, yielding $q_A(0) = 1$, $\delta_q(0) = 1 - q(0)$ and $\Delta_q \simeq [1 - q(0)] p(0)^{c/s}$ (Equation 8.3a). Conversely, with a probability of $1 - q(0)$, the favorable allele arises on a non- m background, yielding $q_A(0) = 0$, $\delta_q(0) = 0 - q(0) = -q(0)$ and $\Delta_q \simeq -q(0) p(0)^{c/s}$. Using these results, the expected allele-frequency change is

$$E(\Delta_q) = q(0) \cdot [1 - q(0)] p(0)^{c/s} + [1 - q(0)] \cdot [-q(0) p(0)^{c/s}] = 0 \quad (8.7b)$$

Taking the expectation of Equation 8.7a and using Equation 8.7b yields

$$H_h = E(H) = H_0 - 2E[\Delta_q^2] \quad (8.7c)$$

where

$$\begin{aligned} E[\Delta_q^2] &= q(0) \left[[1 - q(0)] p(0)^{c/s} \right]^2 + [1 - q(0)] \left[-q(0) p(0)^{c/s} \right]^2 \\ &= q(0)[1 - q(0)] p(0)^{2c/s} \end{aligned} \quad (8.7d)$$

Combining Equations 8.7c and 8.7d yields

$$H_h = H_0 \left(1 - p(0)^{2c/s} \right) \quad (8.8a)$$

Recalling that this result is an approximation (as Equation 8.3a approximates the allele frequency change), our final result is

$$\frac{H_h}{H_0} \simeq 1 - p(0)^{2c/s} \simeq -\frac{2c}{s} \ln[p(0)] \quad \text{for } c/s \ll 1 \quad (8.8b)$$

Following from our previous discussion, for a sweep starting from a single mutation, we can improve on Equation 8.8b by replacing $p(0) = 1/2N$ by $1/(4N_e s)$, yielding

$$\frac{H_h}{H_0} \simeq 1 - (4N_e s)^{-2c/s} \quad (8.8c)$$

Stephan et al. (1992) and Barton (1998) presented more accurate (and complex) expressions for the reduction in heterozygosity in a finite population.

An alternative way to obtain Equation 8.8b is to consider the fraction, f_s , of the initial associations that persist when A is fixed (Equation 8.1c), as with a probability of f_s^2 , neutral alleles at our site for two randomly drawn chromosomes (under a catastrophic sweep) are identical-by-descent and hence (in the absence of mutation) homozygous. With a probability of $1 - f_s^2$, two randomly drawn alleles are not identical-by-descent (from the sweep), displaying the pre-sweep heterozygosity value. Hence, from Equation 8.3b, which assumes additive selection,

$$\frac{H_h}{H_0} = 1 - f_s^2 = 1 - p(0)^{2c/s} \quad (8.8d)$$

When dominance is present (implying a heterozygote fitness of $1 + 2hs$ instead of $1 + s$), Equation 8.8b holds, with $2hs$ replacing s (for $h > 0$). For a complete recessive ($h = 0$, with fitnesses of $1 : 1 : 1 + 2s$), Ewing et al. (2011) showed that

$$\frac{H_h}{H_0} \simeq \frac{\eta}{1 + \eta} \quad \text{where} \quad \eta = c \sqrt{4N_e/s} \quad (8.8e)$$

As expected, a recessive sweep produces a much weaker signal, reflecting the greater chance for recombination given the much longer time to fixation ($\sim \sqrt{N_e}/s$ generations; Ewing et al. 2011). It is important to stress that Equations 8.8d and 8.8e both refer to the reduction in heterozygosity *immediately following* a sweep. This is the maximal signature, as mutation will gradually rebuild neutral variation, an effect we will examine shortly.

Finally, we can examine the accuracy of Kaplan and Hudson's approximation (Equation 8.6a), which states that a sweep influences all sites with $c/s \leq 0.01$, using Equation 8.8b to find the reduction in heterozygosity for sites at this critical value. Assuming there is a single copy of the selected allele at the start of selection, $p(0) = 1/(2N)$, the simple approximation given by Equation 8.8b (with $c/s = 0.01$) yields

$$\frac{H_h}{H_0} = \frac{2c}{s} \ln(2N) = 0.02 \ln(2N) \quad (8.9)$$

The dependence on N is very weak. For example, for $N = 10^4$, Equation 8.9 gives an 80% reduction ($H_h/H_0 = 0.20$), while for $N = 10^9$, it corresponds to a 57% reduction. A more refined analysis can be performed using the drift-corrected expression Equation 8.8c, with $4N_e s$ replacing $2N$.

Example 8.3. Assume a recombination rate of 1 cM/Mb ($c_0 = 0.00001$ per kb), and consider the expected reduction in heterozygosity at a site 10 kb away from a sweep ($c = 10 \cdot 0.00001 = 0.0001$). For an allele with additive fitness effects, with $s = 0.01$ and $N_e = 10^6$, Equation 8.8b yields $H_h/H_0 \simeq 0.19$, so that (ignoring any new mutation) only 19% of the initial heterozygosity is present immediately following a sweep. For a dominant allele, we replace $s = 0.01$ by $2s = 0.02$ in Equation 8.8b, giving $H_h/H_0 \simeq 0.10$. Finally, when the favored allele is recessive,

$$\eta = c \sqrt{4N_e/s} = 0.0001 \sqrt{4 \cdot 10^6/0.01} = 2$$

and Equation 8.8c yields $H_h/H_0 \simeq 0.67$. Using the same parameters, the values for H_h/H_0 at different distances away from the selected site are as follows:

	1 kb	5 kb	10 kb	25 kb	50 kb	100 kb
Dominant	0.01	0.05	0.10	0.23	0.41	0.65
Additive	0.02	0.10	0.19	0.41	0.65	0.88
Recessive	0.17	0.50	0.67	0.83	0.91	0.95

The sweep from a dominant allele has the largest effect (roughly twice the reduction at small distances compared to additive selection), while the effect of a recessive allele is fairly weak except at very short distances from the site. For these three modes of gene action and $s = 0.01$, a 50% reduction ($H_h/H_0 = 0.5$) in heterozygosity occurs over a distance of 5 kb on either side of a selected recessive allele, the distance is 31 kb when additive, and the distance is 66 kb when dominant, giving the size of the sweep regions as 10, 62, and 132 kb, respectively.

The Messer-Neher Estimator of s

As Equation 8.6b illustrates, one can manipulate any of these expressions for the reduction in H to obtain an estimate of s (given H_0 and c). In Chapter 9, this approach is placed into a more sophisticated likelihood framework where the entire spatial pattern of genetic variation (as a function of the distance, c , from a putative site) is used to estimate s . These approaches all require knowledge of the recombination rate, c . How can we estimate s in situations with little or no recombination, such as in an organelle genome, on a very small chromosome, or in a highly inbred or asexual species? A creative solution to this problem was presented by Messer and Neher (2012).

As a favored allele exponentially increases in frequency during its initial sojourn to fixation, new mutations can appear on its initial haplotype. While rare, these mutations will mostly be at a higher frequency than those arising after fixation, as each hitchhikes up to some modest frequency. By considering a region around a putative selected site and counting the resulting haplotypes following a recently completed sweep, Messer and Neher obtained a very simple approximate relationship between the frequencies of the ranked haplotype classes. Letting n_0 denote the number of the most frequent haplotype, n_1 the next frequent, and so forth, they found that

$$\frac{n_i}{n_0} \simeq \left(\frac{\mu}{i s} \right)^{1-(\mu/s)} \simeq \frac{\mu}{i s} \quad (8.10)$$

namely, a power-law relationship as a function of the total mutation rate, μ , for the region being considered and the strength, s , of the favored allele. For example, for $\mu/s = 0.02$, n_0 is 50 and 100 times more frequent, respectively, than n_1 and n_2 . Based on the relationship given by Equation 8.10, Messer and Neher developed a regression-based estimator of s .

While this approach works on genomic regions showing little to no recombination (the authors applied it to HIV), it also requires deep population sequencing, as the higher mutational classes (n_i for $i > 2$) are rare. For example, for $\mu/s = 0.1$, this approach requires accurate estimates of frequencies with an expected value around 2% (assuming a regression fitted with four values, and hence requiring the class n_4), implying a sample size of around 10^3 sequences. While c (the recombination rate over the chosen haplotype length) does not appear in Equation 8.10, Messer and Neher found that simply replacing μ by $\mu + c$ works well if the ancestral diversity is high but overestimates the rate of formation of new haplotypes if this diversity is low. They found that simply pruning the collection of haplotypes to ignore those that were clearly generated by recombination slightly underestimates s but otherwise performs rather consistently.

Recovery of Variation Following a Sweep

The signal left by even a strong sweep is transient, as new mutations will eventually restore heterozygosity at neutral sites back to their equilibrium value ($H_0 = 4N_e\mu$) before the sweep. Kim and Stephan (2000) found that the expected heterozygosity t generations after

a completed sweep is approximately

$$E[H(t)] \simeq H_0 \left[1 - (4N_e s)^{-2c/s} \cdot e^{-t/(2N_e)} \right] \quad (8.11)$$

where $H_0(4N_e s)^{-2c/s} = H_0 f_s^2$ is the reduction immediately following the conclusion of the sweep. Mutation following a cleansing sweep recovers variation, and this can be envisioned as a decay in the initial reduction, $H_0 f_s$, eventually driving this back to zero (and hence driving heterozygosity back to its original value, H_0). From Equation 8.11, the initial reduction decays by an amount of $1/(2N_e)$ in each generation, with the cumulative decay of this initial variation due to drift being $(1 - 1/(2N_e))^t \simeq \exp(-t/2N_e)$. The expected time to recover half the variation lost during the sweep (its half-life) is $\exp(-t_{0.5}/2N_e) = 0.5$ or $t_{0.5} = -2 \ln(0.5)N_e \simeq 1.4N_e$. Note the counterintuitive and important result that the ratio $E[H(t)]/H_0$ is *independent* of the actual mutation rate, μ . This is because a low (or high) mutation rate implies a slow (or fast) accumulation of new mutations following the sweep but also implies a low (or high) target heterozygosity to reach that point.

Effects of Sweeps on the Variance in Microsatellite Copy Number

These results on the behavior of nucleotide diversity (heterozygosity) during and after a sweep apply to SNP data. Because per-nucleotide mutation rates are very low (Chapter 4), the infinite-sites model offers a good approximation for such data, as recurrent neutral mutation during the sweep can largely be ignored because back mutations are unlikely and mutations are rare in general. Both of these assumptions are violated when microsatellite markers (simple tandem repeats [STRs]) are considered. These have high mutation rates (on the order of 10^{-2} to 10^{-4}), and recurrent mutation can regenerate the same allele (scored as the number of repeats at a site). A further complication is that a commonly used measure of STR variability is not heterozygosity, but rather the variance, V , in repeat number among alleles at the microsatellite marker.

Given the considerable uncertainty about the mutational dynamics of STRs, as well as a wealth of potential models (reviewed by Bhargava and Fuentes 2010), we only consider briefly results from the simple stepwise mutation model (an STR allele of length k has equal probability of changing to length $k + 1$ or $k - 1$). Under this model, Wiehe (1998) found that if V_0 denotes the initial variance in repeat number, its expected value, V_h , immediately following the sweep has a very similar form to Equation 8.8b

$$\frac{V_h}{V_0} = 1 - \beta \cdot p(0)^{2c/s} \quad (8.12a)$$

the difference being a scaling factor of $\beta < 1$, which discounts the removal of variation by the sweep from the continual input from new mutation. Note that even at completely linked sites ($c = 0$), the fraction of variance after a sweep is not zero, but rather $1 - \beta$, due to mutational variation being generated during the sweep event itself. Under a simple model where the total mutation rate scales with allele length ($k\mu$ is the rate of an allele containing k repeats), Wiehe found that

$$\frac{V_h}{V_0} = 1 - p(0)^{(4\mu+2c)/s} \quad (8.12b)$$

When $4\mu + 2c > s$, little depression in the copy-number variance is expected. In this setting, mutation rates are such that new STR alleles are generated at a high rate even as the sweep is occurring, so that even if only the descendants of the single original haplotype are fixed, they will still show significant variation. For example, given an STR mutation rate of $\mu = 1/400$, s must exceed 0.01 for any significant sweep signal. Hence, STR-based scans are likely to miss all but the strongest of sweeps.

Using results from Slatkin (1995b), the rate of recovery in V following the sweep is a modification of Equation 8.11

$$V(t) = V_0 \left(1 - p(0)^{(4\mu+2c)/s} \cdot e^{-t/(2N_e)} \right) \quad (8.12c)$$

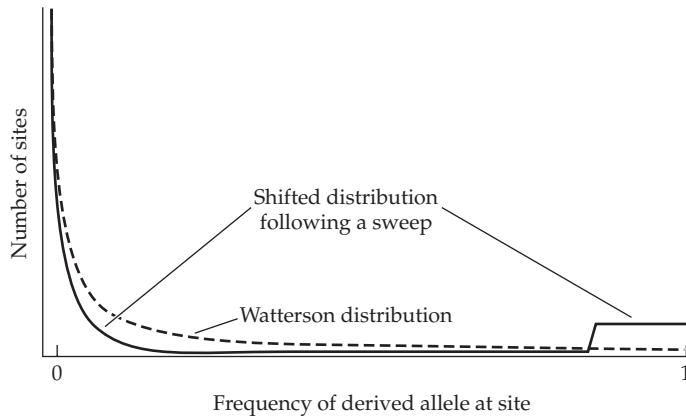

Figure 8.5 The effect of a hard sweep on the unfolded site-frequency spectrum of derived alleles. Under the equilibrium neutral model, this distribution is hyperbolic, an L-shaped curve that is monotonically declining, with most derived alleles being at low frequencies (the Watterson distribution; Equation 2.34a). The effect of a sweep is to shift some derived alleles to very high frequencies while shifting the others to frequencies near zero, resulting in a more U-shaped distribution (Equation 8.13).

As with Equation 8.11, $t_{0.5} \simeq 1.4N_e$ generations are required to recover half the decrease in V immediately following the sweep. It is often stated that microsatellites recover variation faster because they quickly generate new mutations *following* a sweep. This is incorrect, as the high level of variation is due to mutations arising *during* the sweep, not following it. Equation 8.12c again shows that the time to recover variation following the sweep (the time to decay the reduction present immediately following the sweep) is independent of the mutation rate.

The Site-Frequency Spectrum

Recall the concept of a frequency spectrum (Chapter 2), the expected distribution of the frequencies of different alleles or sites in a sample. In particular, the site-frequency spectrum (SFS), $\phi(x)$, gives the expected frequency of sites having a frequency of x for the derived (most recent) allele, and our focus is on how a sweep changes the SFS for linked, neutral alleles. Under the equilibrium neutral model, the SFS is given by the Watterson distribution of $\phi(x) = \theta/x$ (with $\theta = 4N_e\mu$ referring to the expected per-nucleotide heterozygosity value; Equation 2.34a), with most sites having very low derived-allele frequencies. As shown in Figure 8.5, a sweep transforms the (unfolded) SFS of derived alleles from the L-shaped Watterson distribution to a more U-shaped one (Fay and Wu 2000; Kim and Stephan 2002), with *excesses of both low- and high-frequency sites*. When considered as a folded frequency spectrum (the spectrum over 0 to 0.5 based on the minor-allele frequency; Chapter 2), these excesses result in an increase in the fraction of sites with rare minor allele frequencies. Przeworski (2002) showed that both of these excesses are present immediately following a sweep, but that the excess of sites with high-frequency derived alleles rapidly dissipates (within $0.2N_e$ generations) as they become fixed. The excess of sites with rare alleles persists a bit longer (roughly $0.5N_e$ generations), as it is bolstered by new mutations following the sweep.

As detailed in Example 8.4, Fay and Wu (2000) found that a sweep transforms a pre-sweep Watterson distribution, $\phi(x)$, into a new post-sweep SFS, $\phi^*(y)$, which is a function of the critical parameter, f_s , for the impact of a sweep (Equation 8.1d), with

$$\phi^*(y) = \begin{cases} \theta \left(\frac{1}{y} - \frac{1}{1-f_s} \right) & \frac{1}{2N} \leq y \leq 1-f_s \\ 0 & 1-f_s < y < f_s \\ \frac{\theta}{1-f_s} & f_s \leq y \leq 1 - \frac{1}{2N} \end{cases} \quad (8.13)$$

These expressions show how a sweep distorts the frequency spectrum toward both higher and lower frequencies of derived alleles. Linked neutral alleles are swept toward fixation (inflating the high-frequency range) if they are on the original haplotype of the new favorable mutation (i.e., in coupling with the favorable allele). If x is the frequency of the derived neutral marker allele, then x is the probability it is coupled with the favorable allele and changed to a new (post-sweep) frequency of $y = f_s + x(1-f_s)$ (Equation 8.1e). Otherwise, when not on the favorable haplotype (in repulsion), which occurs with probability $1-x$, the linked neutral allele is swept toward loss (a new frequency of $y = x[1-f_s]$).

If two *concurrent* sweeps are influencing the same region, the resulting site-frequency spectrum is rather different from the pattern for a single hard sweep. Simulations by Chevin et al. (2008) found an *excess of intermediate-frequency alleles* in such cases, mimicking the signature of balancing selection. However, concurrent sweeps also generate both an excess of high-frequency derived alleles and a deficiency of low-frequency alleles. The combination of these three features seems unique to concurrent sweeps.

Example 8.4. The derivation of Equation 8.13 follows in large part from Equation 8.1e, the expected change in marker allele frequency following a sweep for a given value of f_s . Let x denote the frequency of a linked neutral derived allele before the start of selection and y its frequency immediately following the sweep. We assume a pre-sweep Watterson SFS, $\phi(x) = \theta/x$ (Equation 2.34a). Given a single favorable mutation occurring at random on one of the existing chromosomes, then if x is the frequency of a linked neutral allele, with a probability of x , then the allele is in coupling phase with the new mutation; otherwise (with a probability of $1-x$), it is in repulsion phase.

First consider a neutral derived allele (at a frequency of x before the sweep) that is in repulsion with the favorable allele. From Equation 8.1e, the post-sweep frequency is $y = x(1-f_s)$, for which the range is obtained as follows. For derived alleles that are initially near fixation ($x \simeq 1$), $y = (1-f_s)$, while rare alleles are driven toward zero. Because our focus is on segregating alleles, the lower limit becomes $1/(2N)$, giving the post-sweep frequency range for neutral markers in repulsion with the favorable allele as $1/(2N) \leq y \leq 1-f_s$. The resulting SFS for derived neutral alleles in repulsion is given by

$$\phi^*(y)dy = (1-x)\phi(x)dx = (1-x)\frac{\theta}{x}dx$$

The first step follows because $(1-x)$ is the probability that a neutral allele (initially at a frequency of x) is in repulsion with the favorable allele, and the second step follows from Equation 2.34a. Recalling (for alleles in repulsion) that $y = x(1-f_s)$, we have both $x = y/(1-f_s)$ and $dx = dy/(1-f_s)$. Substituting for x and dx in this expression yields

$$(1-x)\frac{\theta}{x}dx = \left(1 - \frac{y}{1-f_s}\right) \frac{\theta(1-f_s)}{y} \frac{dy}{1-f_s}$$

which, after multiplication, yields the repulsion piece of the post-selection SFS as

$$\phi^*(y)dy = \theta \left(\frac{1}{y} - \frac{1}{1-f_s} \right) dy \quad \text{for } 1/(2N) \leq y \leq 1-f_s$$

Conversely, with a probability of x , the derived allele is in coupling phase and is swept to a frequency of $y = f_s + x(1-f_s)$. For $x \simeq 0$, $y \simeq f_s + 0(1-f_s) = f_s$, while the upper limit

follows from our restriction to segregating sites, yielding $f_s \leq y \leq 1 - 1/(2N)$. Following the same logic as before yields

$$\phi^*(y)dy = x\phi(x)dx = x\frac{\theta}{x}dx = \theta dx$$

As before, the first step follows because x is the probability that a neutral allele (initially at a frequency of x) is in coupling with the favorable allele. With an allele in coupling, $y = f_s + x(1 - f_s)$, yielding $x = (y - f_s)/(1 - f_s)$ and $dx = dy/(1 - f_s)$. Substituting for dx into the previous expression yields the coupling piece of the post-sweep SFS as

$$\phi^*(y)dy = \frac{\theta}{1 - f_s}dy \quad \text{for } f_s \leq y \leq 1 - 1/(2N)$$

Putting these two pieces together recovers Equation 8.13.

The Pattern of Linkage Disequilibrium

The pattern of linkage disequilibrium (LD) generated by a sweep has been extensively studied (Thomson 1977; Gillespie 1997; Przeworski 2002; Kim and Nielsen 2004; Stephan et al. 2006; Jensen et al. 2007; McVean 2007; Jones and Wakeley 2008; Pfaffelhuber et al. 2008), and it turns out to be both complicated and surprising. The conventional wisdom was that a selective sweep increases LD across the site of selection (Thomson 1977; Przeworski 2002), with the increase in LD *during* a sweep providing a signal of selection (Chapter 9). Starting with Kim and Nielsen (2004), however, it has been realized that the spatial and temporal patterns in LD associated with a sweep are far more subtle.

The temporal dynamics of this structure are shown in Figure 8.6, which plots the dynamics of LD for two linked neutral sites separated by $c = 0.0002$. The midpoint between the sites is set at zero, with the value x representing the position of the selected locus, so that Figure 8.6 displays the expected LD between this pair of neutral sites at different distances from the selected site. For $|x| > 0.0001$, both markers are on the same side of the selected site, while for $|x| < 0.0001$, the selected site is between the markers. Vertical slices on the curve (the shape of the curve at a set time point) represent the expected LD (measured as D ; Equation 2.18) between the two markers as a function of x for a given time point during the sweep. As shown, during the initial phase of the sweep (proceeding from the rear-most slices), strong LD accrues between sites that flank the selected site as the sweep progresses, with LD initially showing a peak at $x = 0$. As the sweep progresses (i.e., as slices move toward the front), the LD for a pair of markers flanking the selected site ($|x| < 0.0001$) approaches zero, while the LD between sites that are both on the same side of the selected site ($|x| > 0.0001$) largely remains intact. The plot in Figure 8.6 is based on a deterministic analysis of a three-locus model (one selected and two neutral) by Stephan et al. (2006). As such, it depicts a very smooth and symmetric view of the LD on either side of the selected site, representing the *average* behavior over a large number of identical sweeps. In reality, however, there is considerable variance in the amount of LD due to finite population size, the stochastic location of rare recombination events, and differences in allele frequencies across markers at the start of the sweep. Simulation studies (e.g., Kim and Nielsen 2004; Schrider et al. 2015) have often found a very asymmetric pattern of LD across a selected site, with a strong signal on one side and little to no signal on the other.

Thus, while LD does indeed increase during the early phase of the sweep of a favorable allele to fixation, it actually starts to *decrease* in the neighborhood of the site once the frequency of the favorable allele reaches roughly 0.5 (Stephen et al. 2006). Upon fixation, the result is a region flanking the selected site that has an LD level *lower* than the background level at unlinked neutral loci, and hence potentially reduced from its initial starting value. Conversely, for pairs of markers on either side of the selected site, LD significantly increases, so that strong LD can be found on the left and/or right sides of a selected site, but with

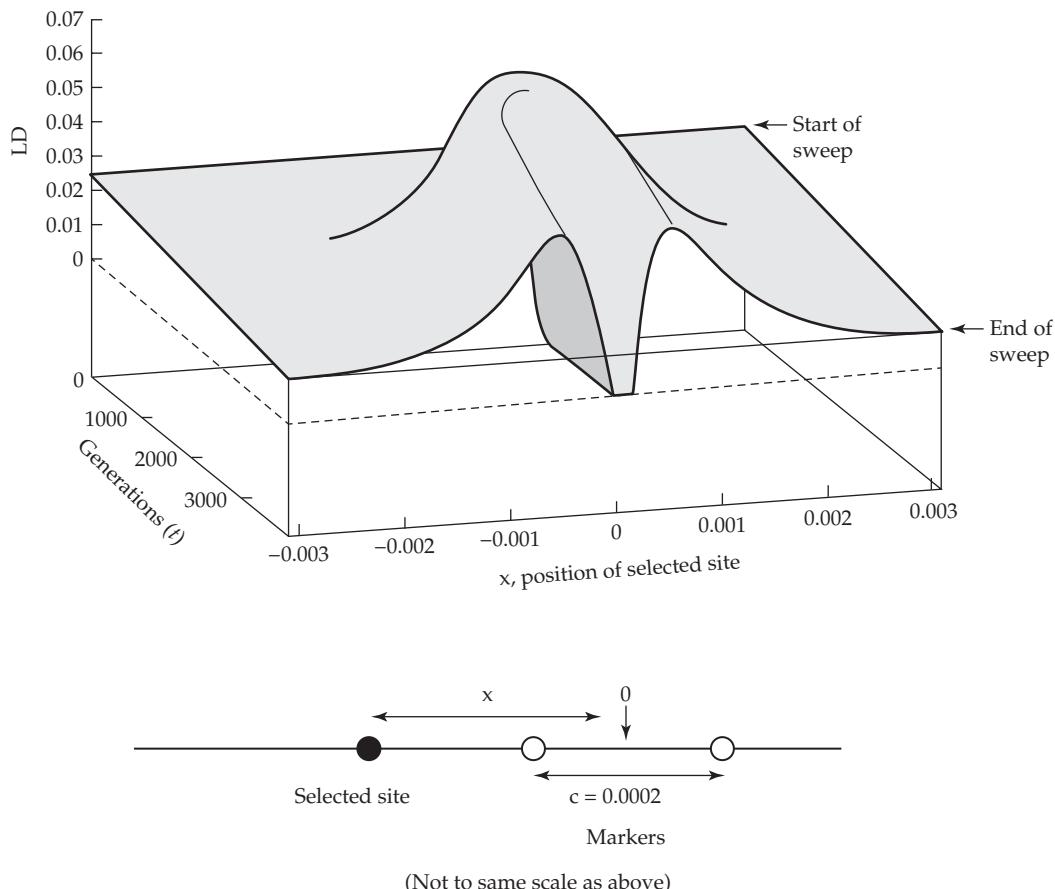

Figure 8.6 The dynamics of linkage disequilibrium (LD) between two neutral markers as a function of their location relative to the selected site. The neutral markers in this figure are separated by $c = 0.0002$, with x (measured in units of c) representing the location of the selected site. A value of $x = 0$ implies that the selected site is exactly between the two markers and it is flanked by the markers provided $|x| < 0.0001$, whereas both markers are on the same side of the site when $|x| > 0.0001$ (see the figure panel). The figure plots the LD dynamics (measured by D) for pairs of markers during the time course of a sweep, which starts at generation 0 (the rear slice along the generations axis) and runs until the conclusion of the sweep (the front slice). One sees a strong signal of LD *across* the site ($|x| < 0.0001$) during the early phase of the sweep (the partial sweep stage), with a sharp increase in LD for markers flanking the selected site. As the favorable allele reaches intermediate frequency, the LD flanking the site starts to decay (the region $|x| < 0.0001$), while the LD on either side largely remains intact ($|x| > 0.0001$). Upon fixation, the result is very little LD between markers that flank the site (often below that in the starting background), while strong regions of LD exist for pairs of markers on the same side of the selected site. (After Stephan et al. 2006.)

no association *across* the site. These results have strong implications for tests of selection (Chapter 9), in that strong LD across the site is expected during a partial sweep (with the selected allele still increasing in frequency). Conversely, for a recently completed sweep, the LD pattern is very different, with LD between neutral sites on the same side of the selected site but little LD across sites. Thus, different LD-based tests are required for these two different situations.

Jones and Wakeley (2008) suggested some caution with these results, as even a very small amount of gene conversion involving the selected site can disrupt these LD patterns and obscure any LD-based hard-sweep signature. In particular, a gene conversion event involving just the favorable site can result in substantial LD *across* a selected site (i.e., between

markers on opposite sides of the site), and hence has the opposite effect of recombination. This happens because a conversion tract that covers the selected site acts like a double-recombinant within that region, transferring a small section of the haplotype around the selected site onto a different haplotype, which has an effect on LD throughout the region, not just at the conversion site. Using current estimates of the rate and the average tract length of conversions in humans, Jones and Wakeley concluded that gene conversion can impact the signal of some sweeps.

Age of a Sweep

A number of researchers have considered estimators for the time since the start of a sweep, typically under the assumption of a catastrophic sweep and no recombination (Wiehe and Stephan 1993; Perlitz and Stephan 1997; Enard et al. 2002; Jensen et al. 2002; Przeworski 2003; Li and Stephan 2005, 2006; Ormond et al 2015). The simplest estimator follows from the infinite-sites model (Chapter 2) and assumes the sweep is essentially complete. Assume that S segregating sites are observed in a sample of n sequences from a nonrecombining region around the site of a sweep. Under the infinite-sites model, the expected number of segregating sites in a sample is $E(S) = \mu T_n$, where μ is the total mutation rate over the entire region of interest and T_n is the total branch length of the entire genealogy of the sample. Under a catastrophic sweep that started τ generations ago, the coalescent tree has its nodes sharply compressed, and can be approximated by a star phylogeny. In this case, the total branch length is $n\tau$ (as the length along each of the n branches is roughly τ), giving $\mu n\tau$ as the expected number of segregating sites, and leading to a simple method-of-moments estimator of the time τ ,

$$\hat{\tau} = \frac{S}{\mu n} \quad (8.14)$$

More sophisticated approaches for estimating τ are discussed in Chapter 9.

Example 8.5. Akey et al. (2004) found a 115-kb region on human chromosome 7 showing signatures of a sweep: excess rare alleles, excess high-frequency derived alleles, and a reduction in nucleotide diversity. Eleven segregating sites were found in a sample of 45 African- and European-American chromosomes. From Equation 8.14, using a mutation rate of 10^{-8} per site per generation, the total mutation rate over the entire region is $115,000 \cdot 10^{-8} = 0.00115$ per generation, yielding

$$\hat{\tau} = \frac{11}{0.00115 \cdot 45} = 213 \text{ generations}$$

using the star phylogeny approximation. Assuming a generation time of 25 years for humans, this translates into ~ 5300 years. Example 9.15 shows how confidence intervals are estimated under this model.

Partial Sweeps

An ongoing selection event (i.e., the favored allele is still increasing in frequency), whether toward fixation or to some internal equilibrium frequency, generates a partial sweep signal. Coop and Ralph (2012) considered an additional scenario, wherein a newly arising allele is rapidly swept up to a frequency of x by selection, after which the environment changes, reducing the strength of selection (perhaps even to the point of making the allele effectively neutral). The key parameter is now t_x , the time to reach this frequency, which, from Equation 8.4e (for additive fitnesses and starting from $p(0) = 1/[2N]$), is

$$t_x = \frac{1}{s} \ln \left(\frac{4N_e s x}{1 - x} \right)$$

Coop and Ralph found that the reduction in heterozygosity (for a neutral marker at recombination distance c) when the sweep pauses at frequency x is

$$\frac{H_h}{H_0} \simeq 1 - x^2 e^{-2ct_x} = 1 - x^2 \left(\frac{4N_e sx}{1-x} \right)^{-2c/s} \quad (8.15)$$

This follows from the probability of sampling a chromosome carrying the advantageous mutation being x and the probability that a site at distance c has not recombined over the t_x generations required to reach a frequency of x being $(1-x)^{t_x} \simeq e^{-ct_x}$, for a total probability of xe^{-ct_x} . The chance of drawing two such alleles is simply the square of this product, which is the expected homozygosity. Coop and Ralph concluded that the initial rapid rise in frequency of a selected allele during the partial sweep determines how much of a sweep signal is generated, even if the allele is ultimately fixed by drift. With recurrent partial sweeps, such shifts in the strength of selection can result in a reduction in heterozygosity (Equation 8.26) but will produce little shift in the frequency spectrum.

Impacts of Inbreeding

Three separate consequences of inbreeding enhance the signal of a sweep. First, under inbreeding, the effective population size is smaller, with $N_e = N/(1+F)$ (Chapter 3), where $F = \eta/(2-\eta)$ for a partially-selfing (with selfing rate η) population in equilibrium (Chapter 23). Equation 8.3g shows the impact of a sweep (measured by the critical parameter, f_s) is slightly larger in smaller populations, although the effect only scales as $\ln(N_e)$. The reason for this slightly greater impact is a faster time to fixation, and hence less opportunity for recombination. This point highlights the other two features of inbreeding that are more impactful on sweeps. First, selection is generally more efficient, especially when the favored allele is recessive or partly recessive. Indeed, the expected time to fixation is reduced at least by a factor of $(1+F)$ under inbreeding (Caballero and Hill 1992b, Glémén 2012). Inbreeding is also more democratic in that allele-frequency change trajectories under different amounts of dominance become increasingly similar under increased inbreeding (Hartfield et al 2017). Second, because of the reduction in the frequency of heterozygotes, recombination is correspondingly weaker, with an effective recombination rate of $c_e \simeq c(1-F)$ (Nordborg 2000). Together these features imply that the length of the sweep signal under inbreeding should be longer relative to the same selection and recombination parameters under panmixia. This results in easier detection of a sweep, but greater obfuscation in terms of localizing the causative site of the sweep (Hartfield et al 2017).

Summary: Signatures of a Hard Sweep

The key summary parameter for the potential impact of a sweep is the fraction of original haplotypes that stay intact following a sweep, $f_s = \Delta_q/\delta_q(0)$ (Equation 8.1d). If $f_s \simeq 1$, the sweep will have a major impact on the structure of variation at linked neutral sites, while if $f_s \simeq 0$, it will have essentially no impact. Table 8.1 summarizes expressions for f_s and also for the population-genetic impacts of a sweep on a linked neutral site. Table 8.2 summarizes more subtle signatures of a sweep beyond the simple reduction in variation. As detailed in the next chapter, all of the observations listed in Table 8.2, either singularly or in combination, have been used as the basis of tests of ongoing or recent selection. It is important to stress that the results in these two tables are *restricted to hard sweeps*, wherein the favorable allele is only present in (at most) a few copies at the start of selection. As shown below, many of these signals are either muted or washed out entirely under soft sweeps.

SOFT SWEEPS

Whereas a hard sweep starts with selection on a single haplotype, a soft sweep refers to situations where, at the start of the sweep, multiple haplotypes contain the favored allele

Table 8.1 Summary of various features associated with a hard sweep of a favorable allele A with fitnesses $1 : 1 + 2hs : 1 + 2s$ (for $h \neq 0$). Let $q(0)$ denote the frequency of a neutral marker allele at the start of selection at a distance (recombination fraction) of c from a strongly selected site ($4N_e s \gg 1$). Assume that the frequency of the favorable allele is $p(0)$ at the start of selection, and let $q(\infty)$ denote the final frequency for a neutral allele initially associated with the favorable allele, and H_h be the heterozygosity at the neutral site immediately following the sweep.

Fraction f_s of initial associations remaining at fixation:

$$f_s \simeq \begin{cases} p(0)^{-c/(2hs)} \simeq 1 - \frac{c}{2hs} \ln[p(0)] & \text{for } p(0) \gg 1/(2N_e s) \\ (4N_e s)^{-c/(2hs)} \simeq 1 - \frac{c}{2hs} \ln(4N_e s) & \text{for } p(0) = 1/(2N_e) \end{cases}$$

Total change in the frequency of a linked neutral marker: $\Delta_q \simeq [1 - q(0)]f_s$

Final frequency of a linked neutral marker: $q(\infty) = q(0) + \Delta_q = f_s + q(0)(1 - f_s)$

Reduction in heterozygosity immediately following the sweep: $\frac{H_h}{H_0} = 1 - f_s^2$

Heterozygosity t generations after sweep completed: $\frac{H(t)}{H_0} = 1 - f_s^2 e^{-t/(2N_e)}$

Table 8.2 Expected population-genetic patterns associated with a hard sweep.

Signatures of spatial patterns of variation near a selected site:

- (1) An excess of sites with rare alleles (in either the folded or unfolded frequency spectrum).
- (2) An excess of sites with high-frequency *derived* alleles in the unfolded frequency spectrum.
- (3) Depression of genetic variation, often *asymmetrically*, around the site of selection.

Signatures in the spatial pattern of LD differ during the sweep and after its completion:

- (4a) When a favorable allele is at moderate frequency (a partial sweep), we see an excess in LD throughout the region surrounding the sweep.
- (4b) As the favorable allele approaches fixation, we see an excess in LD on either side of the site, but a *depression* in LD between markers flanking the site.

Signatures of a sweep are *very fleeting*.

- (5) Remaining on the order of $0.5N_e$ generations for signature (1), $0.4N_e$ generations for (2), $1.4N_e$ generations for (3), and $0.1N_e$ generations for (4b).

(Figure 8.4). Under a single-origin soft sweep, a single copy of the mutation arose in an environment that did not yet favor it, drifting around before an environmental change placed all of the haplotypes associated with it under positive selection. A response using existing variation, such as a soft sweep or a polygenic sweep, is also referred to as a **standing sweep** (or, more precisely, a **standing-variation sweep**). Under a multiple-origin soft sweep, the favored variant consists of a collection of independent mutational lineages, which arose in the standing variation before the allele became favored and/or *during* the sojourn to fixation for this allele.

A powerful way to understand many of the results presented below is to use time-scale arguments (Messer and Petrov 2013a). For example, the **establishment time** is the expected

time for the appearance of a new mutation that is destined to become fixed. If this time is short relative to the time to fix such an allele once it appears (the **fixation time**), then multiple mutations (and hence a soft sweep) are expected. Likewise, in a geographically structured population, if the establishment time within a deme is short relative to the time of spread of favorable alleles between demes, a sweep through the entire population is likely to again involve the contributions of multiple favorable mutations.

Signatures of a Soft Sweep

The effect of a single-origin soft sweep is to diminish, and perhaps even erase, most of the signatures expected under a hard sweep (Table 8.2). If the favorable variant is at a very low frequency at the start of selection ($p[0] < 1/[4N_e s]$), a hard-sweep signature may be generated. However, hard-sweep signatures are very unlikely when the initial frequency exceeds this threshold. This erosion of hard-sweep signatures is even more dramatic for multiple-origin soft sweeps (Pennings and Hermisson 2006b). If $\theta_b = 4N_e \mu_b$ is the scaled mutation rate for beneficial alleles, the heterozygosity following such a sweep will become

$$\frac{H_h}{H_0} \simeq 1 - \frac{1}{1 + \theta_b} (4N_e s)^{-2c/s} \quad (8.16a)$$

which contrasts with Equation 8.8c for a hard sweep. Thus, even with a completely linked site, the loss of variation is not complete, as

$$\frac{H_h}{H_0} \simeq 1 - \frac{1}{1 + \theta_b} = \frac{\theta_b}{1 + \theta_b} \quad (8.16b)$$

Some variation is preserved following a sweep because independent favorable mutations arose on random haplotypes during the sojourn of the favorable allele to fixation. For $c = 0$, if $\theta_b = 0.01$, then $H_h/H_0 \simeq 0.01$, while if $\theta_b = 0.5$, then $H_h/H_0 = 0.33$. Pennings and Hermisson found that in addition to reducing the heterozygosity signal, soft sweeps also significantly depress any sweep signal in the SFS. Indeed, even when $c = 0$, the folded frequency spectrum after a soft sweep can be very close to the neutral (Watterson) spectrum.

The feature where soft sweeps can leave a strong signature is in linkage disequilibrium (LD). A lower number of haplotypes and a higher level of association between sites relative to drift are expected, at least during a short window following the sweep ($\sim 0.1N_e$ generations). The resulting LD signature, however, is quite different from that for a hard sweep. Under the latter, LD is close to zero *across* the selected site following fixation (Figure 8.6), while under a soft sweep, LD extends *through* a site. This generates different LD-based tests for hard vs. soft sweeps, which are discussed in Chapter 9, with the ω^2 statistic (Equation 9.37) for hard sweeps, and the Z_{nS} test (Equation 9.36b) for soft and ongoing (i.e., partial) sweeps. Pennings and Hermisson found that the power of LD-based tests for detecting soft sweeps is significantly enhanced by ignoring new neutral mutations. They suggest that when a closely related population or sister species is available, using only sites that are shared polymorphisms (and hence not recent mutations) in both populations can improve the power of LD-based tests for detecting soft sweeps.

Under a soft sweep (especially when $\theta_b > 1$), there is no single dominant haplotype, as would be expected under a hard sweep. However, Garud et al. (2015) and Garud and Rosenberg (2015) noted that there may instead be a few dominant haplotypes (provided that $\theta_b < 10$, so that the sweep is not too soft), and suggested a simple modification of a standard hard-sweep test to detect soft sweeps. If p_i denotes the frequency of the i th haplotype in a sample (ranked, so that $i = 1$ is the most frequent), then under a hard sweep, the **haplotype homozygosity** $H_1 = \sum p_i^2$ should be excessive relative to its expectation under neutrality (Chapter 9). (As a notational aside, up to this point, we have used H to denote heterozygosity-based measures, while in the literature \bar{H} is used for both heterozygosity and haplotype-homozygosity measures. Rather than define new notation, we will also use H_1 and H_{12} for haplotype homozygosity measures, as the distinction between them and heterozygosity-based measures should be quite clear from context.)

Garud et al. (2015) suggested a modified haplotype homozygosity statistic, H_{12} , which lumps the first two haplotypes into a single class

$$H_{12} = (p_1 + p_2)^2 + \sum_{i>3} p_i^2 = \sum_i p_i^2 + 2p_1p_2 = H_1 + 2p_1p_2 \quad (8.16c)$$

This test has reasonable power to detect *both* hard and soft sweeps. Under a hard sweep there is only one dominant haplotype, reducing this to the H_1 test as $H_1 \simeq H_{12}$. Under a soft sweep, the favorable site is on multiple haplotypes, and lumping the two most common haplotypes picks up at least part of this signal.

Garud et al. (2015) suggested a further test to distinguish between soft and hard sweeps for situations in which H_{12} is significant. Again, the logic is that under a soft sweep, we expect a few haplotypes to be common, whereas only a single common haplotype is expected under a hard sweep. Their statistic, $H_2 = \sum_{i>1} p_i^2$, is simply haplotype homozygosity with the most common haplotype removed, with the ratio of H_2/H_1 expected to be very small under a hard sweep, but modest under a soft sweep. Using this approach, they found much stronger support for soft, rather than hard, sweeps over a set of 50 regions (detected using H_{12} statistics; Chapter 9) in a North American sample of *Drosophila melanogaster*.

Sweeps Using Standing Variation

The hard-sweep model implies a lag in adaptation, with populations experiencing an environmental change having to wait for favorable mutations to appear in order to respond. In contrast to this situation, artificial selection for most traits in outbred populations generates an immediate response (Chapter 18), showing that a large reservoir of **standing** (or preexisting) **variation** typically exists for most traits. Thus, hard sweeps are expected to be more frequent when standing variation is low, such as in small or inbred populations, or for traits with a previous history of strong selection. On the other hand, while much of the initial selection response might occur from standing variation in outbred populations (a standing sweep), new mutations play a critical role in the continued response once this initial variation has been exhausted (Chapters 26 and 27). The molecular signature resulting from a sweep arising from standing variation has been examined by Innan and Kim (2004), Przeworski et al. (2005), and Berg and Coop (2015).

Innan and Kim (2004) were interested in domestication selection, clearly a radical change in the environment to a new selection regime. The reduction in neutral diversity at linked sites in this case can be much less than for a hard sweep, as much of the initial response may be based on alleles that were segregating before domestication started. Hence, the time to the most recent common ancestor for the favorable allele may significantly predate the start of selection. Innan and Kim found that if the frequency of the favored allele at the start of selection is greater than 0.05, at best only a weak reduction in background variation will be generated by a sweep. However, a factor not considered by these authors is that domestication usually involves a strong bottleneck, which can result in a preexisting allele being reduced to one (or a very few) lineages that survived the bottleneck before being selected, generating a more hard-sweep pattern. A potential example of this situation is the maize domestication gene *tb1*. While this locus shows a classic hard-sweep pattern (Figure 8.2), the domestication allele was created by an insertion of the retroposon *Hopscotch* that predated domestication by at least 20,000 years (Studer et al. 2011). Using DNA from ancient maize samples, Jaenicke-Després et al. (2003) suggested that domestication selection started to occur on *tb1* roughly 4,400 years ago.

Further insight into the signal from a standing sweep was provided by Przeworski et al. (2005), who found that as long as the initial frequency of a selected allele is $< 1/(4N_e s)$, the signal is the same as for a hard sweep. With higher initial allele frequencies, the situation is more complex. In some settings, the result is simply a weaker footprint, but with the normal features of a sweep (reduced diversity, excess of rare alleles, and excess of high-frequency derived alleles). However, in other cases, a sweep associated with a very weakly selected preexisting allele can result in an *excess of intermediate-frequency alleles*. In still other settings,

essentially no detectable pattern is seen in the reduction of diversity, the frequency spectrum, or the distribution of LD. In particular, if the new environment favors an *ancestral* allele, especially one at high frequency, there will be no discernible change over the background pattern (Przeworski et al. 2005). The salient point is that selection on standing variation need not leave a hard-sweep signature, and significant ongoing or recent selection can easily be missed, even when strong selection is occurring.

Example 8.6. The myostatin gene (*MSTN*) is a negative regulator of skeletal muscle growth. Mutations in this gene underlie the excessive muscle development in double-muscled (DM) breeds of cattle, such as the Belgian Blue, Asturiana de los Valles, and Piedmontese. Wiener et al. (2003) compared variation at microsatellite loci as a function of their distance from *MSTN* in DM and non-DM breeds. For DM breeds, measures of variation decreased relative to non-DM breeds as the marker loci approached the *MSTN* locus. While this observation strongly suggests a genomic region under selection, the authors expressed skepticism about using this approach to fine-map the target of selection (i.e., localize it with high precision within this region), as the region under detected selection was only localized to a broad area around the known target (*MSTN*). At first glance, this seems surprising, given that *MSTN* variants have a major effect on the selected phenotype (beef production). However, the authors noted that the Belgian Blue was a dual-purpose (milk and beef) breed until the 1950s, and that in both the Belgian Blue and the Piedmontese there are records of *MSTN* mutations before World War I, predating the intensive selection on the double-muscled phenotype. By contrast, they found that the selective signal is stronger in the Asturiana, where the first definitive appearance of the mutation was significantly later. Thus, in both the Belgian Blue and the Piedmontese, selection on this gene likely resulted in a soft sweep (adaptation from preexisting mutations), while in the Asturiana, the time between the initial appearance of the mutation and strong selection on it was much shorter, resulting in a more traditional hard sweep (adaptation from a new mutation). O'Rourke et al. (2012) used haplotype homozygosity to estimate the age of the Belgian Blue mutation (*821dell11*) at ~200–400 years and that of the Piedmontese mutation (*C313Y*) at ~200 years.

Example 8.7. The threespine stickleback (*Gasterosteus aculeatus*) is a species complex of small fish widespread throughout the Northern Hemisphere in both freshwater and marine environments. The marine form is usually armored with a series of over 30 bony plates running the length of the body, while exclusively freshwater forms (which presumably arose from marine populations following the melting of the last glaciers) often lack some, or all, of these plates. Given the isolation of the freshwater lakes, it is likely that the reduced armor phenotype has independently evolved multiple times. What was the mechanism for this?

Colosimo et al. (2005) showed that this parallel evolution occurred by independent fixation of alleles derived from an ancient (~ $2 \cdot 10^6$ years) low-armored haplotype of the *Eda* locus (a component of the ectodysplasin signaling pathway). Surveying populations from Europe, North America, and Japan, they found that most nuclear genes showed a clear Atlantic-Pacific division. Conversely, at the *Eda* locus, low-armored populations shared a more recent history than full-armored populations, independent of their geographic origins, presumably reflecting more recent ancestry at the site due to the sharing of an ancient allele. In marine populations, low-armored alleles at *Eda* are present at low (< 5%) frequency. Presumably, these existing alleles were repeatedly selected following the colonization of freshwater lakes from marine founder populations. Barrett and Schlüter (2008), Messer and Petrov (2013a), and Jensen (2014) reviewed a number of other examples of adaptation from preexisting mutations.

How Likely is a Sweep Using Standing Variation?

Herisson and Pennings (2005), Przeworski et al. (2005), and Berg and Coop (2015) used

population-genetic models to examine the likelihood of a sweep arising from standing variation. To consider the probability of such an event over a series of replicate populations, let $\phi(x)$ denote the distribution of the frequency, x , for the soon-to-be favored allele A , and $u(x)$ its probability of fixation under the new environment given x . The probability, \Pr_{sv} , that a sweep occurs using standing variation at this locus is simply

$$\Pr_{sv} = E[u(x)] = \int_{1/(2N)}^{1-1/(2N)} u(x)\phi(x)dx \quad (8.17a)$$

The limits on the integral confine us to considering only segregating alleles. Przeworski et al. (2005) assumed that $\phi(x)$ is given by the neutral Watterson distribution (Equation 2.34a), while Hermisson and Pennings (2005) considered a more general setting, where the genotypes $aa : Aa : AA$ have fitnesses of $1 : 1 - 2h_d s_d : 1 - 2s_d$ in the old environment and $1 : 1 + 2hs : 1 + 2s$ in the new environment. This allows for the allele to be either neutral ($s_d = 0$) or deleterious ($s_d > 0$) before being favored.

Assuming selection-mutation-drift equilibrium on the allele prior to becoming favored, $\phi(x)$ is a function of N_e , the selection parameters (h_d, s_d), and the mutation rate μ_b of a to A , and can be obtained using diffusion machinery (Chapter 7; Appendix 1). Likewise, the fixation probability under the new fitnesses can also be obtained using diffusion results (Chapter 7). Putting these together, Hermisson and Pennings found that

$$\Pr_{sv} \approx 1 - e^{-\theta_b \ln(1 + R)}, \quad \text{where } R = \frac{2h\alpha_b}{2h_d\alpha_d + 1} \quad (8.17b)$$

with $\alpha_b = 4N_e s$ and $\alpha_d = 4N_e s_d$ being the scaled strengths of selection in the new and old environments, respectively, and $\theta_b = 4N_e \mu_b$ being the scaled mutation rate at which the (eventually beneficial) allele arises.

The alternate scenario to a standing-variation sweep is the need to wait for new favorable mutations to arise and subsequently become fixed (a classic hard sweep). Recall from Chapter 7 that the fixation probability of a single new mutation is $\sim 4hs(N_e/N)$, so roughly $N/(4N_e hs)$ such mutations must appear to have a reasonable chance of one becoming fixed. The expected number of such beneficial mutations arising in each generation is $2N\mu_b$, giving

$$[4hs(N_e/N)][2N\mu_b] = 2hs(4N_e\mu_b) = 2hs\theta_b \quad (8.18a)$$

as the expected number of mutations that are destined to become fixed arising each in generation. The reciprocal of this quantity

$$t_e = \frac{1}{2hs\theta_b} \quad (8.18b)$$

is the mean establishment time for a new favorable mutation (Messer and Petrov 2013a).

Before proceeding, it is useful to rescale time from the number of generations τ to $T = \tau/(2N_e)$. Under this scheme, $\tau = 2N_e T$, with $T = 1$ corresponding to $2N_e$ generations, which is the natural scale for genetic drift (being the expected coalescence time for two neutral alleles; Chapter 2). The expected total number of beneficial mutations that will have appeared by time T is then

$$\tau \cdot 2hs\theta_b = Th(2N_e 2s)\theta_b = Th\alpha_b\theta_b$$

Hence, the probability that at least one favorable mutation that is destined to become fixed will appear by generation T is just one minus the probability that none have appeared, which, from the Poisson distribution, is

$$\Pr_{new}(T) = 1 - e^{-Th\alpha_b\theta_b} \quad (8.18c)$$

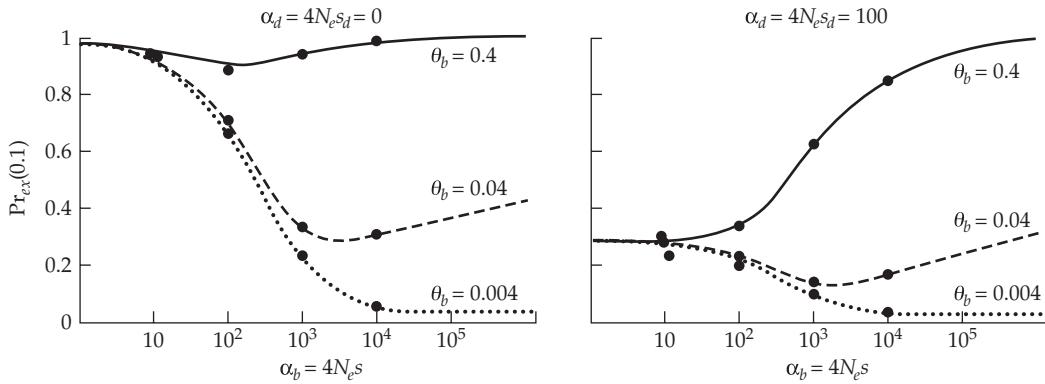

Figure 8.7 Plots of $\text{Pr}_{ex}(0.1)$, the probability of a selected sweep from standing variation, given that a sweep has occurred within $0.1N_e$ generations following a change in the environment (Equation 8.20, with simulated data given by the points). This is a function of the beneficial mutation rate, $\theta_b = 4N_e\mu_b$ (separate curves within each graph), and the scaled strength of selection, $\alpha_b = 4N_e s$, during the sweep (horizontal axis). (Left) The allele is neutral in the old environment ($\alpha_d = 0$). (Right) The allele is deleterious in the old environment ($\alpha_d = 4N_e s_d = 100$) (After Hermisson and Pennings 2005.)

as obtained by Hermisson and Pennings (2005). When $\alpha_b \theta_b$ is small, the waiting time for a mutation that is destined to become fixed is quite long. In such cases, mutation is the rate-limiting step for adaptation, unless there is standing variation to exploit.

The total waiting time (in generations) until the fixation of a favorable allele with additive effects on fitness ($h = 0.5$) is approximately

$$t_{fix} = \frac{1}{s} \left(\frac{1}{\theta_b} + 2 \ln(4N_e s) \right) \quad (8.19)$$

where the first term is the mean waiting time for the first appearance of a successful mutation (the establishment time; Equation 8.18b) and the second is its fixation time (Equation 8.4d). Karasov et al. (2010) and Messer and Petrov (2013a) developed similar expressions.

One might expect that a successful sweep (i.e., the selected allele is destined for fixation) starting early after selection is applied is likely due to standing variation, but as time proceeds, a successful sweep will more likely be due to new mutations. We can quantify this by conditioning on a sweep by time T (assuming that the fixation time of a successful mutation is very small relative to T), giving the probability that it is from an existing allele (i.e., a standing sweep) as

$$\begin{aligned} \text{Pr}_{ex}(T) &= \text{Pr}(\text{existing allele} \mid \text{sweep by generation } T) \\ &= \frac{\text{Pr}_{sv}}{\text{Pr}_{sv} + (1 - \text{Pr}_{sv}) \text{Pr}_{new}(T)} \\ &= \frac{1 - \exp[-\theta_b \ln(1 + R)]}{1 - \exp\{-\theta_b [\ln(1 + R) + Th\alpha_b]\}} \end{aligned} \quad (8.20)$$

This follows because Pr_{sv} is the probability that, in the absence of any new mutation, a variant segregating at the start of the new selection regime will be fixed, while the probability that the fixation will occur via a new mutation (arising by time T) is $(1 - \text{Pr}_{sv})\text{Pr}_{new}(T)$. The denominator is the sum of the probabilities of these two different events, and hence the probability of a sweep occurring by time T . For a sufficiently large T , $\text{Pr}_{new}(T) = 1$ (the probability of a new successful mutation approaches one), and Equation 8.20 reduces to Pr_{sv} (Equation 8.17b). This sets the *lower limit* on the probability that the favorable mutant fixed by the sweep was preexisting in the population before the start of selection. For shorter

amounts of time, there is a reduced chance that the fixed beneficial allele arose after the start of selection, and hence a higher probability that a sweep resulted from standing variation. Figure 8.7 plots Equation 8.20 at $0.1N_e$ generations ($T = 0.05$) after an environmental shift. When both θ_b and α_b are high, most sweeps are from existing variation, even when the allele was deleterious before the shift. When θ_b is small, most sweeps are from new mutations unless both α_b and α_d are small. The reason is that while adaptation from standing variation is unlikely with a small α_b , it is more likely when the standing-allele frequency is not too small (which requires that α_d be small) before the start of selection. Berg and Coop (2015) developed a number of additional results for standing sweeps (assuming a single founding mutation).

Peter et al. (2012) developed an **approximate Bayesian computation** (or ABC)-based approach (Appendix 3) that combines several tests of selection in an attempt to distinguish between sweeps from de novo mutation versus those from standing variation (also see Ormond et al. 2015). Their key idea is that allelic trajectories under either setting are identical once selection starts, but that a preexisting allele starts at some frequency $> 1/(2N)$, while a de novo mutation is initially absent. The fit of several summary statistics of selection (Chapter 9) is then compared with various models assuming drift (i.e., no selection) at some point in the history of that allele. However, simulation studies showed that their test has little power unless selection is strong ($4N_e s > 100$ under additivity). When their test was applied to seven of the strongest known sweeps in humans, two were found to be most likely from standing variation, three fit the hard-sweep model, and two were equivocal. While interesting, this small sample does not provide much insight into the relative frequency of the different types of sweeps, as these loci were generally detected using methods based on strong-sweep signals, creating an ascertainment bias in favor of hard sweeps.

Example 8.8. One measure of how rate-limiting mutation can be is the expected time at which there is a 50% chance that a mutation that is destined to be fixed has arisen, which follows from Equation 8.18c. Suppose that adaptation can only occur through mutation at one of five nucleotide sites, in each case generating an allele with an additive effect on fitness ($h = 1/2$) and a heterozygote advantage of 1% ($s = 0.01$). At each of these five sites, only one third of all new point mutations (assuming equal rates to all four nucleotides) generate the favorable allele, giving the beneficial mutation rate as $(5/3)\mu$, where μ is the per-site rate. In humans, assuming a historical value of $N_e = 10^4$ and a per-site mutation rate of 10^{-8} , we have $h\alpha_b = (1/2)4N_e s = 2 \cdot 10^4 \cdot 0.01 = 200$, while $\theta_b = 4N_e \mu_b = 4 \cdot 10^4 \cdot [(5/3) \cdot 10^{-8}] = 0.00067$, giving $h\alpha_b \theta_b = 200 \cdot 0.00067 = 0.13$. Solving Equation 8.18c for the value of T giving a 50% probability,

$$0.5 = 1 - \exp(-T_{0.5} h\alpha_b \theta_b) = 1 - \exp(-0.13 \cdot T_{0.5})$$

which rearranges to $T_{0.5} = -\ln(0.5)/0.13 \simeq 5.33$, or $5.33(2N_e) = 10.66N_e = 106,600$ generations. Further, once such a mutation that is destined to be fixed arises, it still takes (on average) an additional $2 \ln(4N_e s)/s \sim 1060$ generations to become fixed (Equation 8.4d).

Example 8.9. As a sample calculation of how often sweeps occur from existing versus new mutations, suppose $N_e = 10^6$ and there is a genome average per-site mutation rate of $\mu = 2.5 \cdot 10^{-9}$, yielding $\theta = 4N_e \mu = 0.01$. For a beneficial mutation that can only occur by a change to a specific nucleotide at a specific site, one third of mutations at that site are beneficial, yielding $\theta_b = (1/3)\theta = 0.0033$. For an allele with additive fitness effects ($h = 1/2$) with $s = 10^{-4}$, we have $\alpha_b = 4N_e s = 4 \cdot 10^6 \cdot 10^{-4} = 400$. If this mutation was neutral before being favored, $\alpha_d = 0$, and from Equation 8.17b, $R = 2h\alpha_b = 400$, yielding

$$\begin{aligned} \Pr_{sv} &\approx 1 - \exp(-\theta_b \ln[1 + R]) \\ &= 1 - \exp(-0.0033 \ln[1 + 400]) = 0.013 \end{aligned}$$

Hence, there is only a 1.3% chance that a sweep will occur at this site in the absence of new mutation.

Now suppose that we examine this population at $T = 0.5$, namely, at N_e generations. From Equation 8.18c, the probability that at least one mutation that is destined to become fixed will arise by this time is

$$\begin{aligned}\Pr_{new}(T) &= 1 - \exp(-Th\alpha_b\theta_b) \\ &= 1 - \exp(-0.5 \cdot (1/2) \cdot 400 \cdot 0.0033) = 0.281\end{aligned}$$

Thus, *provided* we see a sweep at this locus by N_e generations, then from Equation 8.20, the probability that it was due to an existing allele present at the time of the environmental shift is

$$\Pr_{ex}(0.5) = \frac{\Pr_{sv}}{\Pr_{sv} + (1 - \Pr_{sv})\Pr_{new}(T)} = \frac{0.013}{0.013 + (1 - 0.013) \cdot 0.281} = 0.05$$

“Hardening” and “Softening” of a Sweep

Population sizes are expected to fluctuate over time, and such demographic complexity impacts whether an initially soft sweep (multiple adaptive haplotypes at the start of selection) is perceived as soft or hard (Messer and Petrov 2013a; Wilson et al. 2014; Hermisson and Pennings 2017). The reason, as seems to be the case for the maize *tb1* gene (Figure 8.2), is that taking a population through a bottleneck (either just before or during a sweep) may leave only a single adaptive lineage, even when several were present before the bottleneck, thus **hardening** an initially soft sweep. Such hardening events result in undercounting the frequency of soft sweeps (and hence the frequency of adaptation from standing variation).

The strength of selection plays a critical role in determining the expected types of sweeps in a population that regularly contracts in size. If selection is sufficiently strong (and $\theta_b > 1$), multiple independent adaptive alleles may have their frequencies increased during the non-bottleneck phase to a level sufficiently high that they avoid being lost during the next bottleneck. For a population with a normal size of N_1 and bottleneck size of $N_2 \ll N_1$, whether a soft sweep is observed depends upon the establishment time, t_e , of new mutations plus the expected time, t_g , until their frequency is $\gg 1/(N_2)$, which means they will successfully pass through the bottleneck. Solving for $p(t) = 1/(N_2)$ in Equation 8.4a gives this latter time as $t_g \simeq (1/s) \ln(sN_1/N_2)$, as found by Messer and Petrov (2013a), while Equation 8.18b yields $t_e = 1/(\theta_1 s)$, where $\theta_1 = 4N_1\mu_b$. Hence, if the time, t_b , between bottlenecks exceeds $t_e + t_g$, a soft-sweep signature is expected; otherwise, a hard-sweep signature is seen, as at most one adaptive lineage is likely to both be present and to escape the bottleneck. In populations with both $\theta_b > 1$ and a history of large size fluctuations, strongly selected sites are thus more likely to produce soft sweeps than are weakly selected ones. Conversely, if most favorable mutations are under modest selection, there will be a bias toward hard sweeps, as the frequencies of most independent lineages are too small to escape the bottleneck.

While demography can harden an initially soft sweep (multiple haplotypes carrying the favorable allele at the start of selection) by allowing only a dominant haplotype to pass through a bottleneck, the converse is also true. That is, a hard sweep can give soft-sweep signals at sites close to, but not at, the selected target, or if one examines the sweep after some amount of time. Schrider et al. (2015) referred to the former as **soft shoulders** and the latter as **soft shadows**. As previously mentioned, the region of greatest decline in variation from a hard sweep is often asymmetric around the selected site. Hence, estimating the location of the sweep by the taking the midpoint of the region of greatest decline can result in an erroneous identification of the shoulder of a sweep as the actual target. Schrider et al. found that the shoulders of hard sweeps often give either soft-sweep or partial-sweep signatures. The same is true for an older hard sweep, whose decaying shadow can again show either partial- or soft-sweep signatures. This

is especially problematic for tests utilizing a small window around some candidate region. As noted by Schrider et al., this leads to the ironic conclusion that spurious partial-and/or soft-sweep signatures become more common as the frequency of hard sweeps increases. Despite some early optimism, Berg and Coop (2015) also highlighted the difficulties in distinguishing between sweep types, thus supporting Jensen's (2014) earlier plea for caution when declaring there is a soft sweep.

Finally, it must be stressed that the distinction between a perceived hard vs. soft sweep is in part a function of the sample size (Messer and Petrov 2013a; Hermisson and Pennings 2017). If the TMRCA in our sample of alleles predates the start of selection, a soft-sweep signature may appear, while if it does not, the signal will be that of a hard-sweep, even when the actual biology was a soft sweep.

Recurrent Mutation of the Favorable Allele Cannot be Ignored

In their analysis of the effects of sweeps from standing variation, Innan and Kim (2004), Przeworski et al. (2005), and Berg and Coop (2015) all assumed a *single origin* for the favorable mutation. Likewise, while the analysis leading to Equation 8.20 does consider recurrent mutation, it simply allows new copies of the favorable allele to arise by mutation once selection starts and keeps track of how long one must wait until a copy that is destined to be fixed arises. It ignores any ongoing mutation either during the fixation of a preexisting copy of the favorable allele or following the introduction of a favorable allele that is destined to undergo fixation. However, even if a sweep *starts* as a single favorable allele on its way to fixation, *additional* new copies can arise by mutation (again in random backgrounds) during the sojourn of the original copy, potentially diffusing any pattern from the sweep over a set of multiple haplotypes. How likely is such a scenario?

Pennings and Hermisson (2006a, 2006b) approached this problem by considering the number of independent lineages of the favorable allele that are expected to be observed in a sample of n sequences following a sweep. Their rather remarkable result is that, to a first-order approximation, this is a function of θ_b , and *not* the strength of selection, α_b . In particular, an upper bound for the probability of a multiple-origin soft sweep (two or more independent lineages in our sample of size n) is

$$\Pr(\text{soft} \mid n) \leq \theta_b \left(\sum_{i=1}^{n-1} \frac{1}{i} \right) \approx \theta_b[0.577 + \ln(n-1)] \quad (8.21)$$

Pennings and Hermisson also showed that the number of distinct lineages in the sample approximates the Ewens (1972) sampling distribution (Equation 2.30a) by using θ_b in place of θ . A more detailed analysis suggests the following general rules: multiple-origin soft sweeps are rare (even in a large sample) when $\theta_b < 0.01$, somewhat common when $0.01 \leq \theta_b \leq 1$, and almost certain when $\theta_b > 1$.

Orr and Betancourt (2001) also examined this problem, but from the perspective of standing variation alone, asking if **Haldane's sieve**, wherein dominant alleles are postulated to be more likely to contribute to selection response than recessive alleles (Turner 1981; Charlesworth 1992), is correct. They were also interested in the number of original copies of an allele that leave descendants in the fixed population. Assuming adaptation from standing variation alone, they found that the dominance of an allele has little effect on its probability of sweeping from standing variation when the dominance relationship is roughly the same under the old, deleterious and new, favorable environments. Recessive deleterious alleles are maintained at a higher frequency than dominant deleterious alleles, which compensates for their lower probability of fixation in the new environment (assuming roughly equal mutation rates for recessive and dominant alleles). Further, they showed that $\theta_b s_b / s_d$ is the critical determinant of the number of independent lineages leaving descendants in the fixed population. When $\theta_b s_b / s_d > \sim 1.3$, the fixed collection of favorable alleles is more likely to contain multiple lineages. If s_b and s_d are roughly of the same magnitude, their effects cancel each other out, again showing the strong dependence of a multiple-origins soft sweep on the value of θ_b .

Multiple-origin soft sweeps are therefore expected to occur under certain biologically realistic conditions. Pennings and Hermisson highlighted two scenarios where this might be expected: very large effective population sizes and large mutational target sizes. An example of the latter is the case where loss-of-function mutations are favored, as the presence of numerous pathways by which function can be lost significantly increases the value of μ_b .

A relevant question regarding multiple-origin sweeps concerns the number of recurrent favorable mutations expected to appear during the sojourn of the favored allele towards fixation. Recalling Equation 8.4d, the expected time for a single copy (a de novo mutation) of the favorable allele to sweep through a population is $\tau \approx 2 \ln(4N_e s)/s$. If N is the population size, then the expected number of new favorable mutations arising in a generation is $2N(1 - x)\mu_b$, where x is the current frequency of the favorable allele. Thus, we can approximate the expected number of new favorable mutations that will arise by noting that the average frequency of a favored additive allele over its sojourn from near zero to near fixation is $1/2$, hence

$$\begin{aligned} E(\text{number of new favorable mutations that arise}) &\approx 2N(1/2)\mu_b\tau = (N/N_e)(N_e\mu_b)\tau \\ &= (N/N_e)(\theta_b/4) \cdot 2 \ln(4N_e s)/s \\ &= 2N\theta_b \ln(\alpha_b)/\alpha_b \end{aligned} \quad (8.22a)$$

as obtained by Pennings and Hermisson (2006a). Although this is the *total* number of recurrent favorable mutations that arise, each has only a probability of $2s(N_e/N)$ of increasing (Chapter 7). Hence, the expected number of new mutations that arise *and* increase in frequency (i.e., are likely to become part of the fixed pool of the favorable allele after the sweep) is approximately $2s(N_e/N)$ times the result in Equation 8.22a, yielding

$$E(\text{number of new favorable mutations that increase}) \approx \theta_b \ln(4N_e s) \quad (8.22b)$$

Again, this is the number of favorable new mutations that increase in frequency during the sojourn of the initial allele to fixation, so that approximately $1 + \theta_b \ln(4N_e s)$ distinct lineages in the *population* are expected at fixation, placing an upper bound on the expected number of lineages in a *sample* of any size from such a population.

Example 8.10. Caspase-12 (a cysteinylyl aspartate proteinase) is involved in the inflammatory and innate immune response to endotoxins (Wang et al. 2006). In humans, most alleles are nulls and nucleotide diversity around this locus is sharply reduced (relative to levels in the chimpanzee), suggesting a selective sweep. Using the current frequency of roughly 0.9 for null alleles, and assuming that the sweep favoring null alleles started shortly before the migration of modern humans out of Africa, the authors estimated $s \approx 0.009$ (using Equation 5.3b). Previous work showed that the fully functional allele attenuates the response to endotoxins (Saleh et al. 2004), increasing the odds of severe sepsis (bacterial infection of the blood). Wang et al. hypothesized that null alleles were favored due to a change in the environment increasing the odds of severe sepsis when this gene is active. Consistent with this hypothesis, two other primate genes related to sepsis are also pseudogenes in humans. Similar findings were reported by Xue et al. (2006).

Example 8.11. To get a feel for the expected number of new favorable mutations that arise during a sweep, consider the values used in Example 8.9 ($N_e = 10^6$, $\theta_b = 0.0033$, $s = 10^{-4}$, $\alpha_b = 400$). From Equation 8.22a (and assuming $N \approx N_e$), we expect

$$2N_e\theta_b \ln(\alpha_b)/\alpha_b = 2 \cdot 10^6 \cdot 0.0033 \ln(400)/400 \approx 90$$

new favorable mutations to arise, but the number expected to increase in frequency (and hence contribute to the pool of favorable alleles following the sweep) from Equation 8.22b is just

$$\theta_b \ln(4N_e s) = 0.0033 \ln(400) = 0.02$$

Hence, even though a large number of favorable mutations arise, none really contribute to the sweep. This is consistent with the general rule that multiple-origin soft sweeps are unlikely to occur when $\theta_b < 0.01$. Suppose we increase θ_b to 0.5, while keeping the other parameter values the same. Now roughly 15,000 recurrent favorable mutations will be expected, three of which are expected to increase (and hence result in a soft sweep).

While the reader may feel that the critical parameter for observing a soft sweep ($\theta_b = 4N_e \mu_b$) is generally expected to be very small, important exceptions can occur. A common view is that the target site for a beneficial mutation is small (a single change at only one or a few sites) and hence the small per-nucleotide mutation rates (10^{-9} to 10^{-8} ; Chapter 4) suggest that such events are highly unlikely. This may indeed be true when adaptation requires a very specific amino acid substitution to be favorable. However, if a potentially large number of sites are targets, then the *total* beneficial mutation rate will be much higher. One example of the latter is the inactivation of a gene that has become deleterious due to a shift in the environment (Example 8.10). A second example is a beneficial regulatory change, which potentially could occur through changes at a number of nucleotide sites, or by other events (such as a mobile-element insertion in some rough neighborhood of the gene) that can influence regulation. We have already seen one example of the latter, the *Hopscotch* insertion underlying the maize domestication allele *tb1*. Another example is the famous peppered moth, *Biston betularia*, whose industrial melanism mutation was generated by a transposable element (van't Hof et al. 2016) that appeared to insert in the *cortex* gene around 1820, about 30 years before the first melanic form was reported (1848).

Mobile elements may thus be an under-appreciated source of adaptive mutations (Casacuberta and González 2013; Villanueva-Cañas et al. 2017). Consistent with this idea, González et al. (2008) found that transposable genetic elements (TEs) may induce adaptation in *Drosophila melanogaster*. In a set of 909 TEs that inserted into new sites following the spread of this species out of Africa, at least 13 show signs of being adaptive (associated with signatures of partial sweeps). They suggested that the majority of these insertions likely induce regulatory changes. The much higher rate of TE mobilization (relative to nucleotide mutation rates), coupled with their much larger target of action (their insertion at a large number of sites can influence regulation over some distance), suggests that μ_b may often be much larger than one expects.

Even independent single-site beneficial mutations may be more likely than expected. A potential human example of this derives from the work of Enattah et al. (2007) on the lactase gene (*LCT*). Variants at this locus are correlated with lactase persistence (the ability to utilize milk as an adult) and hence are candidates for selection following the invention of dairy farming. Enattah et al. found that the *T*₋₁₂₉₁₀ variant upstream of *LCT* appears to have at least two independent origins. In addition to the common northern European allele, an independent origin appears to have occurred in an isolated region in eastern Europe. Further, Tishkoff et al. (2007) found independent mutants at different sites in the *LCT* gene in African populations also leading to lactase persistence.

The second component to θ_b is N_e . While long-term values of N_e may be small (e.g., due to rare, but strong, bottlenecks), short-term values of N_e may be much larger (perhaps approaching the population census size). Current estimates of N_e are often based on levels of nucleotide diversity, which are generated by the cumulative joint action of mutation and drift over rather long periods of time. Conversely, when a favorable mutation appears, during the early phases of a sweep, its population size may still be much higher than its long-term harmonic average, offering the opportunity for multiple favorable mutations to arise during its sojourn.

The notion of independent mutants arising during a sweep is a special example of the more general question of how often the same genes are independently used for specific adaptations (reviewed by Arendt and Reznick 2008). Independent recurrent mutations in even distant taxa may be more common than intuition might suggest. Orr (2005c) considered the probability, P , of the occurrence of a parallel change when n different beneficial mutations can each provide an adaptive solution. Using the framework of extreme value theory (Chapter 27), even when these potential solutions have rather different selection coefficients, the probability that two independent taxa use the same solution (beneficial mutation) is just $P = 2/(n + 1)$. Hence, if the number of paths leading to an adaptation is quite small (e.g., only a few amino acid changes will confer the adaptive change), then *provided* such an event has occurred in two independent taxa, there is a high probability of a parallel change.

Example 8.12. Karasov et al. (2010) examined *Drosophila melanogaster* mutations at the *Ace* locus, which codes for the neural signaling enzyme acetylcholinesterase, a target for many commonly used insecticides. Single nucleotide changes at four highly conserved sites confer partial insecticide resistance, with combinations of these changes conferring successively greater resistance. Single, double, and triple mutations are all found in natural populations. While one model is that these variants existed at the start of major insecticide use (the 1950s), the authors found that mutations in North America and Australia appear to have arisen de novo following the *D. melanogaster* migration out of Africa. Given that only 1000 to 1500 fly generations have elapsed since the start of the widespread use of insecticides that target the *Ace* product, estimates of $\theta \sim 0.01$ based on nucleotide diversity (and hence a θ_b of one third this value at each of the four sites) are not consistent with the independent origins of single new mutations (Equation 8.21) in this gene over this short time scale, and hence multiple new mutations (changes in two or three additional sites) are expected to be extremely unlikely. However, if the actual effective population size was 10^8 instead of the standard assumed value of 10^6 during the past 50 years, then $\theta_b \sim 1$ over this time window, and multiple independent origins by mutation are highly likely. The effective population size that matters for these mutations is that during their origin and spread, not that set by any history predating their appearance (Messer and Petrov 2013a).

Impact of Geographic Structure

Our analyses thus far have assumed a panmictic population, but the effects of population structure on sweep signals can be dramatic. One simple consequence is that hard sweeps from independent mutations in different subpopulations generate a soft-sweep signature when the data are combined (Ralph and Coop 2010; Messer and Petrov 2013a). Given the limitless model space for population structure, current models typically assume one of two highly idealistic forms, representing the ends of the continuum of possible population densities and gene flow in space. At the discrete end are simple two- (or multiple) deme models with weak migration (Slatkin and Wiehe 1998; Santiago and Caballero 2005; Kim and Maruki 2011; Messer and Petrov 2013a; Roesti et al. 2014). At the fully continuous end is a single population with uniform density and migration rates, spread out over some two-dimensional space (Ralph and Coop 2010; Novembre and Han 2012; Messer and Petrov 2013a). As with many complex issues in population and quantitative genetics, the hope is that these simple models capture most of the salient features of more complex ones. Whether this is true remains to be seen, and models incorporating sweeps in structured populations remain an important area for future research (Stephan 2010a).

Consider the simple two-deme models first. In ecology, it is of great interest to distinguish between uniform and heterogeneous selection pressures. A hard sweep initially confined to one deme may represent either a local adaptation to the unique environment

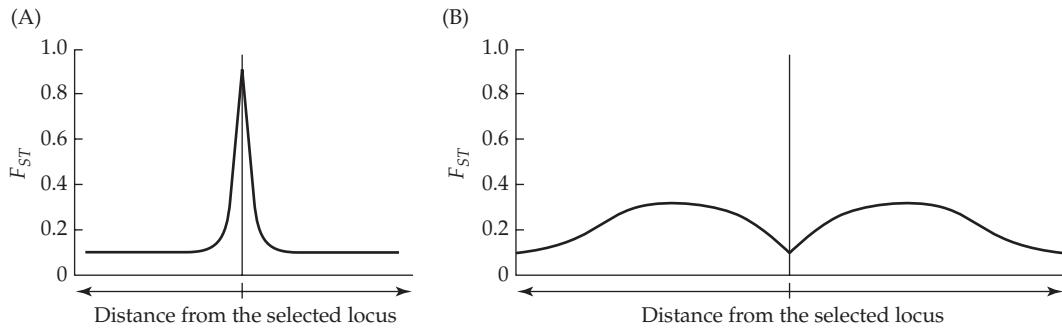

Figure 8.8 The expected pattern of among-population divergence (measured by F_{ST} ; Chapter 2) around a selected site. (A) A localized hard sweep, with an allele that is favored in only a subset of the demes. (B) A global hard sweep, with the same favorable allele fixed over all demes. In both figures, the expected F_{ST} value for markers sufficiently far way from the selected site asymptotes out to the neutral mutation-migration-drift values for the given population structure. (After Bierne 2010.)

of that deme (**heterogeneous selection**), or simply an adaptive mutation with the same advantage in all demes (**uniform selection**) that has not yet spread out of its founding deme. As shown in Figure 8.8, a plot of F_{ST} (Chapter 2) around a selected site shows different patterns of divergence for a localized hard sweep (Figure 8.8A) versus a global hard sweep through all demes (Figure 8.8B). In the former, one sees a spike in population divergence around the selected site, as it is a local advantage, and hence the deme or demes in which it is favored have a very strong divergence at that site.

More striking is the **hill-valley-hill** pattern seen in Figure 8.8B for a global sweep (Bierne 2010; Roesti et al. 2014). For a hard sweep through all of the demes, there is little to no divergence at the selected site, but on either side there is an increase in population divergence, which then declines to the neutral mutation-migration-drift values at more distant sites. This F_{ST} pattern around the selected site arises because migration brings in the favored allele, which, coupled with recombination with local haplotypes, spreads the adaptive allele to specific backgrounds in each deme (for sites at some moderate recombinational distance from the selected site). The net result is that marker diversity among subpopulations (measured by F_{ST}) *increases* for a short distance as one moves away from the site (Figure 8.8B), and also shows an excess of sites with intermediate allele frequencies (mimicking signatures for balancing selection). Bierne (2010) observed such an F_{ST} signature for a set of mussel (*Mytilus edulis*) populations. A one-sided scan away from a length polymorphism in the third intron of the *EF1 α* gene showed a valley-hill pattern, suggesting *EF1 α* as a candidate for a global sweep. See Bierne (2010) for a detailed discussion on distinguishing local from global sweeps.

How often does one expect soft sweeps to occur in a structured population under uniform selection, where different favorable alleles arise by mutation in different demes? Again, a simple time-scale argument can be used in the situation where the population structure consists of a set of discrete demes (Messer and Petrov 2013a). Consider a given deme where the favorable mutation is currently absent, but that receives migrants from a deme (of size N) where it is fixed. If m is the per-individual migration rate between demes, then $2Nm$ favorable mutations are introduced in each generation, each with a probability $2s(N_e/N)$ of fixation (Chapter 7). This yields an approximate waiting time (in generations) for the appearance of a successful migrant from a fixed deme as $t_m \simeq 1/(4N_e ms)$. Conversely, the establishment time, $t_e = 1/(\theta_b s)$, yields the average waiting time for the appearance of new (destined to be fixed) favorable mutations in that deme (Equation 8.18b). When $t_e < t_m$, namely $\theta_b > 4N_e m$ (i.e., $\mu_b > m$), soft sweeps are expected, with the sweep through the metapopulation being the result of independent favorable mutations arising within different demes, as opposed to one mutation from just a single deme (Messer and

Petrov 2013a).

For populations continuously distributed over some area, again independent adaptive mutations can arise in different parts of the range, resulting in a patchwork pattern of alleles, which will eventually resolve into a soft-sweep signature as the process of migration mixes the favored haplotypes (Ralph and Coop 2010; Novembre and Han 2012; Messer and Petrov 2013a). In a key paper, Ralph and Coop started with Fisher's (1937) classic result that the speed ν , at which a favorable allele with additive effects on fitness spreads over a spatially continuous population is $\nu = \sigma\sqrt{2s}$, where σ is the standard deviation of dispersal distance. In a uniform two-dimensional space, a new favorable mutation will spread out from its origin in a radial pattern at a rate of ν . After t generations, the mutation will encompass a region of radius $t\nu$ from its origin, covering an area of roughly $\pi(t\nu)^2$. Turning to the rate at which favorable mutations arise, if ρ is the population density (the average number of individuals per unit area), then the (per unit area, per generation) rate, λ , at which new favorable mutations that are destined to be fixed arise is $2\rho\mu_b \cdot 2s$, as $2\rho\mu_b$ favorable mutations arise per unit area, per generation, each with a chance of $2s$ of becoming fixed.

The final assumption made by Ralph and Coop is allelic exclusion—when two favorable alleles (of different origin) come into contact, they each behave neutrally with respect to each other, and hence the spreading process into each others' range effectively stops (becoming a drift-like process on a much longer time scale). Using these results for the rate of spread ν , and the rate of appearance of new successful mutations, λ , Ralph and Coop found that the key model parameter was a **characteristic dispersal length**

$$\chi = \left(\frac{\nu}{\pi\lambda} \right)^{1/3} = \left(\frac{\sigma}{2\pi\rho\mu_b\sqrt{2s}} \right)^{1/3} \quad (8.23)$$

This is the distance a new favorable mutation must travel before encountering another favorable mutation. If a species range is much less than the characteristic length (which varies over traits, as μ_b and s are trait dependent), then a hard sweep is seen, as independent mutations are unlikely. If χ is short relative to the range, independent mutations are likely, and these will interfere with each other as they come into contact.

In this latter case, populations appear as a patchwork of different alleles, a pattern that can be easily mistaken for local adaptation to selectively heterogeneous environments, when in fact this pattern is generated by independent mutations under uniform selection. Eventually this initial geographic patchwork of different adaptive alleles resolves into a soft-sweep pattern as these alleles, which are now neutral (with respect to each other), diffuse over the range. Even if one allele is superior to all the other advantageous mutations and eventually sweeps through, it will take longer to become fixed because its selective advantage with respect to the other favorable alleles is small. This increases the time for recombination to act, reducing any signature from the final sweep.

Ralph and Coop applied their model by considering the expected characteristic length relative to the range of humans over Eurasia (~ 8000 km). If population densities are low, χ can be sufficiently large that multiple-origin sweeps are unlikely. However, the combination of both a large mutational target and low density can allow for multiple-origin sweeps. Ralph and Coop noted that two complementary settings, moderate density ($\rho = 2$, namely two individuals per km^2) and low mutation ($\mu_b = 10^{-8}$) or low density and high mutation ($\rho = 0.002, \mu_b = 10^{-5}$), yield give $\chi \simeq 3000$ km. Hence, under these conditions, multiple mutations would be expected to be the norm over Eurasia (even under uniform selection).

In contrast with this expectation in humans, Andersen et al. (2012) detected several worldwide hard sweeps in *Caenorhabditis elegans*. They argued that the likely combination of both human-aided dispersal and common selection pressures from agriculture may account for the global nature of these sweeps in an organism that would otherwise be expected to have high population density.

A final issue relating to sweeps and geographic structure is the notion of **divergence hitchhiking** (Via and West 2008). Via and West noted excessive F_{ST} values localized around QTLs for ecological isolation in a pair of incipient aphid species. This observation fits with

Barton's (1979) classic work on gene flow in a cline, wherein regions involved in either partial reproductive isolation and/or divergence selection retain their identity, while the rest of the genome is homogenized by gene flow. When selection opposes recombinants between populations around isolation-inducing sites, the suppression of gene flow will result in such regions showing higher divergence than the background levels.

POLYGENIC ADAPTATION

The strength of a signal left by a hard sweep is a function of the magnitude of selection, with any signal being significantly diminished under soft-selection scenarios. This suggests that weak selection using standing variation at a number of loci is the worst-case scenario for detecting recent or ongoing selection solely from sequence data. Unfortunately, this appears to be *exactly* the situation for many, and perhaps most, quantitative traits (at least initially). As detailed in Chapter 18, almost all traits in outbred populations show some, usually rather significant, responses to artificial selection. The immediate nature of a selection response indicates that standing genetic variation underlies almost all initial responses to selection on complex traits, although contributions from new mutations become increasingly important over time (Chapters 26 and 27).

Recall that the strength of selection $s = \bar{\tau}(a/\sigma_z)$ on a QTL allele underlying a complex trait (Equation 5.21) is a function of the strength of selection on that trait ($\bar{\tau}$, the within-generation change in mean, expressed in standard deviations) and the fractional contribution of the allele to overall trait variation (a/σ_z , the additive effect for that allele, scaled in phenotypic standard deviations). With modest selection on the trait (say the mean is $0.1\sigma_z$ higher in the survivors following selection) and a modest contribution from an underlying QTL (an effect of 0.01 standard deviations), $s = 0.001$. Assuming a recombination fraction of 1 cM/Mb, Equation 8.6a suggests that a sweep at such a site should influence roughly $0.02(0.001/0.01) = 0.002$ Mb = 2000 bases. This is a small region, and yet it represents the *best-case* scenario, a hard sweep. Under a soft sweep (as when the selection response is derived from existing variation), this signal is further degraded. Moreover, for most complex traits, the situation is likely even worse. This is because the response to selection is distributed over a number of loci, allowing for substantial change in the trait mean with only modest allele-frequency change at any underlying loci (Chapter 24). In the case of changing the mean to some new optimum value, any resulting signal would likely be diffused by weak partial sweeps based on standing variation over a modest to large number of sites.

Given these concerns, Pritchard and Di Rienzo (2010) and Pritchard et al. (2010) have suggested that such polygenic adaptation is likely to leave little, if any, signal under traditional screens (also see Chevin and Hospital 2008; Pavlidis et al. 2012). This prediction was observed in a scan of selection on cattle by Kemper et al. (2014). Strong signals were seen around major loci that define breeds (e.g., the absence of horns and coat color loci), and five major loci with strong effects on production traits (stature, milk production, muscle mass) also showed signatures, but not as strong. However, no significant traditional signals were observed around a large number of small-effect QTLs known to be involved in strongly selected production traits.

How might such “**polygenic sweeps**” be detected? An interesting suggestion was offered by Hancock et al. (2010a, 2010b), who looked for subtle allele-frequency shifts that were concordant among human populations experiencing similar environments but in different geographic regions (also see Fumagalli et al. 2011; Fraser 2013; Berg and Coop 2014). Such approaches (examined in detail in Chapter 9) clearly have power issues (being a function of the number of independent replicates under the same environmental conditions) and also rely on the same alleles responding in the same environmental conditions. One interesting variant of this idea involved a comparison of height-QTL allele frequencies in northern versus southern Europeans (Turchin et al. 2012). Of 139 variants associated with height, the plus allele (increasing height) was more common in northern Europeans in 85 out of 139 cases ($p = 0.01$), with a highly significant average frequency increase of around

1.2%. The nature of this response was truly polygenic, as the effect for any single locus is quite small (average effects are $\leq 10^{-2}\sigma$, and involve small allele-frequency changes). Robinson et al. (2015) reported a similar story for both height and body mass index, while Mathieson et al. (2015) reported evidence for polygenic selection on height using ancient DNA (a set of 230 Western Eurasians who lived between 6000 and 300 BC).

The lack of power for sweep-based tests for detecting single sites under polygenic selection arises (in part) from low expected allele-frequency change at any particular site. In the extreme (the infinitesimal model), there can be a significant shift in the mean with essentially no detectable allele-frequency change at the underlying loci (Chapter 24). However, selection *will* generate LD, even among unlinked selected loci, which reduces the additive variance (Chapters 16 and 24). Chapter 12 discusses the $Q_{ST} - F_{ST}$ method of comparing the population structure of the genetic variance of a trait (Q_{ST}) with that for neutral molecular markers (F_{ST}), and the related Q_X test of Berg and Coop (2014). Q_{ST} is impacted not just by allele-frequency change, but also by LD, and thus can give a signal even when allele-frequency change is not detectable. Hence, Q_{ST} -based approaches (which suffer from their own host of problems; see Chapter 12) potentially offer one solution for detecting signals of polygenic sweeps (when gene action is additive).

Because the expected signal for any *single* site under polygenic selection is expected to be (at best) very hard to detect, most of the approaches for attempting to detect polygenic selection are in effect *trait-based*, relying on some composite measure, such as an estimated genotypic value obtained by summing GWAS (or QTL) effect-size estimates over a large number of sites (e.g., Berg and Coop 2014). Hence, these approaches can work for scans of *specific traits* using genomic information about those traits. However, at present, they are not applicable to a genomic scan of random markers. A number of such trait-assisted marker methods (candidate markers are chosen because they impact a known trait) for detecting selection are examined in Chapter 12, while Chapters 9 and 10 focus on detecting selection simply from genomic information without any regard to any specific trait.

Under what situations might one expect hard sweeps versus polygenic adaptation? Given the vast reservoir of standing variation for most traits, a shift to a new environment will likely have an initial polygenic response, but a major allele or major mutation could still occur and have very dramatic effects (Chapter 25). Thus, hard sweeps are expected in situations where little standing variation for the trait is present, as might occur for traits with a long history of consistent directional selection or those with a simple genetic basis (i.e., that are only influenced by a few loci). In such cases, any further response might be mutation limited. However, it can also be the case that low standing variation is in part due to one (or more) alleles of major effect initially residing at a low frequency because of deleterious fitness effects in the original environment (Lande 1983). A sudden shift in the environment may increase selection pressure to the point where the major effect on a trait now gives the allele a net selective advantage, which can result in a hard sweep (from standing variation) if the allele is sufficiently rare (we revisit this topic in Chapter 25).

GENOME-WIDE IMPACT OF REPEATED SELECTION AT LINKED SITES

Up to this point, our focus has been on the local impact of a single sweep. There is a much broader picture as well—*recurrent* hitchhiking events can have profound effects over the entire genome, a topic first introduced in Chapter 3. Indeed, Maynard Smith and Haigh (1974) proposed that **recurrent selective sweeps** could depress variation throughout a genome, providing insight into the observation that levels of polymorphism (having an expected value of $4N_e\mu$ under the equilibrium drift model) only weakly scale with N_e (as noted in Chapter 4, an evolutionary decrease in μ with increasing N_e is likely a contributing factor). Large-scale sequencing has led to the current view that recurrent selection at linked sites does indeed have a profound effect on many, and perhaps most, genomic regions, reducing standing levels of variation by lowering N_e (reviewed by Lynch 2007; Leffler et al. 2012; Cutter and Payseur 2013; Corbett-Detig et al. 2015). Such a reduction in N_e increases the frac-

tion of new mutations that are effectively neutral, potentially increasing substitution rates in regions where weakly deleterious mutations are common. The current debate concerns how much of these genome-wide effects are due to recurrent sweeps (adaptive evolution) versus background selection against deleterious mutations (purifying selection). Building on our discussion on N_e in Chapter 3, our goal in this section is to introduce the basic theoretical results relevant to this issue, many of which follow from the above machinery for sweeps. In light of the theory, we also examine the empirical data. It is worth stressing that in the following discussion we are not considering the effects of *specific* sweeps at specific sites, but rather the expectation of their impact over all times and sites, where beneficial and deleterious mutations are expected to occur (roughly) uniformly over a chromosome.

Association Between Levels of Variation and Localized Recombination Rates

Early studies in *D. melanogaster* showed that regions with reduced recombination also have reduced genetic variation, which is typically measured by the amount, π , of nucleotide diversity at putatively neutral sites (Aguadé et al. 1989; Begun and Aquadro 1991; Berry et al. 1991). The fact that between-species divergence does not appear to be depressed in these regions suggests that a reduction in the mutation rate is not the culprit, and the initial interpretation was that this pattern is generated by recurrent sweeps of favorable mutations, which reduce linked neutral variation. While such positive correlations between levels of recombination and π are widespread, they are by no means universal. Such an association may be restricted to particular regions, such as chromosome arms, or it may be missing entirely in a species. For example, Flowers et al. (2012) and Cutter and Payseur (2013) found a positive correlation between π and the per-base-pair recombination rate in at least some genomic regions in 14 of 20 sampled organisms, showing that while common, this pattern is not universal. Many features, such as the strength and frequency of adaptive sweeps or background selection, likely vary over genomic regions, and could account for the lack of a consistent pattern. In particular, predicted patterns of variation should not be based on recombination rates alone, but rather on the ratio of the mutational target size for fitness effects relative to the recombination rate. For the same level of recombination, a stronger effect is expected in more gene-rich regions (under both background-selection and recurrent-sweep scenarios).

As whole-genome sequencing becomes widespread, broader surveys of the relationship between π and c over entire genomes (as opposed to randomly selected regions) should provide further insight into the underlying causes and constraints. In an initial survey of 40 obligately sexual eukaryotes, Corbett-Detig et al. (2015) found that the effects of linked selection are pervasive, with levels of variation positively correlated with local recombination rates. Further, the strength of this association is larger in species with larger census sizes, N (using adult body size and range as surrogate variables for N), as might be expected, given that larger populations allow selection to overpower drift over a wider range of selection coefficients. The authors fit likelihood-based models for background selection (BGS), recurrent sweeps (hitchhiking, HH), and BGS+HH, finding that the BGS model significantly improved the fit in all cases. Evidence for HH (based on a likelihood-model fit with either HH or BGS+HH) was stronger in species judged to have larger census sizes. The authors concluded that BGS was pervasive over all population sizes, suggesting (as did Cutter and Payseur 2013), that *BGS, not neutrality, should be the default model for tests of positive selection*. However, while BGS was important at all population sizes, Corbett-Detig et al. (2015) found that recurrent sweeps become progressively more important as population size increases. One caveat with their analysis was raised by an earlier study by Romiguier et al. (2013), who found that body size and species range are not very predictive of π , and hence may be poor predictors of N_e .

Example 8.13. Some insight into the relative contributions of gene density versus recombi-

nation rates to patterns of variation can be gleaned by comparing species that show different associations between regional gene density and recombination rates. In rice, the highest gene density is found in high recombination regions (the chromosome arms), and Flowers et al. (2010) found that localized levels of variation were negatively correlated with gene density, but either uncorrelated or weakly *negatively* correlated with recombination rate. They suggested that the negative association of variation with gene density (less variation in more gene-dense regions) is consistent with background selection. Accounting for the observed negative association with recombination (higher variation in regions of low recombination) is more problematic. One possible explanation is Hill-Robertson interference (Chapter 7), as selection during the domestication of rice would be more efficient under higher recombination rates, resulting in stronger sweeps (and hence lower levels of π) in regions with elevated recombination.

The genome of the nematode *Caenorhabditis elegans* is structured in a very different fashion than rice. In *C. elegans*, high gene density occurs in the low-recombination regions around chromosome centers, lower gene density with higher recombination in chromosome arms, and intermediate gene density with no recombination at chromosome tips. Rockman et al. (2010) examined the genomic distribution of **local expression quantitative trait loci** (eQTLs) in *C. elegans*, defined as QTLs influencing the expression of genes close to the mapped eQTL location (within one LOD score; see LW Chapter 14). Simply based on gene density, one might expect an excess of eQTLs in chromosome centers, as more genes are located there. In fact, however, Rockman et al. observed the opposite, with 34% of transcripts in the low-density arms having local eQTLs, but with only 10% of transcripts from the high-density centers having local eQTLs. Rockman et al. suggest that background selection (BGS), which is expected to be higher in the centers (there is a higher ratio of gene density to recombination), could account for this reduction in variation. BGS could also account for the observation that only 20% of the transcripts from chromosome tips have eQTLs. Although there is little recombination, sites in the tips are only linked to deleterious mutations on one side, and hence experience somewhat weaker background selection. A striking feature of this analysis is that the authors were not judging variation by sequence diversity, but rather through a *functional* screen (measuring the presence or absence of eQTLs). In their words, “the propensity of traits to vary in *C. elegans* is explained by processes independent of the functions of the individual transcript,” with those processes involving selection at linked sites.

Impact of Recurrent Hard Sweeps on Levels of Neutral Variation

As illustrated in the previous example, levels of recombination often vary widely over the genome. In a region with low recombination (such as telomeric and centromeric regions, very small chromosomes such as the fourth of *D. melanogaster*, and most of the heterogametic sex chromosome), even weak selection at a distant location can have an impact. In the extreme case where an entire genome has *no* recombination (such as in some bacteria or organelles), a single advantageous mutation can sweep a single genomic type to fixation. Laboratory populations of bacteria often show the phenomena of **periodic selection** (Atwood et al. 1951a, 1951b; Kock 1974; Dykhuizen 1990; Guttman and Dykhuizen 1994), wherein genetic diversity builds up slowly over time, only to be rapidly removed before starting to build all over again. Presumably, this is due to the periodic fixation of newly appearing favorable mutations, which generate sweeps that fix single chromosomal lineages. In this setting, the standing level of variation is a function of the frequency of sweeps. If it is sufficiently common, the population never has a chance to reach mutation-drift equilibrium before the next sweep, while if rare, the population may be at the mutation-drift equilibrium for much of the time. Thus, *the rate of adaptation at least partly determines the amount of neutral variation*, a theme returned to throughout this section.

For a population of constant size undergoing periodic hard sweeps, Wiehe and Stephan (1993) found the equilibrium level of heterozygosity to be a decreasing function of the rate of adaptation, λ . Here, λ is defined as the number of beneficial mutations destined to become fixed that arise in each generation. This is given by the product of the number of new beneficial mutations arising in each generation ($2N\mu_b$) and their individual fixation

probabilities ($2sN_e/N$)

$$\lambda = (2N\mu_b)(2sN_e/N) = \theta_b s \quad (8.24a)$$

where $\theta_b = 4N_e\mu_b$. Typically, we take μ_b as a per-nucleotide rate, which scales λ on a per-nucleotide basis, so that $L\lambda$ is the expected rate for a region of L nucleotides. We have assumed no epistasis in fitness, so that each new beneficial mutation adds a fitness contribution that is not influenced by the current genotype.

Wiehe and Stephan found that with recurrent sweeps, the expected heterozygosity, as measured by nucleotide diversity, π , at linked neutral sites, is

$$\frac{\pi}{\pi_0} \simeq \frac{c_0}{c_0 + \lambda \gamma \kappa} = \frac{1}{1 + \lambda \gamma \kappa / c_0} \quad (8.24b)$$

where $\pi_0 = 4N_e\mu$ is the average heterozygosity at a single site for an equilibrium neutral population under no sweeps, c_0 is the average per-nucleotide recombination rate over the region of interest (such as an entire chromosome), $\gamma = 2N_e s$ is the scaled strength of selection per adaptive nucleotide, λ is the per-nucleotide adaptive substitution rate over the region of interest, and there is a constant, $\kappa \simeq 0.075$. For $c_0 > \lambda \gamma \kappa$, because $1/(1+x) \simeq 1-x \simeq e^{-x}$ for $|x| \ll 1$, Equation 8.24b rearranges to

$$\frac{\pi}{\pi_0} \simeq 1 - \frac{\lambda \gamma \kappa}{c_0} \simeq \exp(-\lambda \gamma \kappa / c_0) \quad (8.24c)$$

Rearranging the linear approximation gives the **Stephan regression** (Stephan 1995) for explaining the average variation, π , within a region as a function of the region's per-base recombination rate, c_0 ,

$$\pi = \pi_0 - (\pi_0 \lambda \gamma \kappa) x, \quad \text{where } x = 1/c_0 \quad (8.24d)$$

Fitting Equation 8.24d, Wiehe and Stephan (1993) obtained an estimate of $\lambda \gamma \simeq 1.3 \cdot 10^{-8}$, based on 17 loci in medium to high recombinational backgrounds in *D. melanogaster*. For a modest recombination rate of 1 cM per megabase ($c_0 = 0.01/10^6 = 10^{-8}$), applying Equation 8.24b with this value of $\lambda \gamma$ yields

$$\frac{\pi}{\pi_0} \simeq \frac{10^{-8}}{10^{-8} + (1.3 \cdot 10^{-8} \cdot 0.075)} = 0.911$$

or roughly a 9% reduction in background heterozygosity. For smaller recombination rates, say 0.1 cM per megabase ($c_0 = 10^{-9}$), standing levels of variation are reduced by 49%. In a region of high recombination (2.5 cM/Mb, $c_0 = 2.5 \cdot 10^{-8}$), the reduction in π is only 3.7%. Hence, in regions of low recombination, recurrent selective sweeps can have a dramatic effect on standing levels of variation. Additional estimates of $\lambda \gamma$ are summarized in Table 8.3, and further developed in Chapter 10.

Example 8.14. Using machinery from Chapter 10 on a set of X-linked genes in *D. melanogaster*, Andolfatto (2007) and Jensen et al. (2008) obtained estimates of λ of $7.5 \cdot 10^{-10}$ and $4.2 \cdot 10^{-11}$ (respectively) for the per-nucleotide adaptation rate (summarized in Table 8.3). Consider a region with a length of 100 kb. Under Andolfatto's estimate, the per-generation rate of adaptive substitutions over a region of this size is $10^5 \cdot 7.5 \cdot 10^{-10} = 7.5 \cdot 10^{-5}$ or one sweep in roughly every 13,300 generations. Under Jensen's estimate, a sweep influencing this region occurs roughly every 238,000 generations. Potential reasons for such a vast difference in the estimates will be examined shortly.

A Few Large or Many Small Sweeps?

Because reduction in diversity from sweeps is a function of the product $\lambda\gamma$, the same average reduction in π could be caused by either a few large sweeps (where λ is small and γ large) or many smaller sweeps (where λ is large and γ small), as long as their product is held constant. With rare, strong sweeps, there would be dramatic reduction in variation over a fairly large region, but many regions would see little effect, as no recent sweep would have occurred in their vicinity. Conversely, with many weaker sweeps, most regions would be influenced, but each by a smaller amount. While the expected value of π is the same under both models, the variance in π is expected to be much greater under rare but strong sweeps (Jensen et al. 2008).

Distinguishing between the strong and weak selection scenarios requires an independent estimate of either λ or γ in addition to an estimate of $\lambda\gamma$. Methods to accomplish this are more fully developed in Chapter 10, but one approach is as follows. Suppose L sites within a region of interest are examined between two populations that separated t generations ago (for a total divergence time of $2t$). If a total of D sites show divergence, $d = D/L$ is the per-site divergence. Ignoring multiple mutations at the same site, if α denotes the fraction of all divergent sites that are adaptive, $d\alpha$ is the per-site number of adaptive fixations that occurred over $2t$ generations. This gives the rate as $\lambda = d\alpha/(2t)$. Estimates of t can be obtained from several sources (such as rates of neutral divergence), but estimates of the adaptive fraction, α , are more elusive. However, as detailed in Chapter 10, estimates of α for coding regions follow by noting that, under the assumption of neutrality, the ratio of the number of silent to replacement polymorphic sites should equal the ratio of the number of silent to replacement substitutions (Example 10.1). An excess of replacement substitutions presumably reflects the role of adaptive evolution, and the amount of excess provides an estimate of α (e.g., Example 10.1), and hence of λ . As detailed in Chapter 10, this approach for estimating α makes the strong assumption of long-term constancy in N_e .

Letting d_a denote the per-site rate of amino acid divergence, and substituting $\lambda = d_a\alpha/(2t)$ into Equation 8.24b, yields the **Andolfatto regression**

$$\pi \simeq \pi_0 \frac{c}{c + \lambda \gamma \kappa} = \pi_0 \frac{c}{c + [\alpha \gamma \kappa / (2t)] d_a} = \frac{\pi_0}{1 + \beta x} \quad (8.25)$$

where $x = d_a/c$ and $\beta = \alpha \gamma \kappa / (2t)$, and because λ is now measured on a per-amino acid basis, c is now the recombination rate per codon (Andolfatto 2007). In other words, scaling the per-site divergence, d_a , for each gene by its local rate of recombination, c , yields a nonlinear regression between observed nucleotide diversity, π , and the recombinational-scaled divergence, d_a/c . When one assumes a constant recombination rate, c , among the sampled sites, the regression is just on $x = d_a$ (which varies over regions), where now $\beta = \alpha \gamma \kappa / (2tc)$, which (with estimates of α , c , and t) returns γ (as is done in Figure 8.9). Chapter 10 reviews other approaches for estimating α and/or γ from joint polymorphism and divergence data at single loci.

A technically more demanding approach for gaining insight into the parameters of adaptation is to jointly estimate two of these three parameters (λ , γ , or $\lambda\gamma$) using the spatial pattern of genetic variation over a genomic region (Macpherson et al. 2007; Jensen et al. 2008). Figure 8.10 shows the motivation for this idea. Jensen et al. (2008) noted that strong selection should produce a higher variance in π and other measures of genetic variation that are impacted by a sweep (Table 8.2), for example, the number of segregating sites (S), an excess of high-frequency derived alleles, and pairwise linkage disequilibrium (LD). Using simulations, they examined the behavior of the coefficient of variation (CV) for summary statistics for these quantities as a function of the size, L , of the unit of analysis. Over small regions (L of 500 to 1000 bp), there was little difference in the CV between the rare and strong and the frequent and weak sweep models, but as the size of the analysis region increased, so did the CV for strong, but not weak, selection. Based on this observation, Jensen et al. (2008) developed an approximate Bayesian computation (ABC) approach that jointly considers

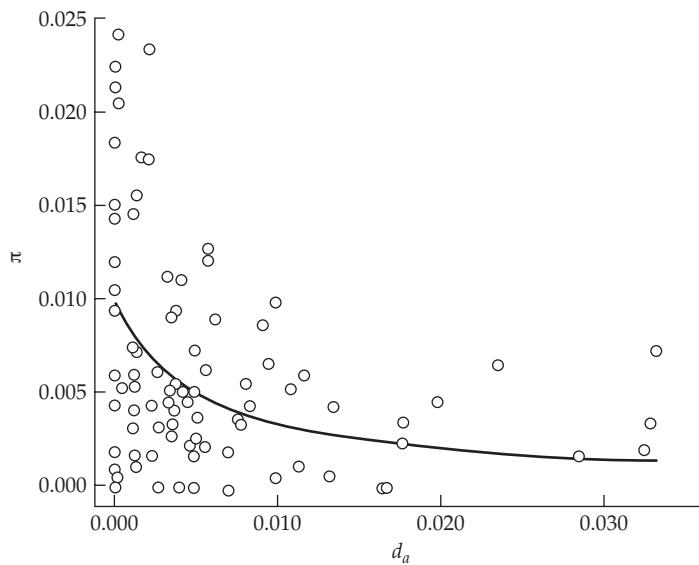

Figure 8.9 An example of the Andolfatto regression of nucleotide diversity, π , on the per-site amino acid divergence, d_a , in *Drosophila miranda*, under the assumption of the same recombination rate (c) among all sampled sites. In this setting, the regression given by Equation 8.25 becomes $\pi = \pi_0 / (1 + \beta x)$, where $x = d_a$ (the mean number of amino acid substitutions per codon in the region for the estimated π value) and $\beta = \alpha\gamma\kappa / (2tc)$. The solid curve is the least-squares fit of Equation 8.25, which gives estimates of π_0 and γ (as α , c , and t were independently estimated). (After Bachtrog 2008.)

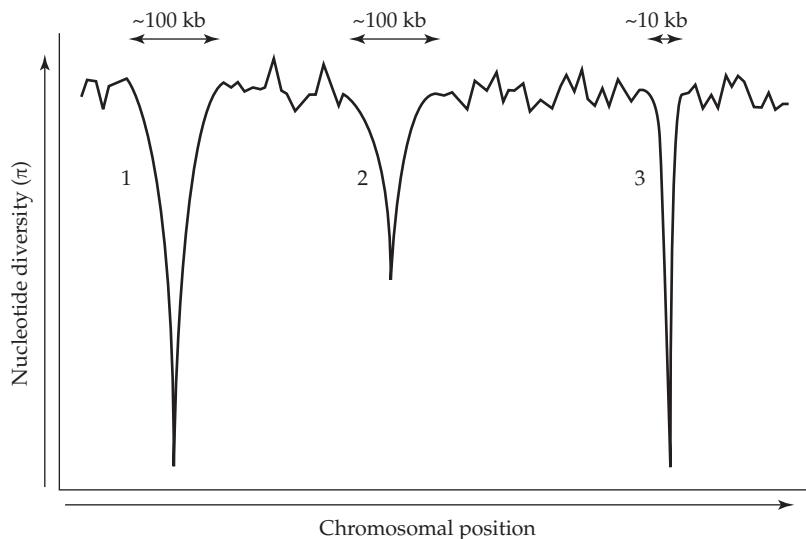

Figure 8.10 The pattern of nucleotide diversity over a large region may provide clues about the frequency and strength of past sweeps. Within this hypothetical region, three hard sweeps have occurred. Sweep 1 is a strong, recent sweep; sweep 2 is a strong older sweep; and sweep 3 a weak, recent sweep. Strong sweeps result in a depression in variation over a significant region (1). As the signal from a past sweep decays, its window of influence stays roughly the same size, but its impact within that window vanishes over time. An old, strong sweep leaves a weak signal of depressed variation over a fairly large region (2), while an old weak sweep leaves a signal similar to (2), but over a much smaller region. (After Macpherson et al. 2007.)

Table 8.3 Estimates of the per-nucleotide adaptive evolution rate, λ , and its components for several *Drosophila* species, aspen (*Populus tremula*), and humans. Depending on the study, the scale of analysis is either chromosomal or genome-wide. Methods for estimating individual components of the product $\lambda\gamma$ are developed in Chapter 10. Here $\gamma = 2N_e s$ is the scaled strength of selection, λ is the rate of adaptive substitutions per base pair, per generation, and s is the average strength of selection of a beneficial mutation. The species listed provided the polymorphism data used in these methods, while an outgroup was used for other estimates of λ (Equation 10.11a).

the means and variances of summary statistics measuring these various sweep features to obtain separate estimates of λ and s (for details see Example A3.9).

Macpherson et al. (2007) also used the chromosomal pattern of nucleotide diversity around putative sweeps to obtain separate estimates of λ and $\lambda\gamma$. As above, an estimate of the latter was obtained from the regression (Equation 8.24b) of π on c_0 (nucleotide diversity on local recombination rates). They then introduced a new statistic, Q_s , the ratio of a minimal estimate of heterozygosity within a region of fixed length (a window) to the average heterozygosity over the region scanned by the windows. They showed that the expected value of Q_s is a function of both λ and $\lambda\gamma$, so that the joint pair of statistics, Q_s and π , allows for separate estimates of λ and $\lambda\gamma$. One significant caveat, as stressed by the simulations of Schrider et al. (2015), is that the observed minimal region of heterozygosity may poorly correspond to the selected site, which can bias estimates using this method.

As summarized in Table 8.3, while estimates of the product, $\lambda\gamma$, for various studies in *Drosophila* are reasonably compatible, individual estimates of its components γ (or s) and λ differ by several orders of magnitude. There are several potential reasons for this. Different studies of even the same species may use different populations as well as different sets of genes, such as autosomal (Macpherson et al. 2007) versus X-linked (Andolfatto 2007; Bachtrog 2008; Jensen et al. 2008). However, the different methods employed may be the major contributor to the significant disparity between studies. Estimates based on short regions (single genes) as the unit of analysis, such as those by Andolfatto (2007) and Bachtrog (2008), found small estimates of γ and s in *D. melanogaster* (γ between 35 and 74, implying an s of around 10^{-5}). Estimates based on much longer regions (10–100 kb), such as Macpherson et al. (2007) and Jensen et al. (2008), found much larger estimates, with $\gamma \approx 10,000$ to 30,000 and $s \approx 0.002$ to 0.01. Estimates obtained by Bachtrog (2008) for *D. miranda* using a number of small regions were intermediate, with $\gamma = 3000$, $s = 10^{-3}$.

Sella et al. (2009) suggested that these estimates of γ and λ may actually be more compatible than their spread suggests (Figure 8.10). Weak selection leaves a strong signal over only a very small region, while strong selection leaves a signal over a much larger region. For example, using a recombination rate of 1 cM/Mb ($c_0 = 10^{-8}$), Equation 8.6a suggests that weak sweeps ($\gamma = 35$, $s = 10^{-5}$) influence at most a few hundred bases, while strong sweeps ($\gamma = 10,000$, $s = 0.01$) can influence almost a hundred kilobases. Sella et al. suggested that methods using small regions (such as single genes) for their units

of analysis are biased toward the detection of weak selection, while methods using much larger regions are biased toward strong selection. If the size of the region of analysis does bias results, then weak selection accounts for most of the observed between-population divergence, while strong selection accounts for most of the reduction in diversity. Sattah et al. (2011) found strong support for this view by examining the pattern of nucleotide variation around substitutions in *Drosophila simulans*. As expected from the neutral theory, there was a slight elevation in standing diversity around silent-site substitutions (higher neutral substitution rates implying higher mutation rates, and thus higher levels of polymorphism). After adjusting for this effect, they found a trough in nucleotide diversity around sites that resulted in amino acid substitutions, as would be expected given a sweep. Using a composite-likelihood approach to test for a sweep given the local diversity pattern around a site (Chapter 9), they estimated that around 13% of the substitutions resulted in sweeps. A mixture model allowing for different strengths of selection fit the genomic data the best and suggested that about 30% of the sweep sites (4% of the total substitutions) were under strong selection, with a mean s value of ~ 0.005 , while the remainder had a mean s of $\sim 4 \cdot 10^{-5}$.

Finally, up to this point our analysis of the impact of recurrent sweeps has assumed that all sweeps were hard. At the other extreme are partial sweeps, where an allele increases rapidly in frequency (to a value of x) in one selective environment, which then changes. Equation 8.15 shows the impact of a *single* partial sweep on π . Coop and Ralph (2012) showed that the reduction in nucleotide diversity due to *recurrent* partial sweeps has a form very similar to Equation 8.24b, namely

$$\frac{\pi}{\pi_0} \approx \frac{1}{1 + \lambda \zeta / c_0} \quad (8.26)$$

where ζ is a function of the time for the sweep to reach its target frequency, x (Equation 8.4e).

Selective Interference and the Hill-Robertson Effect

The above results for recurrent sweeps assume that *concurrent* sweeps influencing the same region are rare. Given that the expected number of new beneficial mutations introduced into the population in each generation scales as NU_b (with U_b being the total beneficial mutation rate for the region of interest), this assumption breaks down in sufficiently large populations. In this setting, multiple sites are segregating beneficial mutations, and sweeps can interfere with each other (Kim and Stephan 2003; Neher et al. 2010; Yu and Etheridge 2010; Neher and Shariman 2011; Weissman and Barton 2012; Neher 2013; Neher et al. 2013).

If sites with segregating beneficial mutations are loosely linked, their effect is to lower the effective population size that a particular site experiences, making selection slightly less efficient (the classic interpretation of a Hill-Robertson effect; Chapter 7). A more dramatic effect occurs when some of these sites are tightly linked, in which case there can be strong **selective interference** among them. One example is **clonal interference** (Gerrish and Lenski 1998), seen in very large populations with nearly complete linkage (i.e., bacteria). Competition occurs among the set of lineages (clones) carrying different beneficial mutations, as each such clone has a strong advantage against lineages lacking such mutations but (at best) only a weak advantage against other beneficial lineages. In a sexual population, recombination can shuffle genomes to combine beneficial mutations, but the dynamics are very different in large asexual populations. In the latter, NU_b is expected to be large, with multiple favorable mutations arising in each generation but with little (or no) recombination. In this setting, simply acquiring a new beneficial mutation is *not* sufficient for the fixation of a particular genome, as additional beneficial mutations continue to arise and an otherwise favorable genome may not acquire *new* additive favorable mutations as quickly as other genomes and thus become lost (Desai and Fisher 2007). Neher et al (2010) showed that while the appearance of favorable new mutations scales linearly with N (as NU_b), selective interference significantly *reduces* the probability of individual fixation as N increases, resulting in an eventual rate of adaptive evolution that scales as $\log(NU_b)$.

Weissman and Barton (2012) extended this analysis to sexual species. Let $\Lambda = L\lambda$ be the total rate of adaptation over a region of length L nucleotides with a total recombination rate of $C = Lc_0$, where c_0 is the average recombination rate between adjacent nucleotides. If $\Lambda_0 = L\lambda_0$ is the expected rate of adaptation ignoring the effects of interference, then

$$\Lambda \simeq \frac{\Lambda_0}{1 + 2\Lambda_0/C} \quad \text{or} \quad \lambda \simeq \frac{\lambda_0}{1 + 2\lambda_0/c_0} \quad (8.27a)$$

Expressing this as

$$\Lambda/C \simeq \frac{\Lambda_0/C}{1 + 2\Lambda_0/C} \quad (8.27b)$$

shows that for very large populations, where $\Lambda_0/C \gg 1$ (i.e., $\lambda_0/c_0 \gg 1$), the upper limit of adaptation is given by $\Lambda \simeq C/2$ (or $\lambda \simeq c_0/2$). For example, for a region of 1 centimorgan ($C = 0.01$), the total rate of adaptive substitutions over that region is bounded by $\Lambda \leq 0.005$, or the appearance of one successful beneficial mutation in every 200 generations. There is an additional effect from selection at unlinked sites, which reduces the rate further by $\exp(-4\Lambda s)$, which (for small s) is negligible relative to the effects of linkage. Weissman and Barton used their results to examine the impact of selective interference on the levels of variation at linked neutral sites. For small values of λ_0/c_0 , there is not much interference among sweeps and Equation 8.24b is a good approximation for the loss of linked neutral variation. Conversely, when interference is strong, substantial neutral variation can still be maintained, as the density of sweeps (λ/c_0) approaches a limiting asymptotic value and the coalescent times for pairs of neutral alleles (and hence the amount of variation that is maintained) is a function of sweep density.

This notion of interference among linked selected sites is not restricted to beneficial alleles. Indeed, it may have a significant impact when tightly linked, weak *deleterious* alleles are involved. We have referred to situations where selection at one site influences the effectiveness of selection at a second as a Hill-Robertson (HR) effect (Chapter 7). As the previous discussion on selective interference illustrates, while the HR effect is usually regarded as a reduction in N_e , this is not the whole story (Felsenstein 1974; Comeron and Kreitman 2002; Neher and Shariman 2011; Schiffels et al. 2011; Neher 2013; Neher et al. 2013), as selective interference must also be considered. With free recombination between selected sites, gametes quickly arise that contain multiple favorable alleles, giving a wider range of fitness values and hence more efficient selection due to a higher additive variance in fitness. Conversely, with linkage, the production of gametes with multiple favored alleles is retarded (selection generates negative linkage disequilibrium among favorable alleles; Chapters 5 and 16), resulting in a smaller additive variance in fitness among individuals in the population and hence less efficient selection.

Background Selection: Reduction in Variation Under Low Recombination or Selfing

Charlesworth et al. (1993a) challenged the view that the reduction of variation in regions of low recombination was evidence for periodic selective sweeps (and hence the frequent substitution of adaptive alleles). They noted that the same pattern can be generated by selection *against* new deleterious mutations. Hence, purifying selection can potentially account for this pattern of reduced variation without the need to invoke adaptive selection. This occurs because the removal of new deleterious mutations also lowers the effective population size, and in a sufficiently long region of low recombination, the number of targets for mutation may be large enough to generate a high total deleterious mutation rate and therefore a significant reduction in variation. They referred to this process as **background selection**, **BGS**, which was introduced in Chapter 3. We review (and generalize) some of our results from that chapter here in order to more fully contrast BGS with recurrent sweeps.

Charlesworth et al. (1993a) estimated the potential impact of BGS as follows. First, consider a neutral site completely linked to a region in which new deleterious mutations arise at a rate of U (per diploid). A key assumption is that these new mutations are sufficiently deleterious to be removed rapidly, so that the population is at an equilibrium with

the removal of mutation-bearing chromosomes through selection that is balanced by the creation of new chromosome types (haplotypes) by mutation. If we assume that the fitness of a new deleterious mutation (in the heterozygous state) is $1 - s$ and that fitness over the loci is multiplicative, the expected number of deleterious mutations per gamete at the mutation-selection equilibrium is $U/(2s)$ (Kimura and Maruyama 1966). Further, the number of mutations follows a Poisson distribution, so the probability of a mutation-free gamete is given by the zero term of a Poisson,

$$f_0 = \exp\left(-\frac{U}{2s}\right) \quad (8.28)$$

The effect of background selection is to reduce the effective population size from N_e to $f_0 N_e$, giving an expected reduction in neutral variation of $\pi/\pi_0 = f_0$ as well. Because selfing reduces the opportunity for recombination, the effects of background selection can be quite significant in highly selfing populations, such as in many plants. Charlesworth et al. (1993a) noted that the reduction in π in strict selfers is given by Equation 8.28, with s replaced by $2s$, the selection against mutant homozygotes (assuming additivity).

Hudson and Kaplan (1995) extended these results by allowing for recombination. For a neutral locus in the middle of a region of length L with a total recombination frequency of C ,

$$\frac{\pi}{\pi_0} \simeq \exp\left(-\frac{U}{2s + C}\right) \quad (8.29a)$$

where $U = L2\mu$ is the total diploid deleterious mutation rate within this region and $C = Lc_0$, and where (as above) μ and c_0 denote the average rates of deleterious mutation and recombination per nucleotide. When the total amount of recombination within the region is large relative to s ($C \gg s$),

$$\frac{\pi}{\pi_0} \simeq \exp\left(-\frac{2\mu}{c_0}\right) \quad (8.29b)$$

and thus the decline in heterozygosity is approximately independent of the strength of selection. Note that this expression is of the same form as the exponential approximation for recurrent sweeps (Equation 8.24c). Likewise, because $e^x \simeq 1 - x$ for $|x| \ll 1$, it follows for moderate to high recombination ($2\mu/c_0 \ll 1$) that

$$\frac{\pi}{\pi_0} \simeq 1 - \frac{2\mu}{c_0} \quad (8.29c)$$

This is the same form ($\pi/\pi_0 = 1 - b/c_0$) as our result for moderate to high recombination under recurrent selective sweeps ($b = 2\mu$ in Equation 8.29c, $b = \lambda\gamma\kappa$ in Equation 8.24c). As a consequence, in regions of moderate to high recombination, the regression of π on c_0 cannot distinguish between hitchhiking and background selection.

Conversely, in regions where recombination is weaker (so that the linear approximation given by Equation 8.29c no longer holds), the functional form of the relationship between π with c_0 differs between BGS and recurrent sweeps, potentially offering some hope of resolution between the two competing models in regions with very low recombination rates. Both Hudson and Kaplan (1995) and Charlesworth (1996) found that the BGS model gave a poor fit in *D. melanogaster*. Hudson and Kaplan were able to improve the fit of a BGS model to the third chromosome of *D. melanogaster*, but only after assuming much smaller selection coefficients for the low-recombination regions than used for the recombining regions on this same chromosome. The problem, as noted by Kaiser and Charlesworth (2009), is that the standard BGS model *overpredicts* the reduction in π in regions of very low recombination. They reasoned that this poor fit might occur in regions where U is sufficiently large that multiple deleterious alleles are segregating at any given time. As with beneficial mutations, multiple segregating deleterious mutations interfere with each other, reducing the efficiency of selection and resulting in less reduction in variation at linked sites. Incorporating this

effect into their simulation results yielded reductions consistent with observed values in regions of very low recombination. We return shortly to the implications of such selective interference in regions of very low recombination.

A complicating factor when modeling background selection is **Muller's ratchet** (Muller 1964; Felsenstein 1974): in a region of very low recombination, the class of chromosomes carrying no deleterious mutations may become lost due to drift. If such an event occurs, then without recombination, there is no way (other than by extremely fortuitous back mutations) to recover mutation-free chromosomes. At this point, a new class (say, harboring just a single deleterious mutation) now becomes the most fit chromosomal type. This new class also may eventually be lost by drift, leading to chromosomes with two deleterious mutations now being the most fit class, turning the ratchet once again, and so on. The assumption leading to Equation 8.28 is that the zero class is at equilibrium (i.e., is unlikely to be lost in reasonable biological time).

Recall our discussions of effective neutrality in Chapter 7, where drift overpowers selection unless $N_e|s| \gg 1$. Under background selection, an unselected effective population size of N_e is reduced to $\sim f_0 N_e$, requiring $s f_0 N_e \gg 1$ for selection to overpower drift (and hence preventing the fixation of most deleterious alleles). Thus, weak selection and/or a small N_e are required for the ratchet to operate. Provided that $f_0 N_e s > 10$, selection is efficient enough to prevent operation of the ratchet and the reduction in effective population size from background selection is well approximated by Equation 8.28. When the ratchet is operating, in addition to reducing the background variation, an excess of rare alleles is generated, skewing the site-frequency spectrum (Gordo et al. 2002). This has significant implications if one is trying to distinguish between BGS and recurrent sweeps.

Of course, it is likely that *both* background selection and recurrent sweeps operate at some level. Kim and Stephan (2000) showed that Equation 8.24b can be modified to give the approximate diversity when both act, yielding

$$\frac{\pi}{\pi_0} \simeq \frac{f_0 c_0}{c_0 + \lambda_c f_0 \gamma \kappa} = \frac{1}{(1/f_0) + (\lambda_c \gamma \kappa / c_0)} \quad (8.30a)$$

where $f_0 N_e$ is the effective population size after correcting for BGS. This reduction in effective population size changes the scaled strength of selection from $\gamma = 2N_e s$ to the value appearing in Equation 8.30a, namely, $f_0 \gamma = 2N_e f_0 s$. The more subtle correction is that the reduction in effective population size from BGS (which changes with c_0) also changes the fixation probabilities for new favorable mutations, so that λ , the product of the fixation probability and the number of new adaptive mutations arising per generation, is now a function of the recombination rate, c_0 (and it is indexed as λ_c in Equation 8.30a to remind the reader of this fact). Kim and Stephan (2000) suggested that recurrent sweeps are likely to be more important in regions of very low recombination, while BGS is more relevant in high-recombination regions. On a practical note, comparison of Equations 8.24b and 8.30a shows that *ignoring background selection results in an inflated estimate of $\lambda \gamma$* , and hence an inflated estimate of the rate of adaptation (Kim 2006).

Partial sweeps, wherein selection changes a selected allele to some moderate frequency, also change the coalescence rate relative to drift at linked neutral loci, although not as dramatically as for a completed hard sweep. Corbett-Detig et al. (2015) used the partial sweeps model of Coop and Ralph (Equation 8.26) and showed that Equation 8.30a can be generalized to

$$\frac{\pi}{\pi_0} \simeq \frac{1}{1/f_0 + \eta/c_0} \quad (8.30b)$$

where η is the number of new favorable mutations arising per generation times the pairwise coalescence rate (per generation) due to sweeps. The key feature is that the scaling with respect to c_0 is the same as in Equation 8.30a.

Our penultimate comment on BGS is to stress that it is not strictly a phenomenon of coding sequences. Indeed, the rather high rate of sequence conservation (and hence, functional constraints) seen for some noncoding DNA in *Drosophila* has important implications

for background selection. Taking into account both its abundance and average level of constraint (Chapter 10), Andolfatto (2005) and Halligan and Keightley (2006) suggested that *Drosophila* noncoding DNA is likely a much larger deleterious-mutation target (by at least a factor of two) than coding DNA. This is still an open issue, as the actual fraction of non-coding DNA that may have a function is the subject of much debate (ENCODE Project Consortium 2012; Doolittle 2013; Fu and Akey 2013; Graur et al. 2013).

Finally, as first introduced by McVicker et al. (2009), one can use functional genomics data to construct a more granular accounting of background selection (Example 8.15). While this approach may seem overly technical, it leverages all available genomic information to more fully account for BGS. Because some level of BGS is always expected (deleterious mutations being ever-present), removing any of its potential influence is critical to understanding the roles of other forces in shaping the genome.

Example 8.15. Consider the impact of background selection on a neutral target site, i , due to k linked conserved sites (and hence, targets for background selection). Building on Hudson and Kaplan (1995), sum the impact over each potential site (assuming multiplicative fitnesses) and allow for a distribution of fitness effects over different classes of sites. The impact of background selection on site i is to reduce N_e to $B_i N_e$, where

$$B_i = \exp \left(- \sum_{j=1}^k \int_0^1 \left[\frac{\mu_i}{s(1 + c_{ij}/s)^2} \right] \phi_j(s) ds \right) \quad (8.31a)$$

The term in the brackets is simply Hudson and Kaplan's (1995) expression for the impact of a deleterious mutation of effect s at distance c_{ij} from the target site j (an approximation of this leads to Equation 8.29a). The integral is taken over the distribution $\phi_j(s)$ of fitness effects for site j , and the results are summed for each potential site of background selection. While initially this expression seems unduly complex, it allows us to sum over sites with different effects, such as potential replacement sites and known conserved regions. For example, with v different classes of functional sites,

$$B_i = \exp \left(- \sum_{\ell=1}^v \sum_{j=1}^{k_\ell} \int_0^1 \frac{\mu_\ell}{s(1 + c_{ij}/s)^2} \phi_\ell(s) ds \right) \quad (8.31b)$$

where we assume the same mutation rate, μ_ℓ , and distribution of deleterious fitness effects, ϕ_ℓ , for all linked sites in category ℓ . With a large amount of genomic data in hand (such as the site-frequency spectrum over a large number of sites), one can start to fit the distribution $\phi_\ell(s)$ of fitness effects within a class using the method of maximum likelihood (Chapter 9). See McVicker et al. (2009) for details.

Background Selection vs. Recurrent Selective Sweeps

While both BGS and recurrent sweeps reduce neutral variation in regions of low recombination, they represent very different processes of purifying selection versus adaptive change. As such, evolutionary geneticists have spent considerable effort trying to distinguish between the two, but no clear answer has yet emerged (Hudson 1994; Andolfatto 2001; Sella et al. 2009; Charlesworth 2009, 2012; Stephan 2010b). As comparison of Equations 8.24c and 8.29c shows, for regions of moderate to high recombination, both processes predict a relationship of the form $\pi/\pi_0 \simeq 1 - b/c \simeq e^{-b/c}$, where b is an unknown constant to be estimated. Hence, there is little resolution using the relationship between recombination and heterozygosity in moderate- to high-recombination genes. However, this is *not* the case for regions of low (but not too low) recombination. Innan and Stephan (2003) noted that in

this region the regression of π on c is convex for recurrent sweeps and concave for BGS (compare Equations 8.24b and 8.29a). They applied this approach to a set of low-recombination X-linked genes in *D. melanogaster*, and found that recurrent sweeps gave a much better fit than BGS. However, when they examined two highly selfing species of tomatoes (*Lycopersicon*), BGS provided the better fit. In humans, Hellmann et al. (2008) found that recurrent sweeps gave a better fit than BGS but cautioned that this may simply be an artifact of the simplistic nature of the BGS model leading to Equation 8.29a (i.e., assuming no variation in s).

One distinct prediction between BGS and recurrent sweeps is the expected effect on the site-frequency spectrum (SFS). Under the “strong” version of BGS, deleterious mutations have *strong* effects ($4N_e|s| \gg 1$) and are quickly removed by selection. In this case, the effect is to simply lower N_e to $f_o N_e$, but not otherwise change the frequency spectrum away from its neutral shape (Charlesworth et al. 1993a, 1995). Conversely, under selective sweeps, an excess of sites with rare alleles is expected (Braverman et al. 1995; Kim 2006). As detailed in Chapter 9, a standard indicator of an excess of rare alleles (relative to the neutral Watterson SFS) is a negative value of Tajima’s D statistic (Equation 9.24a), and such values are often (but not always) associated with genes showing reduced variation in regions of low recombination in *Drosophila* (e.g., Langley et al. 2000). A survey of 29 *D. melanogaster* genes by Andolfatto and Przeworski (2001) revealed a highly significant positive association ($r^2 = 0.31, p = 0.002$) between Tajima’s D and recombination rate—as the recombination rate decreased, D became more negative. Such an observation is consistent with a recurrent sweep model, but not with the strong BGS model.

Nevertheless, while findings like these are suggestive of recurrent selection as opposed to BGS, they are not as conclusive as one might think. In fact, a model with *weakly* deleterious alleles can generate an excess of rare alleles relative to neutrality (Tachida 2000; Comeron and Kreitman 2002; Comeron et al. 2008). While a weak BGS model will not generate a significant reduction in variability relative to neutrality (Golding 1997; Neuhauser and Krone 1997; Przeworski et al. 1999), a process generating both strong and weak deleterious alleles could generate both a reduction in variability *and* a negative skew in the frequency spectrum (Gordo et al. 2002). Likewise, a more careful analysis of BGS under very low recombination shows that selective interference can also generate negative D (Kaiser and Charlesworth 2009). It is worth emphasizing that BGS and recurrent sweeps are but two of many possible models of selection. Equally realistic models of linkage to sites experiencing fluctuating selection coefficients can generate the same patterns (Gillespie 1997, 2000).

Sweeps, Background Selection, and Substitution Rates

Both recurrent sweeps and background selection are expected to lower the effective population size, N_e , and hence reduce neutral variation at tightly linked sites. Do these processes also influence the rate of divergence at such sites? For *strictly* neutral alleles ($s = 0$), changes in N_e have no effect on the substitution rate, which is simply equal to the rate of mutation, μ , to neutral alleles (Chapter 2). However, when alleles have a *distribution* of fitness effects (so that some values of s may be very small, but not zero), this is no longer true. Accepting the view that many mutations may be slightly deleterious (Ohta 1973, 1992, 2002), the same allele can be **effectively neutral** ($4N_e|s| < 1$) in smaller populations, while being deleterious in larger populations (when $4N_e|s| \gg 1$). In genomic regions where the effect of recurrent sweeps and/or background selection is expected to be strong (such as regions of low recombination), an *increase* in the divergence rate might be expected, as the fraction of new mutations that are effectively neutral increases. Likewise, in such regions, the rate of adaptive changes may decrease, as weakly favorable mutations are overpowered by the effects of drift, thus reducing their fixation rates. This alteration of the substitution pattern through the fixation of a greater fraction of weakly deleterious alleles and a decrease in the fixation rate of adaptive changes is an example of a Hill-Robertson effect.

As highlighted in Example 8.16, the direction of a potential change in the rate of replacement substitutions as recombination decreases is a function of whether there are more

weakly positively selected alleles (the rate goes down) or weakly negative selected alleles (the rate goes up). Betancourt and Presgraves (2002) found, in a comparison of ~250 genes between *D. melanogaster* and *D. simulans*, that the nonsynonymous divergence rate is reduced in regions of low recombination, consistent with reduced fixation of weakly positive alleles in these regions due to a reduction in N_e . However, their gene set contained a large number of male accessory gland proteins (*Acps*), which are rapidly evolving and hence might have biased their results. When the *Acps* genes were removed from the analysis, there was no significant relationship between substitution and recombination rates. Among *Acps* genes, rapid protein evolution was largely confined to regions of high recombination, again consistent with a reduction in N_e retarding the rates of adaptive evolution for these genes.

Conversely, for genes in regions with essentially *no* crossovers in *D. melanogaster* and *D. yakuba* (such as on the tiny fourth chromosome), *elevated* rates of replacement substitution of amino acids are found, consistent with weakly deleterious alleles behaving as if effectively neutral due to a reduction in N_e in low-recombination regions (Haddrill et al. 2007). Similarly, in comparisons of the small (and largely nonrecombining) “dot” chromosome of *D. americana* with its other autosomes, Betancourt et al. (2009) found an increased rate of replacement substitutions on the dot. Further, estimates of the fraction, α , of adaptive substitutions (using methods discussed in Chapter 10) were significantly smaller for the dot than for the other autosomes, suggesting that the increase in replacement substitutions was largely due to the fixation of slightly deleterious alleles. Finally, Bullaughey et al. (2008) found no effect of recombination on rates of protein evolution over the human, chimpanzee, and rhesus macaque lineages. This lack of any consistent relationship between divergence and recombination rates is perhaps not surprising. The nature of any potential signal is population-specific, depending on the distribution of selection coefficients relative to the reduction in N_e in low-recombination regions. In particular, if only a very small fraction of alleles becomes effectively neutral due to a reduction in N_e , the impact will be negligible. Such can be the case for species whose effective population size is already small (such as some mammals), where further reduction in N_e by linked selection effects is unlikely to significantly change the frequency of effectively neutral mutations.

Because both BGS and recurrent sweeps can reduce diversity in regions of low recombination, we can also ask the related question of whether the amount of *divergence* at a site influences the amount of *linked neutral variation* within populations. This is a different question from that of whether linkage influences divergence. Under a strictly neutral model (Chapter 2), the amount of divergence and polymorphism is a function of the mutation rate, so sites with higher divergence should also display higher levels of polymorphism (when jointly compared in the same population so that N_e is approximately constant across genes). Under recurrent sweeps, if a gene shows a high rate of divergence due to more frequent sweeps, this is expected to lower diversity due to the local reduction in N_e that accompanies these sweeps. Such a negative correlation between synonymous nucleotide diversity and the substitution rate at replacement sites is seen in *Drosophila melanogaster* (Andolfatto 2007), *D. simulans* (Macpherson et al. 2007), *D. miranda* (Bachtrog 2008; Jensen and Bachtrog 2010), *D. pseudoobscura* (Jensen and Bachtrog 2010), the European rabbit (*Oryctolagus cuniculus*, Carneiro et al. 2012), the European aspen (*Populus tremula*, Ingvarsson 2010), and humans (Cai et al. 2009).

Cai et al. (2009) suggested that selection at linked sites in humans appears to reduce nucleotide diversity at putative neutral sites by 6% genome-wide and by 11% in the gene-rich half of the genome. McVicker et al. (2009) obtained even higher values: between 19% and 26% for autosomes and between 12% and 40% on the X. One reason for this apparent discrepancy between studies is that Cai et al. excluded regions immediately adjacent to genes, which are likely to experience some of the strongest linkage-related effects due to selection at nearby sites. Reduction in diversity at these various genomic locations could be due to recurrent sweeps, BGS, or (most likely) a combination of both. Several groups have suggested that the human data are better explained by BGS (Hernandez et al. 2011; Lohmueller et al. 2011; Alves et al. 2012). An analysis by Hernandez et al. suggested that

classic sweeps have been rare in recent human history. Although local troughs in nucleotide diversity are found around amino acid substitutions (as expected under recurrent sweeps), this reduction in variation is essentially the same as seen around synonymous substitutions. This last observation is more consistent with BGS than with recurrent sweeps (if one assumes that synonymous sites are indeed neutral). This is in sharp contrast to the findings of Sattah et al. (2011) in *Drosophila*, where the data are more consistent with recurrent sweeps.

A confounding factor in these human studies was noted by Enard et al. (2014): sites showing nonsynonymous substitutions may simply reside in regions with *less* functional constraints and thus *weaker* BGS, resulting in an inflated level of neutral variation. Detecting reduced variation around substituted sites requires that the impact of sweeps in reducing variation will overpower the impact of reduced BGS in increasing the level of neutral variation. Enard et al. found that the correlation between the strength of BGS and amount of sequence conservation significantly reduces any signal from sweeps (i.e., reduced variation around substituted sites) in humans. They argue that the lack of an association between substitutions and lower diversity (which led Hernandez et al. 2011 and Lohmueller et al. 2011 to conclude that classic sweeps are rare in humans) is likely a byproduct of failing to account for variation in BGS levels. After being corrected for this effect, Enard et al. found numerous signatures of positive selection in humans.

Example 8.16. Modern rice was domesticated from *Oryza rufipogon* to form the indica (*Oryza sativa indica*) and japonica (*O. sativa japonica*) lineages (Huang et al. 2011). Lu et al. (2006) examined the ratio of the replacement- to silent-site substitution rates, K_a/K_s (Chapter 10), between both subspecies and an outgroup, *O. brachyantha*. In a comparison of over 15,000 genes, the K_a/K_s ratio for divergence between indica and japonica was 0.498. Conversely, in a comparison of roughly 5000 genes between japonica and the outgroup, $K_a/K_s = 0.259$, a highly significant difference. This increase in K_a/K_s between the domesticated lineages occurs throughout the genome, with most regions showing elevated values when comparing the two modern cultivars on the outgroup. Regions of lower recombination showed the largest K_a/K_s values, with a highly significant negative regression of K_a/K_s on the recombination rate. The authors interpreted these data to imply an increase in the fixation rate of deleterious alleles due to a decrease in N_e during the domestication of both cultivar lineages. If the increase in K_a/K_s ratios was due to the accelerated fixation of favorable alleles, this ratio should *increase* along with the recombination rate, as the effective population size is higher in regions of higher recombination, thus increasing the fixation rate of favorable alleles. Conversely, the fixation rate of (slightly) deleterious alleles should increase with decreasing recombination, as the smaller N_e in these regions allows more of these alleles to behave as if effectively neutral. The initial founding of lines during the early phases of domestication reduced N_e , a process that the authors suggest was exacerbated by strong selfing, and hence reduction of the effective amount of recombination throughout the genome. This reduced recombination resulted in the influence on larger regions of the genome by selective sweeps associated with the fixation of domestication genes, further reducing N_e .

To examine whether there was indeed an increased fixation rate for slightly deleterious alleles, the authors analyzed the nature of replacement substitutions, using a regression method developed by Tang et al. (2004). When comparing indica and japonica, a disproportionate amount of change involved radical amino acid replacements over conservative replacements, with the authors estimating that around a quarter of the replacement substitutions were likely deleterious. No such pattern was seen when comparing the divergence between the wild rices *rufipogon* and *brachyantha*.

Sweeps, Background Selection, and Codon Usage Bias

One of the most sensitive indicators of localized changes in N_e is provided by the behavior of sites under very weak selection ($|N_e|s| \sim 1$). Under this setting, weakly favorable alleles are still selected for, while weakly deleterious alleles are selected against. However, a small

decline in N_e in such settings (be it from recurrent sweeps and/or background selection), or in the effective strength of selection (e.g., from interference among multiple segregating selected alleles) can make a significant fraction of these weakly selected alleles behave in a neutral fashion. Hence, if one has a group of sites within a species where we expect an average of $N_e|s| \sim 1$ over the genome, *localized* reductions in N_e may leave a signature, as within this region the pattern shifts from weak selection to effective neutrality. One potential set of such markers involves synonymous codons, which in *some* species (such as certain *Drosophila*) appear to have a genome-wide average of $N_e|s| \sim 1$ (Lynch 2007).

Although synonymous codons are typically used as proxies for neutral sites, the observation of **codon usage bias** (the nonrandom use among the set of all synonymous codons for a given amino acid) in many organisms suggests that this is only approximately correct. In reality, synonymous sites often appear to be under very weak selection for **optimal** (or **preferred**) codons, which are found to be more frequent than expected (after correction for mutational bias, which can be substantial). As potential alleles under very weak selection, synonymous codons may be rather sensitive (at least in some species) to subtle changes in N_e . We first examine the evidence suggesting there is selection on synonymous codons and the genomic patterns of codon usage before considering what this might tell us about selection at linked sites. We stress that local changes in N_e are expected to generate *subtle* signals at weakly selected sites that can be detected only when one examines the average pattern over hundreds of genes.

The classical view of codon bias is that selection is likely to be stronger on more highly expressed genes, so that bias is expected to vary over genes. Further, the actual strength of selection, which is postulated to be generated by improved transitional efficiency and accuracy due to the optimal codon matching the most abundant tRNA for that amino acid, is expected to be quite weak—so weak, in fact, that for an average gene, bias is expected to be significant only in organisms with sufficiently large effective population sizes. Surprisingly, however, bacteria, yeast, and *Drosophila* all have roughly similar levels of bias, despite their perceived great differences in effective population size (Powell and Moriyama 1997). This is tantalizingly reminiscent of Lewontin's (1974) observation that the level of average protein heterozygosity within a species (the surrogate for genetic variation at the time) is much narrower than expected given the range of census population sizes. As mentioned in Chapter 4, this trend is in part due to the evolution of lower mutation rates in populations with larger effective population sizes.

One of the first studies to suggest that *segregating* synonymous alleles may be under selection was performed by Akashi (1995) in *Drosophila*. By using an outgroup, Akashi polarized segregating alleles (Chapter 2), to determine the ancestral allele (that fixed in a sister species) and its new mutation. For a particular amino acid showing codon usage bias, **preferred codons** are those used more frequently than expected (correcting for any mutational bias), while **unpreferred codons** are those used less frequently than expected. Akashi placed segregating and fixed differences into two categories: those involving a preferred codon that mutated to an unpreferred one (denoted by $P \rightarrow U$), and those involving an unpreferred codon that mutated to a preferred one ($U \rightarrow P$). Under the expectation that $P \rightarrow U$ alleles are slightly selected against and $U \rightarrow P$ alleles are weakly selected for, Akashi compared the divergence to polymorphism ratio of $P \rightarrow U$ to that for $U \rightarrow P$. If unpreferred codons are selected against, we would expect a higher ratio of polymorphism (the ratio of segregating U to P alleles) to divergence (the ratio of fixed U to P mutations), as alleles under weakly deleterious selection can segregate (contributing to polymorphism levels) but are unlikely to be fixed (Figure 7.1). The polymorphism ratio was indeed greater than the divergence ratio in both *D. simulans* and *D. pseudoobscura*, while an excess of unpreferred fixations was seen in a sample of 28 *D. melanogaster* genes (Akashi and Schaeffer 1997). The authors attributed this latter observation to the three- to six-fold reduction in N_e in *D. melanogaster* relative to *D. simulans* reducing the effectiveness of selection on weakly selected sites. An important cautionary note for such studies is that mutational bias must be fully accounted for, otherwise pressure from this force may mimic selection. Historically, many early pa-

pers simply compared the frequency of third-base nucleotides to genome-wide nucleotide frequencies, but the latter can be a poor proxy for any underlying mutational bias.

Example 8.17. Maside et al. (2004) examined codon usage in *Drosophila americana*, a member of the *virilis* species group. Using *virilis* as an outgroup, they observed 84 synonymous substitutions (fixed differences or divergence) between the two species and 144 segregating synonymous sites within *americana*. Following Akashi, the authors classified these as either $P \rightarrow U$ or $U \rightarrow P$ changes, and observed the following pattern:

	Substitutions	Polymorphic (<i>americana</i>)	Polymorphism/Divergence
$P \rightarrow U$	52	124	2.38
$U \rightarrow P$	32	20	0.62

This roughly four-fold higher ratio of polymorphism to divergence for the putative deleterious mutations ($P \rightarrow U$) is highly significant (Fisher's exact test yields $p = 6.4 \cdot 10^{-5}$). Similarly, note that the divergence ratio for these two classes

$$\frac{P \rightarrow U}{U \rightarrow P} = \frac{52}{32} = 1.625$$

is substantially less than the polymorphism ratio ($124/20 = 6.2$).

Finally, if the class U is indeed deleterious, we would expect $P \rightarrow U$ mutations to be at lower frequencies within the population sample than $U \rightarrow P$ mutations, and such a significant difference was observed. This difference in the site-frequency spectrum was first noticed by Akashi (1999) for *D. simulans*, which was shifted toward lower frequencies for unpreferred mutations and toward higher frequencies for preferred mutations.

How strong is selection against unpreferred codons? Using the Poisson random field (PRF) method for analysis of the pattern of fixed differences and polymorphic sites (examined in detail in Chapter 10), estimates of $N_e|s| \sim 1$ were obtained for *simulans* and *pseudoobscura* (Akashi 1995; Akashi and Schaeffer 1997). An alternative approach to estimate $N_e|s|$ follows from Equation 7.37, which gives Li's (1987) expression for the expected frequency, \tilde{p} , of a preferred codon at the mutation-selection-drift equilibrium,

$$\tilde{p} \simeq \frac{\exp(2\gamma)}{\exp(2\gamma) + \zeta} \quad (8.32)$$

where $\gamma = 2N_e s$ is the scaled strength of selection for preferred codons and $\zeta = \mu_{P \rightarrow U}/\mu_{U \rightarrow P}$ measures any mutation bias (also see Bulmer 1991; McVean and Charlesworth 1999, 2000; Zeng and Charlesworth 2009, 2010; Zeng 2010). If ζ is known, Equation 8.32 can be used to directly estimate γ for a given synonymous codon set (averaged over genes). Maside et al. (2004) offered an alternative (but related) procedure that does not involve estimating ζ . They showed that the fraction, p_U , of segregating sites where the *derived* allele is the unpreferred synonymous codon (i.e., $P \rightarrow U$ mutations as opposed to the derived allele being a $U \rightarrow P$ mutation) in a sample of n alleles can be expressed as a function of γ alone. Using this approach, which measures contemporaneous selection coefficients (unlike PRF estimates which use divergence data, and hence are influenced by historical selection; see Chapter 10), Maside et al. (2004) obtained an estimate of $N_e|s| \simeq 0.65$ in *D. americana*.

Thus, for several *Drosophila* species, the strength of selection on synonymous codon usage is roughly $N_e|s| \simeq 1$, suggesting the possibility that small localized genomic changes in N_e can significantly impact codon bias. The prediction is that *codon bias is reduced in regions where N_e is lowered*. Three observations offer support for this, with bias being less extreme: (1) in regions of low recombination, (2) for genes that are rapidly diverging, and (3) in the middle of long exons. We examine each of these observations in turn, again

with the caveat that most of these observations come from *Drosophila*. Organisms where the scaled strength of selection is weaker (i.e., those with much smaller N_e) or much stronger (i.e., those with much larger N_e) might not show these trends, as in these cases an order of magnitude change in the N_e for a genomic region will still leave drift overpowering selection (small baseline N_e) or selection still overpowering drift (large baseline N_e).

There are mixed reports of codon bias depending to some extent on recombination rates in *Drosophila*. Kliman and Hey (1993) examined roughly 400 loci in *D. melanogaster*, finding reduced codon bias in regions of low recombination. The relationship was not linear, but rather was only apparent for genes in the regions of lowest recombination. A much larger study involving 14,000 *melanogaster* genes by Hey and Kliman (2002) attempted to control for concerns of a potential mutation bias toward G/C bases (commonly used in the optimal codon) in regions of high recombination (Marais et al. 2001; Duret and Galtier 2009). Again, a significant positive correlation between codon usage bias and recombination rate was seen for regions of low recombination, while genes in regions with a modest to high recombination rate ($c > 1.5$ cM/Mb) showed no association. Finally, Haddrill et al. (2007) found essentially no codon bias for genes in *D. melanogaster* and *D. yakuba* residing in regions with no recombination, and Betancourt et al. (2009) found that a significantly smaller fraction of genes on the small (dot) chromosome of *D. americana* used optimal codons relative to sites on larger chromosomes. Taken together, these observations suggest that in some *Drosophila* species, codon bias is less severe in regions of very low recombination, consistent with reduced efficiency of selection from a local decrease in N_e .

In addition to these regional effects over the scale of a small chromosomal segment, there are also reports of effects on much finer scales, namely gene-by-gene and even different regions within the same gene. For example, genes undergoing multiple sweeps (and hence higher rates of substitutions) might be expected to have lower effective population sizes, and hence less codon bias. In a study involving roughly 250 genes, Betancourt and Presgraves (2002) found that those with higher replacement rates tended to show less codon usage bias in both *D. melanogaster* and *D. simulans*. Maside et al. (2004) examined over 600 *melanogaster* genes, also finding a negative association between rates of replacement substitution and codon bias. However, they also noted that both codon bias and replacement rates are correlated with gene expression, so perhaps the latter is the driver for the correlation. Andolfatto (2007) found both reduced codon bias and reduced synonymous-site diversity, among the more rapidly evolving proteins in a survey of roughly 140 proteins on the high-recombination region of the X chromosome from *D. melanogaster*. Similar results are reported by Bachtrog (2008) for *D. miranda*. While most observations are restricted to *Drosophila*, Ingvarsson (2010) found a weakly negative (but not significant) relationship between codon bias and protein evolution rates in the European aspen (*Populus tremula*). One important caveat about these negative associations between the strength of codon bias and divergence rates is that relaxed selection on both the gene sequence and codon bias can also generate this pattern.

On an even finer scale are reports of correlations between codon bias and gene length in *Drosophila* (Comeron et al. 1999). For short genes (less than 750 bp), those residing in regions of lower recombination show reduced codon usage bias, but this effect is less for genes with longer coding regions. Moreover, the length of a coding region is negatively correlated with bias (longer genes have less bias) over all recombination values. Strikingly, Comeron and Kreitman (2002) found that codon bias decreases in the *middle* of long exons. A more detailed analysis by Qin et al. (2004) showed that codon bias decreases at the ends, as well as the middle, of long genes in *Drosophila*, while yeast and several species of bacteria showed no such pattern. Comeron and Guthrie (2005) estimated the strength of selection, γ , on synonymous codons and found this to be significantly reduced in long versus short genes. Consistent with a reduction in the efficiency of selection, longer exons also had higher rates of synonymous substitution, as would be expected if reduction in N_e made weakly deleterious synonymous mutations behave in a more neutral fashion. However, any factor resulting in a reduction in selective constraints could also generate such a pattern.

All of these signals of more neutral patterns of codon usage in specific genomic regions are consistent with the effects of selection at linked sites. Both recurrent sweeps and background selection could generate this reduction in bias in regions of low recombination, while the observation of lower codon bias for genes with high replacement-substitution rates is consistent with recurrent sweeps (Kim 2004). The most interesting observations, however, involve the very fine-scale differences, in particular the decrease in bias in the middle of long exons. Loewe and Charlesworth (2007) suggest that background selection could generate such a pattern, with sites in the middle of exons having deleterious mutations arise for some distance on both sides of them, increasing their local U value, and thus creating a local decrease in N_e . These very fine-scale effects are very sensitive to recombination. Hey and Kliman (2002) found that gene density (when measured by the number of genes per kilobase) had no effect on codon bias. However, very tightly spaced genes did exhibit bias, showing that potential linked effects of selection operate over very short distances.

An additional explanation for these very short range effects is *interference among selected sites*. Models of background selection and recurrent sweeps typically assume that alleles are under strong enough selection to have only a short persistence time in the population. Conversely, alleles under weak selection segregate for longer periods of time, allowing for multiple segregating mutations of weak effect within a gene, with interference among these alleles reducing the efficiency of selection. For example, if selected mutations are in negative LD, this reduces the additive variance in fitness (Chapter 16), lowering the efficiency of selection (Chapters 5 and 13). Likewise, within a set of alleles that are nearly selectively equivalent, drift can occur, reducing the efficiency of selection on any particular allele.

This reduction in selection efficiency due to interference among linked sites has been called a **small-scale Hill-Robertson effect** (Comeron et al. 1999), **weak selection Hill-Robertson interference** (McVean and Charlesworth 2000), and **interference selection** (Comeron and Kreitman 2002). If multiple weak, positively selected alleles are segregating in a tightly linked region (such as multiple preferred codons within an exon), they mutually interfere with each other, resulting in weaker selection and a smaller codon usage bias. To see this, suppose that all favorable segregating sites have the same advantage. The frequency of this *entire set* of alleles increases over time, but within this set, the behavior of individual sites is essentially neutral. The same is true for a collection of weakly deleterious alleles. The key is extremely tight linkage. Simulation studies (Comeron and Kreitman 2002; Comeron et al. 2008) have shown that selective interference can indeed produce a decrease in codon bias in the middle of long exons, with bias decreasing with the number of selected sites. Its effect, however, is *extremely local*, except in regions of extremely low recombination.

McVean and Charlesworth (2000) showed that selective interference can also account for the puzzling observation of the relative insensitivity of codon usage bias to changes in N_e seen in cross-species comparisons (Powell and Moriyama 1997). When selective interference is present, it tends to moderate the effects of selection, making the expected bias relatively similar over several orders of magnitude in N_e . Selective interference can reduce bias even in genes in regions of moderate recombination because there is still tight linkage over very small regions segregating multiple sites under weak selection (McVean and Charlesworth 2000). As noted by Comeron and Kreitman (2002), exons and their adjacent control regions are prime candidates for selective interference, as the physical clustering of functional sites offers the possibility of weak selection over a number of tightly linked sites.

One final unexplained aspect of codon bias is the intriguing observation that X-linked genes tend (as a group) to have higher codon bias than autosomal genes in *D. melanogaster* (reviewed by Campos et al. 2012). Given that one would expect the effective population size of X-linked genes to be lower than those for autosomes ($\sim 3/4$; see Lynch 2007 for an extended discussion of the assumptions leading to this approximation), these arguments suggest that X-linked bias should be reduced. Campos et al. examined whether increased recombination on the X might counter this by reducing Hill-Robertson effects from selection at linked sites. The argument for higher average recombination on the X in *Drosophila* is that

this chromosome spends two thirds of the time in females, which have normal recombination, and one third of the time in males, with no recombination. Conversely, autosomes spend equal amounts of time in both sexes, resulting in a one third higher expected effective recombination rate on the X. When comparing sets of X and autosomal genes with similar effective recombination rates (using regions of the X with lower rates and autosomal regions with higher rates, such that their scaled recombination values are roughly equal), Campos et al. still observed higher X-linked codon bias, suggesting that this pattern results from stronger selection for preferred codons for X-linked genes (relative to autosomes) in *D. melanogaster*, rather than from localized changes in effective population size (also see Zeng and Charlesworth 2010). One possible molecular basis for this apparently stronger selection for codon bias on X-linked genes is that *Drosophila* performs dosage-compensation by overexpressing X-linked genes in males (to twice the level for X-linked genes in females). This potentially results in X-linked and autosomal genes experiencing differing selection pressures for expression.

A Paradigm Shift Away From the Neutral Theory of Molecular Evolution?

As ably summarized by Charlesworth (2010), molecular population genetics has a rich and dynamic history. Its current focus traces back to the **neutral theory of molecular evolution**, which was born in the late 1960s in response to the higher than expected levels of protein polymorphism found in natural populations (Kimura 1968b; King and Jukes 1969), and gained strength through the 1980s as more molecular data became available (Kimura 1983). Under initial versions of the neutral theory, the vast majority of new mutations were assumed to be either neutral or rather strongly deleterious. As selection is expected to rapidly remove the latter, such mutations contribute little to the levels of polymorphism and even less to divergence (Figure 7.1). Under this view, advantageous mutations can indeed occur, but they are assumed to be extremely rare and rapidly fixed (or lost) when they arise, resulting again in little impact on polymorphisms and (given their rarity) at best a modest impact on divergence. Given these assumptions, it then follows that most fixed differences between populations or species and most segregating variation within a population or species are due to neutral variation.

Ohta (1973, 1992, 2002) presented an important modification, the **nearly-neutral** (or **slightly deleterious**) **theory**, allowing for slightly deleterious alleles, which can be close to effectively neutral and hence contribute significantly to polymorphisms but far less to divergence (reviewed by Akashi et al. 2012). A key prediction from both versions of the neutral theory is that regions with fewer functional constraints (and therefore a higher fraction of neutral or nearly neutral mutations) evolve faster. This prediction is strongly supported by the observation of slower substitution rates at replacement sites than at synonymous sites in protein-coding genes, and ever faster rates in pseudogenes.

The key assumption of all versions of the neutral theory is that while purifying selection can be very common, ***adaptive evolution at the molecular level is rare***, so that most segregating alleles and most substitutions involve alleles that are effectively neutral. Some researchers have questioned this key assumption, calling for a more nuanced view of the nature of stochastic changes in allele frequencies that can dominate weakly selected sites (Hahn 2008; Rockman 2012; but see Nei et al. 2010 for a contrary opinion). As discussed in Chapter 10, the estimates of high α values (the fraction of replacement substitutions that are adaptive) in some species are strongly at odds with the view of neutral or nearly neutral theories. A second potential problem relates to genomic effects from selection at linked sites, the most celebrated of which is the correlation between recombination rates and levels of variation already noted. If this is due to background selection, such a correlation is still consistent with the classical neutral theory, being generated by the removal of new deleterious mutations. However, if periodic selective sweeps generate this correlation, then much of the genome may be impacted by ***positive selection***, either directly or indirectly through the effects of selection at linked sites, which change the local effective population size. Finally, observations consistent with selective constraints on silent sites and even noncoding DNA

in some species (reviewed in Chapter 10) are also somewhat problematic for the neutral theory. While the removal of new deleterious mutations (BGS) falls under the umbrella of neutral theory, the converse, fixation of slightly favored sites (such as the fixation of a silent mutation to a preferred codon), is an example of positive selection. The inescapable conclusion from the *Drosophila* data is that weak selection is occurring throughout the genome, with patterns of variation being shaped by selection at linked sites. These effects can operate over quite small scales, on the level of differences between the ends and middle of a long exon, presumably due to interference among weakly selected sites. Whether these observations generalize beyond *Drosophila* remains an open question.

The great irony of gaining a deeper appreciation for how rampant selection (and especially weak selection) is throughout the genome (of at least some species) is that it likely makes *more* alleles behave as if they were effectively neutral. Kimura's original grand vision of the role of selection acting as a giant filter, through which only neutral and a very few advantageous alleles pass, now appears to have been replaced by the role of selection throughout the genome making weakly selected alleles behave in a more neutral fashion. Chapter 3 introduced Gillespie's (1997, 2000) concept of **genetic draft**, whereby the frequencies of neutral alleles fluctuate more from their random association with ongoing sweeps than they do from drift. While drift may be important in small populations, in sufficiently large populations, sweep-generated stochastic fluctuations of allele frequencies can still overpower weak selection. A combined analysis of drift and draft by Schiffels et al. (2011) found effective neutrality when the absolute value of a selection coefficient of an allele is less than $1/(2N) + \lambda$ (N being the census size, and λ the per-nucleotide rate of adaptive evolution at linked sites; Equation 8.24a), a feature they refer to as **emergent neutrality**. When N is small, the rate of adaptation, λ (which scales as NU_b for small to medium values of N), is likely small, and drift dominates. Conversely, when N is large, $1/N$ can be dominated by λ . For a very large N , interference among sweeps strongly constrains λ , causing a transition of the scaling of the adaptation rate from NU_b to $\ln[NU_b]$ (Neher 2013). Thus, at *every* population size, stochastic fluctuations in allele frequencies are important, but the forces underlying them differ. Drift dominates in small populations, and draft in large populations. Once the draft stage is reached, because λ increases with N (albeit very slowly), a *higher fraction* of new alleles becomes effectively neutral as population size increases. When coupled with selective interference among weakly selected sites, this leads to a view whereby much of the segregating variation in a large population may be effectively neutral. However, it is not due to a lack of positive selection, but rather a *consequence* of it.

9

Using Molecular Data to Detect Selection: Signatures from Recent Single Events

For the past 20 years, there has been a tendency on the part of journal editors and reviewers to assume that every case of alleged statistical evidence for positive selection is worthy of publication, even in the absence of a plausible biological mechanism underlying the alleged selection. Hughes (2007)

While the ubiquity of **purifying** (or **negative**) **selection** (the removal of deleterious alleles, i.e., background selection) at the molecular level is well established, the frequency of **positive** (or **adaptive** or **Darwinian**) **selection** remains unclear. Because of this, the development of methods to detect the latter is a major growth industry in evolutionary genetics. There is a massive population-genetics literature on this subject, and a partial (but not exhaustive) list of reviews includes Kreitman (2000), Nielsen (2001), Ford (2002), Bamshad and Wooding (2003), Schlotterer (2003), Guinand et al. (2004), Nielsen (2005), Storz (2005), Wright and Gaut (2005), Biswas and Akey (2006), Sabeti et al. (2006), Thornton et al. (2007), Holderegger et al. (2008), Pavlidis et al. (2008), Stinchcombe and Hoekstra (2008), Akey (2009), Nei et al. (2010), Oleksyk et al. (2010), Siol et al. (2010), Stephan (2010a), Crisci et al. (2012), Fu and Akey (2013), Vitti et al. (2013), Bank et al. (2014), Forester et al. (2016), Malaspina (2016), Stephan (2016), Vatsiou et al. (2016), and Xiang-Yu et al. (2016).

As detailed in Chapter 8, a single recent event of positive selection can leave a transient signal in the pattern of linked neutral variation. The detection of such events is the subject of this chapter. Most approaches for detecting recent or ongoing selection use the segregating variation in a sample from a contemporaneous population, and we loosely refer to these as **polymorphism-based tests**. Because such signals are transient, these methods work only over ecological time scales, detecting events that are either ongoing or that concluded less than $\sim N_e$ generations ago. In contrast, a *history* of positive selection on a gene over evolutionary time can leave a *cumulative* signal in the pattern of substitutions. **Divergence-based tests** to detect these patterns, which require data on substitutions between species (or very distantly related populations), are developed in Chapter 10 (which also covers tests that jointly use polymorphism and divergence data). These different approaches are complementary, as an adaptive substitution could leave a strong (but fleeting) signature over an ecological time scale but essentially no signal in that gene over an evolutionary time scale (adding just one more substitution in a potential background of numerous neutral fixations). Likewise, the vast majority of adaptive events that have shaped a gene likely occurred in its distant past, leaving no currently detectable polymorphism pattern and only potential signals in divergence data (Chapter 10).

Because the search for sites under selection can be seductive, it is important to stress that the methods developed in this chapter have *limitations*. They *potentially* can be useful in detecting *some* events involving a single selective event at a single site, allowing for the prospect of studying individual (as opposed to cumulative) selective events. As discussed in Chapter 8, one source of these limitations is the nature of the signal left by the sweep itself. First, it is *very fleeting*, typically persisting for only $0.1N_e$ to N_e generations, depending on the feature being examined (Table 8.2). Second, *only a fraction of such events*, even if ongoing or very recent, can be detected. A weak, but nontrivial, selection event may be too small to leave a meaningful signal against a noisy molecular background. Finally, even very strongly selected sites may not be detectable, especially if they involve soft or polygenic sweeps (Chapter 8). Even with all these concerns, the most critical problem with polymorphism-

based tests is the *confounding effect from demography and population structure*. For example, rapid expansion following a population bottleneck leaves a sweep-like signal over the entire genome, while the presence of population subdivision can mimic balancing selection. One reason for the vast number of tests discussed below is that no single one is best in all settings, and the search to find strong signals *unique* to positive selection has, for the most part, been unsuccessful.

Besides being fundamentally important to our understanding of evolution, tests of selection can also be helpful to a breeder. Scans for ongoing and recently selected sites can provide a useful complement to QTL- and association-mapping studies. In these latter approaches, one specifies the traits of interest and then searches for marker-trait associations (LW Chapters 13 through 16). While this is a powerful approach, it is limited by having to specify the traits of interest. In a population undergoing selection for (say) water stress, one might miss pathways for adaptation that are not obvious and hence do not involve the traits chosen to be mapped. Conversely, one could perform a genomic scan on a population under relatively recent water stress to look for sites showing signatures of ongoing or recent selection. These, in turn, could suggest genome regions harboring genes for traits or pathways under selection, without having to specify particular traits. This approach has been termed **natural selection mapping** (Kohn et al. 2000), **hitchhiking mapping** (Schlötterer 2003), and **reverse ecology** (Li et al. 2008), and is widely used in the search for **domestication genes** responsible for the transition from wild relatives into domesticated lines. We review the results of several such scans at the conclusion of the chapter.

Finally, it is important to stress that our focus over these next two chapters is on using marker information *independent* of any specific traits. As mentioned in Chapter 8, polygenic response is likely to leave little, if any, detectable signal at *single sites*. However, a composite signal may be generated over a *collection* of such sites (i.e., a collection of unlinked, or loosely-linked, loci underlying the trait). Such trait-augmented marker approaches—wherein a set of markers is chosen because they impact a specific trait, with tests based on summary statistics over this ensemble of markers—are covered in Chapter 12.

AN OVERVIEW OF STRATEGIES BASED ON SEGREGATING VARIATION

For a multitude of reasons, there is no single omnibus test for selection. First, different scenarios (e.g., hard sweeps, soft sweeps, partial sweeps, balancing selection) leave different, and often conflicting, signatures (Chapter 8), so that tests for one type (e.g., hard sweeps) may easily miss signatures from another (e.g., soft sweeps). Second, different tests are designed to detect signals from *different time periods* during (and following) a sweep. Third, different sampling schemes are possible. Many tests assume there is only a single sample from a current population, but one might instead have contemporaneous samples from several related populations or a temporal series of samples from a single population.

Advances in genomics have enormously expanded our ability to score molecular variation, and this is reflected in the historical development of tests. The first test followed changes in a single allele at one locus through time (Examples 9.1 and 9.2), while later tests evolved to use data from **genomic scans**, where a very large number of sites are scored, and potentially phased (generating haplotype, as opposed to sequence, data). Haasl and Payseur (2016) suggested the terms **GWSS** (**genomewide scans for natural selection**) when a whole genome is scanned, and **ESS** (**exomic scans for natural selection**) when only coding or transcriptome sequences are used. Approaches to detect recent selection can be classified into five categories, which loosely follow the historical development of the field:

- 1) Excessive allele-frequency change.** The first formal test of selection was proposed by Fisher and Ford (1947), who used the machinery developed in Chapter 2 for the divergence under drift to test for excessive change in a time-series of allele frequencies from a single population. While perhaps the most unambiguous signature of selection, this approach requires long-term monitoring of a population and having some rea-

sonably independent estimate of N_e . The ever-increasing availability of **ancient DNA (aDNA)** samples opens up exciting new data sets for this type of analysis (Mathieson et al. 2015, Malaspina 2016; Schraiber et al. 2016).

2) Excessive allele-frequency divergence. Lewontin and Krakauer (1973) proposed using the divergence between a series of contemporaneously sampled populations (presumably from a common ancestor) to test for selection. The machinery from Chapter 2 predicts the expected divergence under drift, as measured by Wright's F_{ST} statistic for population structure. Loci displaying excessive F_{ST} values relative to drift are selection candidates. Using an incorrect model of population structure can seriously compromise these tests.

The above two categories require samples from multiple populations (either temporally or spatially), which limits their widespread use. A less demanding design is a single population sample, as employed by the three remaining categories.

3) Chromosomal spatial patterns of variation. As detailed in Chapter 8, a sweep leaves a characteristic decrease in polymorphism around a selected site, and a number of formal likelihood tests are based on the expected pattern of the nucleotide diversity, π , as a function of the recombination distance, c , from the sweep (Equation 8.8a). Early versions of these tests assumed that the population was in mutation-drift equilibrium at the start of the sweep, while more recent versions have relaxed this strong assumption.

The final two categories divide tests by whether they assume an infinite-sites, or an infinite-alleles, framework, using the neutral equilibrium results for these models developed in Chapter 2. Recall that the infinite-sites framework considers a sequence as a series of separate sites (e.g., SNPs), while the infinite-alleles framework treats each different DNA sequence (haplotype) as a different allele (Figure 2.9). Both models assume that the region being considered is small enough that recombination within the sample can be ignored. Given the large (and diverse) number of tests in both of these categories, each section reviewing these different approaches concludes with a summary table of proposed tests (Table 9.1 for infinite-sites and Table 9.3 for haplotypes).

4) Changes in the site-frequency spectrum. Under the infinite-sites model, the frequency spectrum of neutral sites at mutation-drift equilibrium is given by the Watterson distribution (Equation 2.34). Starting with Tajima (1989), a number of tests have been proposed that search for shifts in this spectrum following a sweep, such as an excessive number of sites with rare alleles or with high-frequency derived alleles. The major complication with this class of tests is that changes in population demography (such as a recent expansion or contraction) or the presence of population structure (migration between partly isolated populations) can mimic signatures of selection.

5) Tests based on haplotype information. Under the infinite-alleles model, the number of alleles (haplotypes) in a sample at mutation-drift equilibrium is given by the Ewens sampling formula (Equation 2.30a) and their allele-frequency spectrum by Equation 2.33b. Starting with Ewens (1972) and Watterson (1977, 1978), a number of tests have used these expressions to detect departures from the neutral equilibrium model. As with tests based on the site-frequency spectrum, significant departures can occur for neutral alleles if the population is not in equilibrium or if population structure is present.

Two other strategies use haplotype information. The first searches for the distinct signatures in the pattern of pairwise linkage disequilibrium (LD) predicted around a hard or a soft sweep (Table 8.2). The second considers the frequency of a neutral allele as a function of its age (Equation 2.12). Under neutrality, a common allele is an old allele, with shorter blocks of LD, reflecting a longer history of recombination. The presence

of high-frequency alleles with **long haplotypes** (large blocks of LD) offers a signature of selection (these are often called LRH, for **long-range haplotype**, tests). A key point is that haplotype structure provides *signals that can be missed by site-frequency and hard-sweep tests*, and thus offers more power in some settings.

Attempts to Account for Departures From the Equilibrium Model

Most tests for selection are based on the null hypothesis of the neutral equilibrium (or standard neutral) model (Chapter 2). While rejection of this null can indeed imply a signature of selection, rejection can also occur if a neutral population is not in mutation-drift equilibrium. Cavalli-Sforza (1966) noted that demography and population structure should leave a common signal over all genes within a genome, and this observation has been used in attempts to correct for any genome-wide nonequilibrium features in the data. The simplest approach is the **outlier method**, whereby values of the test statistic are computed for a large number of genes, with outliers suggesting potential targets of selection. This is an *enrichment method*, not a formal test. The second approach is to use data from presumably neutral markers unlinked to a region of interest to infer the population history (e.g., bottlenecks, expansions, population structure). These histories can then be used to simulate the coalescent structure (Chapter 2) for neutral alleles under this nonequilibrium model, which in turn can be used to generate the distribution of the test statistic under this more appropriate null. A final approach is to use presumably neutral sites to generate an **empirical site-frequency spectrum** to use in place of the equilibrium Watterson distribution.

These approaches are based on information from a large number of loci obtained in a genomic scan, with the assumption that most sites are not under positive selection and hence provide information to better shape the null hypothesis. This critically relies on the validity of Cavalli-Sforza's assumption of a common demographic or population structure signal over all loci, upon which any additional signal from selection is placed. Unfortunately, this need not be the case, especially in a population that is expanding over space. **Allelic surfing** can occur, wherein random alleles (and new mutations) on the leading edge of a wave of population expansion can "surf" (this wave) rather quickly to high frequencies in newly founded parts of the population (Edmonds et al. 2004; Klopstein et al. 2006; Hallatschek et al. 2007; Travis et al. 2007; Excoffier and Ray 2008; Hallatschek and Nelson 2008, 2009; Excoffier et al. 2009a; Hallatschek 2011). Because neutral alleles on the leading wave of expansion are largely random, surfing *does not affect all genomic locations equally*, and as a result can mimic signatures of selection even after correcting for demography or structure based on others markers within the sample. This is especially troublesome as the model species most surveyed for recent selection—humans, cosmopolitan human commensal *Drosophila* (*melanogaster* and *simulans*), and *Arabidopsis*—all have undergone massive range expansions. Hofer et al. (2009) found that while a large fraction of the human single-nucleotide polymorphisms (SNPs), short tandem repeats (STRs), and indels show large (greater than 0.3) differences in frequency across world populations, this pattern is easily accounted by allelic surfing, suggesting that this phenomenon can be a considerable problem in the search for sites under recent selection in humans.

SNP Ascertainment Bias

Another (increasingly historical) concern is **SNP ascertainment bias**, which arises when molecular variation is scored using prechosen SNPs. In a typical SNP discovery setting, one sequences a relative small pool of individuals (the **SNP discovery panel**) to "discover" SNPs—polymorphic nucleotides whose minor allele is above some critical frequency in the panel. These are then used to score a much larger sample of individuals, thus creating a severe bias in favor of SNPs at intermediate frequencies and against rare SNPs. Likewise, if the SNP discovery panel is from a different population than the screened sample, this also creates bias in that important SNPs in the population of interest can be missed (e.g., Ptak and Przeworski 2002). When the frequencies of SNP minor alleles in the discovery panel are known, corrections for ascertainment can be straightforward (Nielsen et al. 2004). However,

SNP discovery is often a more complex process, creating biases that simple methods can reduce, but not remove (Clark et al. 2005). With the ever-increasing availability of whole-genome sequencing, this is rapidly becoming an issue of diminishing concern.

SNP Polarity Assignment Errors

A final source of bias can appear in tests requiring the **polarity** status (i.e., ancestral or derived) of a SNP allele. Recall from Chapter 2 the distinction between **unfolded** and **folded** frequency spectra. The former is based on the frequency of derived alleles (i.e., the Watterson distribution), whereas the latter is based on the frequency of the minor allele and thus is immune to polarity assignment errors. Typically, polarity is accessed using an outgroup, with the outgroup allele assumed to be the ancestral state. This is a parsimony assumption, which requires that no back or parallel mutations occur, and that the site is monomorphic in the outgroup. Incorrect polarity assignments can result in mislabeling a low-frequency derived allele as a high-frequency ancestral one, and even a few such errors can significantly impact certain tests (Baudry and Depaulis 2003; Hernandez et al. 2007).

Background Selection as the More Appropriate Null?

Recently, it has suggested that strict neutrality may not be the correct null hypothesis. Cutter and Payseur (2013) and Corbett-Detig et al. (2015) have both stressed that background selection (BGS) is a more appropriate null, given how widespread BGS appears to be (Chapter 8). If BGS is taken as the null, then test comparisons must accommodate differences in gene density per recombination unit, as the impact for BGS is expected to scale with this ratio (Chapter 8). If one is attempting to correct for nonequilibrium features by using a set of putatively neutral markers in a comparison with a possible region under selection, care must be taken to ensure that these markers are from regions with a similar gene-density to recombination value as the region of interest.

Structure of the Remainder of This Chapter

The rest of the chapter is structured into treatments based on our five categories of tests. These categories were largely constructed for convenience of presentation, and some tests draw upon ideas from several different approaches. Given the amount of information in this chapter, we have tried to make the discussion of each category largely autonomous of the others, thus allowing readers to skip directly to the section most appropriate for their needs. We conclude with a brief review of scans for recent positive selection in humans and domesticated organisms.

ALLEL-FREQUENCY CHANGE IN A SINGLE POPULATION

There are several settings where tests based on allele-frequency change may be appropriate. One is a population monitored over some reasonable period of time, which was the basis for the first formal test by Fisher and Ford (1947), of whether a specific gene is under selection (Examples 9.1 and 9.2). The second is a population under artificial selection, which has also been proposed as an approach for QTL mapping for a trait of interest (Nuzhdin and Pasyukova 1991; Keightley and Bulfield 1993; Nuzhdin et al. 1993; Ollivier et al. 1997). Most recent are studies where candidate allele frequencies are estimated from a small sample of ancient DNA and then compared with their frequencies in a more contemporary sample (e.g., Schraiber et al. 2016).

While excessive allele-frequency change is perhaps the most unambiguous signal of selection, there are power issues when the number of generations separating the first and last samples is modest (De Kovel 2006). Given that the time scale for significant allele-frequency change under selection is $\sim 1/s$ (Equation 5.3c), sampling based on a modest number of generations requires strong selection for a signal. In particular, to detect a significant change even in the absence of drift requires that the sample size, n , and number of generations, t ,

satisfy $tn \gg 1/s$.

Allele-frequency Change Over Two Sample Points: The Waples Adjusted Test

Chapter 4 considered the estimation of N_e from allele-frequency change, a setting where one typically averages over a number of loci to reduce the evolutionary sampling variance. Here our task is the complementary problem. Given some estimate of N_e , is the observed change in allele frequency at a candidate locus excessive? If so, this presumably reflects directional selection acting at, or close to, this region. In theory, one could also test for too little divergence (reflecting balancing selection), although this is rarely done, given the high sampling variance (and hence low power), unless sample sizes are extremely large.

In the early literature, a number of workers tested for excessive divergence by simply querying whether allele frequencies in two samples were significantly different. As noted by Gibson et al. (1979) and Waples (1989b), this is inappropriate, as it does not account for the evolutionary *drift variance* in allele frequencies

$$\sigma^2(p_t) = p_0(1-p_0) \left[1 - \left(1 - \frac{1}{2N_e} \right)^t \right] \simeq p_0(1-p_0) \frac{t}{2N_e} \quad \text{for } t \ll N_e$$

where p_0 is the initial allele frequency (Equation 2.14a). Consider a population sampled at two time points (0 and t), with sample sizes of n_0 and n_t , respectively. The estimated divergence is

$$\hat{\delta}_t = \hat{p}_t - \hat{p}_0 \tag{9.1a}$$

This divergence has an expected value of zero (as $E[\hat{p}_t] = p_0$), with a variance of

$$\sigma^2(\hat{\delta}_t) = \sigma^2(\hat{p}_t - \hat{p}_0) = \sigma^2(\hat{p}_t) + \sigma^2(\hat{p}_0) - 2\sigma(\hat{p}_t, \hat{p}_0) \tag{9.1b}$$

where $\hat{p}_i = p_i + e_i$, the true value plus an error due to finite sampling. Because these are draws from a binomial distribution, the sampling variance of the initial frequency is

$$\sigma^2(\hat{p}_0) = \frac{p_0(1-p_0)}{2n_0} \tag{9.2a}$$

while the final allele frequency is influenced by both the drift and sampling variances (Waples 1989a, 1989b)

$$\begin{aligned} \sigma^2(\hat{p}_t) &= p_0(1-p_0) \left[1 - \left(1 - \frac{1}{2n_t} \right) \left(1 - \frac{1}{2N_e} \right)^t \right] \\ &\simeq p_0(1-p_0) \left[\frac{1}{2n_t} + \frac{t}{2N_e} \left(1 - \frac{1}{2n_t} \right) \right] \end{aligned} \tag{9.2b}$$

If sampling is done (without replacement) before reproduction, then $\sigma(\hat{p}_t, \hat{p}_0) = 0$, and substitution of Equations 9.2a and 9.2b into Equation 9.1b yields

$$\sigma^2(\hat{\delta}_t) \simeq p_0(1-p_0) \left[\frac{1}{2n_0} + \frac{1}{2n_t} + \frac{t}{2N_e} \left(1 - \frac{1}{2n_t} \right) \right] \tag{9.2c}$$

If sampling is done either after reproduction or with replacement, this generates a covariance between the sample estimators \hat{p}_t and \hat{p}_0 ; see Nei and Tajima (1981b) and especially Waples (1989a, 1989b) for details. Assuming this is not the case, so that $\sigma(\hat{p}_0, \hat{p}_t) = 0$, Equation 9.2c yields the correct variance for the null hypothesis of random genetic drift, giving the test statistic as

$$\frac{\hat{\delta}_t^2}{\sigma^2(\hat{\delta}_t)} \tag{9.2d}$$

which is approximately χ_1^2 -distributed. This is the **Waples adjusted test** (Waples 1989b).

The application of this test requires an accurate estimate of p_0 to compute the sample variance (Equation 9.2c). While the sample estimate, \hat{p}_0 , can be used, this can be improved upon by noting that the expected allele frequency change is zero, meaning that \hat{p}_t also contributes information about p_0 . A simple average of the two frequencies is not appropriate, as \hat{p}_0 has a smaller drift variance and the two estimates may differ in informational value due to differences in sample size, n_i . Given these concerns, Schaffer et al. (1977) and Waples (1989b) proposed a generalized (i.e., weighted) least-squares (GLS) estimator (LW Chapter 8) for p_0 . Let $\mathbf{p} = (\hat{p}_0, \hat{p}_t)^T$ denote the two sample estimates and denote its sampling variance-covariance matrix by

$$\mathbf{V} = \begin{pmatrix} \sigma^2(\hat{p}_0) & \sigma(\hat{p}_0, \hat{p}_t) \\ \sigma(\hat{p}_0, \hat{p}_t) & \sigma^2(\hat{p}_t) \end{pmatrix} \quad (9.3)$$

Finally, let $\mathbf{1} = (1, 1)^T$ be a vector of ones. The underlying statistical model is $p_i = p_0 + e_i$, which can be written in general linear model form as $\mathbf{p} = p_0 \mathbf{X} + \mathbf{e}$, where \mathbf{V} is the covariance matrix for the vector, \mathbf{e} , of residuals and $\mathbf{X} = \mathbf{1}$. Recalling LW Equation 8.34 for GLS regression, the resulting estimate of p_0 is given by $(\mathbf{X}^T \mathbf{V}^{-1} \mathbf{X})^{-1} \mathbf{X}^T \mathbf{V}^{-1} \mathbf{p}$, which reduces to

$$\text{GLS}(p_0) = \frac{\mathbf{1}^T \mathbf{V}^{-1} \mathbf{p}}{\mathbf{1}^T \mathbf{V}^{-1} \mathbf{1}} \quad (9.4)$$

because both quadratic products are scalars.

Example 9.1. One of the classic papers in evolutionary biology is Fisher and Ford's (1947) study of the *medionigra* gene in the scarlet tiger moth *Panaxia dominula*, a colorful day-flying species with one generation per year. A single diallelic locus has a major effect on the forewing pattern. Individuals that are homozygous for the *dominula* allele have multiple forewing spots, while individuals that are homozygous for the *medionigra* allele have a darkly suffused forewing with, typically, two small spots (the *bimacula* phenotype). Heterozygotes show an intermediate pattern, which is called the *medionigra* phenotype. In 1938, Ford began studying a small colony of this species in Cothill Fen, just southwest of Oxford, England. Starting in 1941, capture-recapture data were used to estimate the census population size, with the smallest estimated size between 1941 and 1947 being 1000. In 1939 ($t = 0$) the frequency of the *medionigra* allele was estimated (from a sample size of $n_0 = 223$) as $\hat{p}_0 = 0.092$, while by 1947 ($t = 8$), its sample frequency had decreased to $\hat{p}_8 = 0.037$ ($n_8 = 1341$). Taking $N_e = 1000$ (this being the smallest estimated census value over any of the generations, and hence most favorable to supporting drift), do these data show evidence of a departure from drift?

For simplicity, assume sampling without replacement, so that $\sigma(\hat{p}_0, \hat{p}_t) = 0$, with the variances are given by Equations 9.2a and 9.2b. The resulting covariance matrix, \mathbf{V} , becomes

$$\frac{\mathbf{V}}{p_0(1-p_0)} = \begin{pmatrix} \frac{1}{2 \cdot 223} & 0 \\ 0 & \frac{1}{2 \cdot 1341} + \frac{8}{2000} \left[1 - \frac{1}{2 \cdot 1341} \right] \end{pmatrix} = \begin{pmatrix} 0.0022 & 0 \\ 0 & 0.0044 \end{pmatrix}$$

Because \mathbf{V}^{-1} appears in both the numerator and the denominator of Equation 9.4, the unknown constant, $p_0(1 - p_0)$, cancels out, allowing us to simply use the above right-hand matrix for \mathbf{V} , yielding

$$\text{GLS}(p_0) = \frac{\mathbf{1}^T \mathbf{V}^{-1} \mathbf{p}}{\mathbf{1}^T \mathbf{V}^{-1} \mathbf{1}} = \frac{49.496}{674.762} = 0.0734$$

Equation 9.2c yields the sampling variance for the difference in allele frequencies as

$$\begin{aligned} \sigma^2(\hat{\delta}_t) &\simeq p_0(1-p_0) \left[\frac{1}{2n_0} + \frac{1}{2n_t} + \frac{t}{2N_e} \left(1 - \frac{1}{2n_t} \right) \right] \\ &= 0.0734 \cdot 0.9266 \left[\frac{1}{446} + \frac{1}{2682} + \frac{8}{2000} \left(1 - \frac{1}{2682} \right) \right] = 0.0004495 \end{aligned}$$

The resulting Waples test statistic for fit to pure drift becomes

$$\frac{(0.037 - 0.092)^2}{0.0004495} = 6.729$$

The probability that a χ^2_1 random variable is this big or larger is 0.0095, implying strong rejection of neutrality. By using different values of N_e in the above calculation, we can find the largest effective population size that would still allow drift to account for these data. For $N_e = 500$, the test statistic becomes 4.19 (a p value of 0.040), while for $N_e = 250$, the statistic is 2.39 (a p value of 0.12). Hence, any effective population size slightly smaller than 500 would be compatible with a hypothesis of the observed allele-frequency change being driven by drift.

Except for a gap between 1979 and 1987, the Cothill Fen population has been surveyed yearly since 1939; see Jones (1989) and Cook and Jones (1996) for reviews (Jones provides a handy table of all data through 1988). O'Hara (2005) used a hierarchical Bayesian analysis to examine a 60-year time series of these data. He assigned genotypes fitness drawn from a lognormal prior, allowing them to vary yearly. While selection was found to significantly contribute to the change in allele frequency, most of the variance was attributable to drift. Cook and Jones (1996) and Mathieson and McVean (2013) estimated a selection coefficient against the *medionigra* allele of around 10% (assuming additivity in fitness), while Mathieson and McVean noted that a recessive model of selection provided a better fit, but required much stronger selection (essentially a lethal). A more recent analysis by Foll et al. (2015) found that both the weakly selected codominant and strongly selective recessive models are supported when N_e is fixed at 500. However, when N_e is jointly estimated from the data, there is stronger support for the lethal recessive model. While this is one of the best temporal data sets available, and selection appears to be strongly acting on a single gene, all of this uncertainty highlights the difficulty of dealing with natural populations.

While one might think that tests based solely on allele-frequency change are among the most convincing, this is not the case. As Example 9.1 shows, rejection of the neutral model can easily result from an overestimation of the true effective population size. Fisher and Ford took their results as evidence against Sewall Wright's notion of the importance of genetic drift. In his reply, Wright (1948a) noted that values of N_e simply based on census numbers can easily be contested by the widespread observation that the effective population size is generally (and often dramatically) lower than the observed number of individuals in the population (Chapter 3). In addition, tests of allele-frequency change suffer from low power. If selection is modest relative to $1/N_e$ or $1/n$ (with n being the sample size), the sample variance can obscure any selection signal. Waples (1989b) examined some of these design issues.

Although we have presented this test for a single locus with just two alleles, its extension to multiple alleles is straightforward (e.g., Waples 1989b; Goldringer and Bataillon 2004). A more subtle issue is the fit of a χ^2 distribution to the test statistic given by Equation 9.2d, which can be poor when alleles are rare, the number of alleles is large, or the number of generations is large (Goldringer and Bataillon 2004). While more sophisticated modifications (e.g., Sandoval-Castellanos 2010) can avoid some of these issues, the use of simulations that incorporate as much of the specific biology of the species as is known (e.g., Mueller et al. 1985) to model the change in the neutral alleles under drift is strongly preferred over parametric tests.

Allele-frequency Change Over a Times Series: The Fisher-Ford Test

The test given by Equation 9.2d assumes we have data from just two time points, but often one has **time-series** data for a number of generations. In such cases, the strong temptation to simply test the two most extreme values should be avoided, as such nonrandom sampling gives a highly biased result. Rather, specific tests have been developed that jointly consider all of the data. Indeed, the original test of Fisher and Ford involved such a temporal sequence of data. While one can use frequencies directly, Fisher and Ford used the arcsin-square-root

transform to both stabilize the variance (making it independent of the initial frequencies) and improve the fit to normality, especially at extreme frequencies (note that the arcsin is measured in radians, rather than degrees). Such variance-stabilizing transformations were discussed in LW Chapter 11.

Let y_t denote the transformed frequency of the allele in generation t . For a t that is small relative to N_e , we find (approximately) that

$$y_t = 2 \sin^{-1} (\sqrt{p_t}) \sim N(y_0, t/[2N_e]) \quad (9.5a)$$

where $y_0 = 2 \sin^{-1} (\sqrt{p_0})$ is the transformed value of the initial frequency. Estimates of allele frequencies are made at k time points, with no requirements about the temporal spacing between samples. Let \mathbf{y} denote the vector of the transformed estimates of the k sampled allele-frequencies, and let $\mathbf{1}$ denote a vector of ones of the same length

$$\mathbf{y} = 2 \begin{pmatrix} \sin^{-1} [\sqrt{p_1}] \\ \vdots \\ \sin^{-1} [\sqrt{p_k}] \end{pmatrix}, \quad \mathbf{1} = \begin{pmatrix} 1 \\ \vdots \\ 1 \end{pmatrix} \quad (9.5b)$$

Finally, we need the covariance matrix, \mathbf{V} , whose elements are independent of the allele frequency (because of the variance-stabilizing transformation; Equation 9.5a). The sample indices denote the sequence of samples, not the actual sampled generation itself (see Example 9.2), with t_i the generation number associated with the i th sample. The diagonal terms of \mathbf{V} are given from Equation 9.2c

$$V_{ii} = \frac{1}{2n_{t_i}} + \frac{t_i}{2N_e} \left(1 - \frac{1}{2n_{t_i}}\right) \simeq \frac{1}{2n_{t_i}} + \frac{t_i}{2N_e} \quad (9.5c)$$

Now consider the covariance between samples i and j , which correspond to generations t_i and t_j , respectively (where $i > j$ and $t_i > t_j$). The estimates for these two sample points have a shared history (from the base value, p_0) of drift up through generation t_j , yielding

$$V_{i,j} = V_{j,i} = \frac{t_j}{2N_e} \quad \text{where } t_j < t_i \quad (9.5d)$$

Note that the covariance with the base generation ($t = 0$) is always zero (which is why the off-diagonal covariances for \mathbf{V} in Example 9.1 were set to zero). The $k \times k$ matrix, \mathbf{V} , contains only those rows and columns corresponding to the k specific generations sampled.

This is now a goodness-of-fit problem for a linear model. Using Equation 9.4, we obtain a generalized least-squares (GLS) estimate of the (transformed) initial frequency

$$\hat{y}_0 = \frac{\mathbf{1}^T \mathbf{V}^{-1} \mathbf{y}}{\mathbf{1}^T \mathbf{V}^{-1} \mathbf{1}} \quad (9.6a)$$

Using this value, the vector of deviations is

$$\boldsymbol{\delta}_{\mathbf{y}} = \mathbf{y} - \hat{y}_0 \cdot \mathbf{1} \quad (9.6b)$$

and the test statistic, the weighted sum of the squared (transformed) allele-frequency differences,

$$\boldsymbol{\delta}_{\mathbf{y}}^T \mathbf{V}^{-1} \boldsymbol{\delta}_{\mathbf{y}} \quad (9.6c)$$

is expected to be approximately χ_{k-1}^2 distributed due to the normality assumption on y_i .

Example 9.2. We now revisit Fisher and Ford (Example 9.1), and consider a test based on the data from 1939, 1943, and 1947, where

Year	t	\hat{p}	$y = 2 \sin^{-1}(\sqrt{p})$	n
1939	0	0.092	0.616	223
1943	4	0.056	0.478	269
1947	8	0.037	0.387	1341

Assuming $N_e = 1000$, the resulting covariance matrix, \mathbf{V} (on the transformed scale), becomes

$$\begin{aligned}\mathbf{V} &= \begin{pmatrix} V_{0,0} & V_{0,4} & V_{0,8} \\ V_{4,0} & V_{4,4} & V_{4,8} \\ V_{8,0} & V_{8,4} & V_{8,8} \end{pmatrix} = \frac{1}{2000} \begin{pmatrix} \frac{2000}{2 \cdot 223} + 0 & 0 & 0 \\ 0 & \frac{2000}{2 \cdot 269} + 4 & 4 \\ 0 & 4 & \frac{2000}{2 \cdot 1341} + 8 \end{pmatrix} \\ &= \frac{1}{2000} \begin{pmatrix} 4.484 & 0 & 0 \\ 0 & 7.717 & 4 \\ 0 & 4 & 8.745 \end{pmatrix}\end{aligned}$$

In addition,

$$\mathbf{y} = \begin{pmatrix} 0.616 \\ 0.478 \\ 0.387 \end{pmatrix}, \quad \mathbf{1} = \begin{pmatrix} 1 \\ 1 \\ 1 \end{pmatrix}, \quad \text{yielding } \hat{y}_0 = \frac{\mathbf{1}^T \mathbf{V}^{-1} \mathbf{y}}{\mathbf{1}^T \mathbf{V}^{-1} \mathbf{1}} = \frac{418.851}{774.701} = 0.541$$

Using this estimate for y_0 , the vector of deviations from the initial value becomes $\boldsymbol{\delta}_y = \mathbf{y} - 0.541 \cdot \mathbf{1}$, returning a test statistic value of $\boldsymbol{\delta}_y^T \mathbf{V}^{-1} \boldsymbol{\delta}_y = 7.964$, which when compared to a χ^2_2 distribution, returns a significance level of 0.0186. For $N_e = 500$, Equation 9.6c returns a value of 5.398, for a significance of 0.067, so the hypothesis that drift alone accounts for the observed pattern of change cannot be rejected under this smaller value of N_e .

A number of generalizations, as well as increasingly sophisticated tests building on the basic elements of the Fisher-Ford framework, have been proposed, including extending this methodology to handle data from high-throughput sequencing. A partial list includes Templeton (1974), Schaffer et al. (1977), Gibson et al. (1979), Wilson (1980), Watterson (1982), Waples (1989b), De Koeyer et al. (2001), Goldringer and Bataillon (2004), Bollback et al. (2008), Wisser et al. (2008), Sandoval-Castellanos (2010), Malaspinas et al. (2012), da Fonseca et al. (2013), Mathieson and McVean (2013), Feder et al. (2014), Lacerda and Seoighe (2014), Steinrücken et al. (2014), Foll et al. (2015), Terhorst et al. (2015), Topa et al. (2015), Gompert (2016), and Schraiber et al. (2016).

In addition to its use in studying natural populations, this machinery can be applied to artificial selection experiments to detect regions of interest. In the pre-genomics era, this approach was pioneered by Stuber and Moll (1972) and Stuber et al. (1980), who looked for shifts in the frequencies of isozyme markers in lines of maize selected for yield. Other examples for maize include Labate et al. (1999) and Coque and Gallais (2006) for yield selection, and Wisser et al. (2008) for disease resistance, while De Koeyer et al. (2001) examined yield in oats. In the genomics era, extensions of this machinery have been used in microorganisms, such as the analysis by Foll et al. (2014) on the target (or targets) of selection for influenza A virus exposed to the drug oseltamivir, as well as with data from **evolve and resequence** experiments (**E&R**), such as those on *Drosophila* (Terhorst et al. 2015; Topa et al. 2015).

Schaffer's Linear Trend Test

A variation of the Fisher-Ford test was suggested by Schaffer et al. (1977), who noted that power might be improved by going beyond a simple lack of fit test against the model $y_t = \mu + e$ (where μ is the transformed initial allele frequency), by asking if a *significant linear trend* is present. The model now becomes

$$y_t = \mu + \beta t + e \tag{9.7a}$$

where a trend is indicated if β is significantly different from zero (the Fisher-Ford test assumes $\beta = 0$). Such a linear trend is not expected under drift but would be expected under directional selection, assuming that the direction of selection is not changing (migration from a population with a different allele frequency could also generate a linear trend). In general-linear-model form (LW Chapter 8), Equation 9.7a becomes $\mathbf{y} = \mathbf{X}\beta + \mathbf{e}$, where

$$\mathbf{X} = \begin{pmatrix} 1 & t_1 \\ \vdots & \vdots \\ 1 & t_k \end{pmatrix}, \quad \beta = \begin{pmatrix} \mu \\ \beta \end{pmatrix}, \quad \hat{\beta} = (\mathbf{X}^T \mathbf{V}^{-1} \mathbf{X})^{-1} \mathbf{X}^T \mathbf{V}^{-1} \mathbf{y} \quad (9.7b)$$

where the elements of \mathbf{V} are given by Equations 9.5c and 9.5d. For the data in Example 9.2, the resulting \mathbf{X} matrix and the GLS estimate, $\hat{\beta}$, of the vector of parameters becomes

$$\mathbf{X} = \begin{pmatrix} 1 & 0 \\ 1 & 4 \\ 1 & 8 \end{pmatrix}, \quad \hat{\beta} = \begin{pmatrix} 0.609 \\ -0.028 \end{pmatrix}$$

Applying LW Equation 8.35, the standard error on the slope is found to be 0.0086, showing that it is highly significant. Stuber et al. (1980) used this approach to infer selection at sites linked to several allozyme markers in a series of selected maize lines. One advantage of the linear-trend test is that it does not require highly accurate estimates of N_e .

Scans and Simulation-based Approaches

As presented, these tests for shifts in allele frequencies are performed one marker at a time, as they herald from the days of testing just one or a few unlinked candidate genes. With a few unlinked markers, Bonferroni corrections (or the slightly more powerful sequential methods; Appendix 4) can be applied to assign overall significance levels. Likewise, FDR approaches can use used to assign **false-discovery rates** among the set of markers declared to be significant (the fraction of tests declared to be significant that are actually from the null; Appendix 4). However, in the **genomic-scan** era, with the potential for thousands of linked markers on each chromosome, tests are no longer independent, thus compromising FDR approaches (Chen and Storey 2006). Even if tests are largely independent, their vast number makes Bonferroni-type corrections untenable for a test to have any power (Appendix 4). How then can these tests be extended to the dense marker maps used in genomic scans?

For starters, analyzing markers one at a time is rather inefficient, in that one potentially loses shared information from linked markers. A better approach is to compute the average allele-frequency change within a small sliding window. Starting with the initial allele frequencies within a given window and either their known or assumed recombination rates, simulations under pure drift (and recombination) can generate a null distribution of average change as a comparison point for the actual observed divergence (e.g., Example 9.3; Johansson et al. 2010). Other, less formal approaches can also be used to simply indicate regions of interest (as opposed to regions that are formally statistically supported); see Figure 9.1.

Birthdate Selection Mapping (BDSM)

A very interesting genomic-scanning approach for sites under selection becomes possible when one has extensive pedigree data, such as for cattle (Decker et al. 2012). With extensive pedigrees, one has information on the date of birth (DOB) of most individuals, whose value can be expressed as years since the start of the pedigree. Individuals with a later date of birth (i.e., more recent in the pedigree) have likely experienced more selection than earlier-born individuals (those deeper down in the pedigree). As such, one expects to find a positive relationship between a marker linked to a selected site and DOB. For example, if allele *A* was initially rare but favored, *AA* individuals are expected to be more common in animals with higher (i.e., more recent) DOB values. Decker et al. turned this

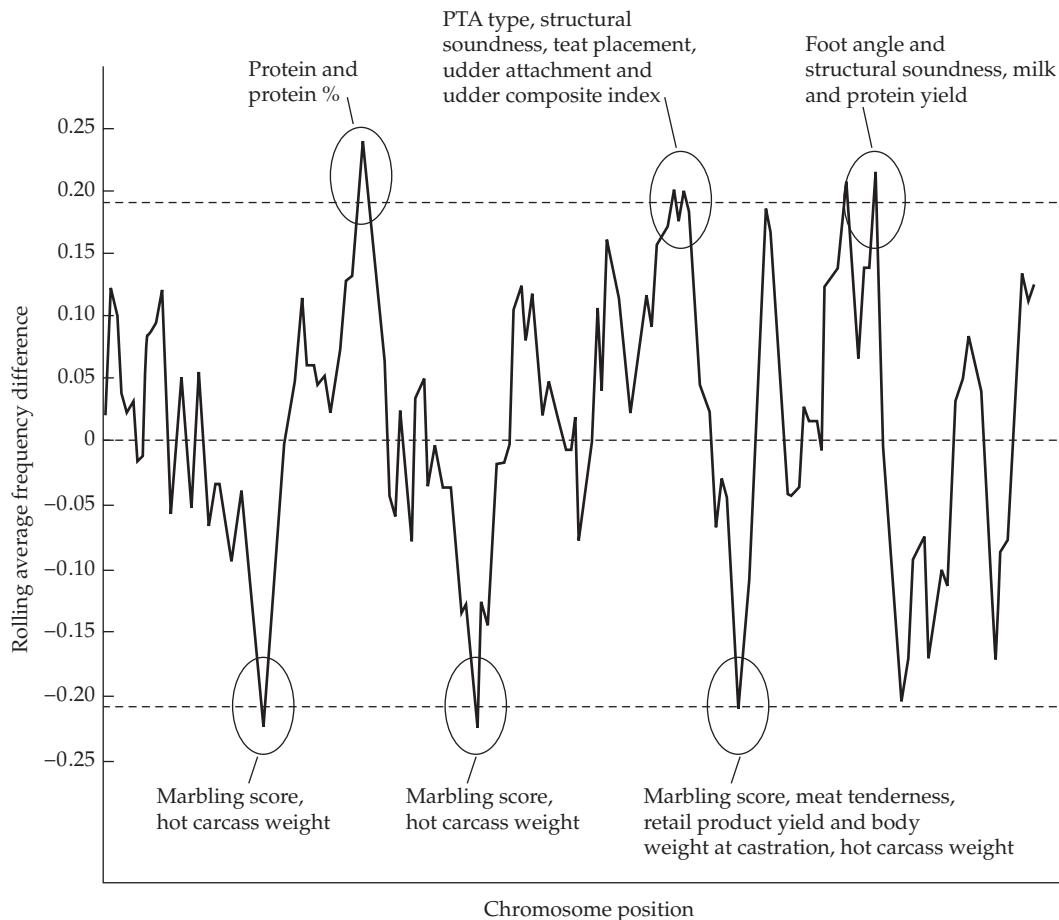

Figure 9.1 A scan of *Bos taurus* chromosome 19, contrasting differences in SNP allele frequencies between specialized dairy (Holstein) and meat (Angus) breeds. Positive values indicate alleles at higher frequencies in Holstein cattle (dairy-specific), and negative values indicate alleles that are more common in Angus cattle (meat-specific). Differences were based on a sliding window of five adjacent markers, using a set of 175 SNPs. The horizontal axis represents chromosomal position, and the vertical axis is the average between-breed difference in SNP allele frequencies over the five-SNP window. The upper and lower dashed lines indicate the 5% threshold levels as assessed via a permutation test (see the text for details). As annotated in the figure, the authors were able to associate these exceptional peaks and valleys with known QTLs for dairy and beef traits. Because QTL intervals tend to be rather vague (averaging around 20 megabases, or roughly 20 cM, for these traits), the significance of these associations with known QTLs, while suggestive, is unclear. (After Prasad et al. 2008.)

relationship around, realizing that by treating DOB values as a quantitative trait, one could use association mapping (LW Chapter 16), with sites showing an association with DOB (i.e., those that are under- or over-represented later in the pedigree) being candidates for selection. This approach is called **birthdate selection mapping** (or **BDSM**), and because association mapping is done in a mixed-model framework (Chapter 19), it accounts for biases introduced by family structure. The authors applied this approach to U. S. Angus cattle born over a 50-year period (roughly 10 generations). A standard random-effects mixed model of association mapping detected 11 loci significantly associated with DOB, while a Bayesian model found that ~2% of the SNPs were strongly associated with DOB. The former model assumes an infinitesimal structure, while the latter allows for genes of larger effect that are embedded in a sea of smaller-effect genes. While **BDSM** requires large, deep pedigrees, it is an intriguing and potentially powerful approach.

DIVERGENCE BETWEEN POPULATIONS: TWO-POPULATION COMPARISONS

While most of the analysis of divergence data in structured populations is based on F_{ST} statistics (Chapter 2), we start with a few comments on the simple situation in which one is comparing a biallelic locus between two populations. As in the case of the divergence of a single population measured at starting and ending time points, divergence can be measured as the squared allele-frequency difference,

$$\hat{\delta}_t = (\hat{p}_{t,1} - \hat{p}_{t,2})^2 \quad (9.8)$$

namely, the squared difference between the frequency in the two populations at some sample time, t , following their isolation from a common ancestor in generation 0. Whether $\hat{\delta}_t$ is too large, or too small, relative to drift can be evaluated using a simple modification of the Waples test, wherein the denominator in Equation 9.2d is replaced by $\sigma^2(\hat{p}_{t,1}) + \sigma^2(\hat{p}_{t,2})$, the sum of the allele-frequency sampling variances for each population (defined as in Equation 9.2b). This expression requires estimates of the divergence time, t , as well as the average effective sizes for both populations. More generally, because $E[\hat{p}_{t,i}] = p_0$, in theory one could sample the two populations at different time points (t_1 and t_2), but now using $\sigma^2(\hat{p}_{t_1,1}) + \sigma^2(\hat{p}_{t_2,2})$ in the denominator of the test statistic.

A common scenario involves the comparison of two subpopulations, descended from a shared ancestor, that presumably have experienced different selection pressures. The typical setting is either selection in one population (e.g., adaptation to elevation assessed by comparing a derived highland population to a lowland control) or lines selected in divergent directions (e.g., meat versus dairy cattle). If one has a fairly dense marker map, adjacent markers should be in LD and the joint use of multiple markers can enhance the signal of selection. A standard approach is a genomic scan using a sliding window of markers, contrasting the average frequency differences between populations for the alleles within windows (Figure 9.1). While the window size is arbitrary, it should be no smaller than the average size of an LD block for the populations being compared.

As with temporal data, the significance of divergence data can be assessed using simulations (Example 9.3), although other, less formal approaches are often used to highlight regions of interest. One example of the latter is the work of Prasad et al. (2008), presented in Figure 9.1, which depicts a scan for excess SNP-frequency differences in a sliding window analysis over *Bos taurus* (cattle) chromosome 19. Regions of interest were identified by a permutation test in which breed labels were randomized over SNPs to generate the null. Threshold values indicate the 95% limit for the range of maximal within-window differences in frequencies between the two populations in the randomized data sets. This permutation approach is only approximate, as it ignores LD among linked neutral markers within breeds (a more careful analysis, based on simulations, is detailed in Example 9.3). However, it still serves to indicate sites likely enriched for differentially selected genes.

Finally, a very simple statistic that often appears in comparisons of selected versus control populations is Grossman et al.'s (2010) ΔDAF statistic. This metric is a natural outgrowth of the type of comparisons shown in Figure 9.1, which focuses on the difference in the **derived allele frequency** (DAF) between a control and a selected population. For a candidate SNP, let \bar{D}_{NS} denote the frequency of the derived allele in a nonselected control population (or its average frequency if multiple control populations are used) and its frequency, D_S , in the putatively selected population, with $\Delta DAF = D_S - \bar{D}_{NS}$. This statistic ranges between plus one and minus one, and standard outlier approaches are used to highlight SNPs with excessive values.

Example 9.3. Hayes et al. (2008) contrasted SNP frequencies between Australian populations of Holstein (dairy) and Angus (beef) cattle, specialized breeds developed by selection from a

common ancestral stock. Whole-genome scans of both populations were performed using 7032 sliding windows of ten adjacent SNPs to measure average allele-frequency change between the corresponding windows for both populations (the difference at each SNP, averaged over all ten sites). Simulations were used to assess significance (extreme departures in average allele-frequency in homologous windows between the two populations) relative to the values expected under drift alone. The authors had to model two issues: linkage and breed formation (time in some initial early domesticated population, and then subsequent time in separate bottlenecks representing the formation of the two specialized breeds).

The authors simulated roughly 300 SNPs per chromosome (to account for LD in addition to allele-frequency change), while the population structure during breed formation was modeled as follows. The authors simulated 900 generations of drift and mutation in a base population of $N_e = 1000$ to generate a common domesticated stock population. Specialized breed formation from this common stock was then simulated by sampling from this stock population to form two subpopulations of size $N_e = 125$, each of which was simulated for an additional 100 generations (these values represented the best assumption regarding these parameters during domestication and breed formation). The observed genome-wide F_{ST} between the Holstein and Angus populations was 0.08, and only simulations whose genome-wide F_{ST} values matched this value were kept as the null.

Taking those windows in the data set that were in the upper 0.1% of excessive divergence (positive or negative) relative to the simulated data resulted in 15 significant regions (windows). Focusing on windows with the uppermost 0.5% of divergence (relative to simulations) yielded 84 candidate regions. To assess what fraction of these extreme windows might be false positives, the authors computed the false-discovery rate (FDR), the fraction of those tests declared to be significant that are likely to be false positives (Appendix 4). FDR provides a measure of how enriched a set of results declared to be significant is for true positives. At a 0.1% level of significance, one expects $7032 \cdot 0.001 = 7.03$ tests to be significant by chance alone, while for 0.5%, this increases to 35 false positives among the 7032 tests for each window. The FDRs are $7/15 = 47\%$ for tests of 0.1%, and $35/84 = 42\%$ for tests at the 0.05% significance level. Hence, the expectation is that slightly over half (53% and 58%, respectively) of the windows initially flagged as significant are true positives.

DIVERGENCE BETWEEN POPULATIONS: F_{ST} -BASED TESTS

When comparisons involve more than two populations or markers with more than two alleles, a more natural measure of divergence is Wright's F_{ST} statistic of population structure (Wright 1951). Recall from Chapter 2 that this statistic measures the fraction of total variation over a set of populations that is due to among-population differences in allele frequencies, and is easily extended to multiple alleles and multiple populations. For a biallelic locus, $F_{ST} = \sigma_B^2(p)/[\bar{p}(1 - \bar{p})]$, where $\sigma_B^2(p)$ is the variance in allele frequency, p , over the populations around its average value, \bar{p} .

There are important caveats when using F_{ST} . First, the analysis of F_{ST} statistics assumes that back mutations are sufficiently rare to be safely ignored. This is not the case for microsatellite (STR/SSR) markers, which have both high mutation rates and a high chance of convergent mutation (alleles of different origins having the same repeat copy number), and their use requires specific divergence metrics, such as R_{ST} (Slatkin 1995a; Goodman 1997). Excoffier et al. (2009b) showed that using F_{ST} in place of R_{ST} for the analysis of STR data can significantly inflate the false-positive rate. Second, the upper limit of F_{ST} is set by the expected heterozygosity, meaning that a highly variable locus has a maximal F_{ST} value smaller than a less variable one (Charlesworth 1998; Hedrick 1999). Jakobsson et al. (2013) and Edge and Rosenberg (2014) provided upper bounds on F_{ST} given the frequency of the most common allele (averaged over all populations), and found that when this is either small (i.e., very many alleles) or large (close to population-wide fixation), F_{ST} is restricted to values far below 1.0. Hence, the levels of diversity within a region constrain the possible F_{ST} values. Various standardization measures of F_{ST} (and related statistics) have been

proposed, and their strengths and weaknesses were reviewed by Meirmans and Hedrick (2011).

Even using these standardizations, F_{ST} -based tests perform poorly when the expected genome-wide divergence due to drift is sufficiently large that many neutral loci are expected to have alternative alleles near fixation between populations. Against such a background, the effect of selection at a candidate region is hard to detect. This situation emphasizes that the tests considered in this chapter apply over *ecological time scales*, as they assume (for the null) that most neutral markers are segregating in most subpopulations, which puts the time scale for their use at no more than $\sim N_e$ generations.

Ecological geneticists have coined the term **landscape genetics** for the study of the distribution of genetic variation over spatial structures (Manel et al. 2003; Manel et al. 2010; Manel and Holderegger 2013), and F_{ST} and allele-environmental correlations (discussed in the next section) are central to this emerging field. As a result, the literature on these classes of tests is rapidly expanding.

Example 9.4. The effectiveness of F_{ST} to detect selection was examined by Taylor et al. (1995), using a putative target of selection in the tobacco budworm (*Heliothis virescens*), a noctuid moth and a major cotton pest in the United States. Pyrethroid insecticides have been used in control efforts, and these act on voltage-gated sodium channels in the nervous system. The historical usage patterns of these insecticides, and hence the putative selection pressures on sodium channel genes, differed over the sampled populations examined by the authors. As a result, they predicted that F_{ST} values at the sodium channel *Hpy* gene should be significantly higher than for background loci, reflecting this differential selection over the sampled subpopulations. Samples of adults from widely spaced locations in the United States revealed an F_{ST} value of 0.041 ± 0.005 at the *Hpy* marker, in contrast to values of 0.002 ± 0.001 at 14 other loci, with the latter result indicating fairly weak population structure in this species.

Outlier Approaches

The underlying premise for most F_{ST} -based tests of selection was the suggestion by Cavalli-Sforza (1966) that all neutral loci should have the same expected value of F_{ST} , reflecting the genome-wide impact of common demographic and population-structure forces. Thus, one can (in theory) use a large number of marker loci to estimate the baseline F_{ST} value for the set of populations being compared, and then search for outlier loci. This approach is easily modified to look for specific loci being outliers in specific populations (e.g., Akey et al. 2002; Kayser et al. 2003; Akey et al. 2010). Loci with excessively high values indicate more divergence than expected under drift, and the possibility that the marker is linked to a site that is under differential selection over the demes. Likewise, excessively low values indicate less divergence than expected under drift, and hence the potential for a site that is under balancing selection near the marker. While the historical interpretation of F_{ST} data follows from these last two statements, results from Chapter 8 on sweeps under *uniform* selection in structured populations suggest that a more nuanced view is needed. Recall from Figure 8.8 that uniform selection over the entire metapopulation can generate excessive divergence (Figure 8.8A) during a hard sweep of a single allele when it is still restricted to a subset of the demes. Similarly, a soft sweep under uniform selection can also generate excessive divergence. Conversely, a completed hard sweep through the sampled demes generates a reduction in divergence relative to background levels of F_{ST} (Figure 8.8B).

The outlier strategy makes two assumptions: the vast majority of scored loci are neutral, and all neutral sites reflect the same underlying population demography. As discussed in the introduction to this chapter, new alleles arising on the leading wave of a population expansion can “surf” to high frequencies, generating excessive values over the expected background. Likewise, differences in the ratio of gene density to recombination rate in dif-

ferent parts of the genome change the expected pattern of background selection, potentially creating outliers even among neutral markers.

A final complication is that when the population structure departs from the island model (equal divergence is expected between all demes; Chapter 2), the variance in F_{ST} is inflated, generating an excess of outliers. An interesting example of this phenomenon appears in the work of Fourcade et al. (2013), who found that river fishes showed an unusually high number of outlier loci. While such an observation might be taken as evidence that river species have higher rates of local adaptation, simulations by these authors showed that species with a **fractal** (highly branching) **population structure** have a greatly inflated variance in F_{ST} relative to the island model. This arises because migration on fractal structures (such as rivers or valleys) generates a complex pattern of correlated allele frequencies. Other types of population structures, such as hierarchical island models (Figure 2.11), population expansions from refugia, and allelic surfing, can all inflate the number of outliers (Excoffier et al. 2009a; Bierne et al. 2013).

Tests Based on F_{ST} -generated Branch-lengths

When migration and new mutation can be ignored, F_{ST} provides an estimate of the divergence time, T (scaled in $2N_e$ generations), between two populations. Rearranging Equation 2.43, taking the log of both sides, and recalling that $\ln(1 - x) \simeq -x$ (for $|x| \ll 1$) yields

$$\ln(1 - F_{ST}) = t \ln\left(1 - \frac{1}{2N_e}\right) \simeq -t/2N_e \quad (9.9)$$

Hence $T = -\ln(1 - F_{ST}) \simeq t/2N_e$, and one can recast an excessive F_{ST} value as an excessive separation time required for drift to account for the observed divergence. These estimated times are called **branch lengths** and (following the Cavalli-Sforza premise) should have the same expected value over all neutral genes. An excessive branch length for a candidate gene relative to some reference set of genes suggests excessive change relative to drift (Vitalis et al. 2001; Rockman et al. 2003), and is the basis of the **population branch statistics (PBS)** of Yi et al. (2010); see Figure 9.2.

The Lewontin-Krakauer Test: Basics

The above outlier methods (for either F_{ST} or branch lengths) are rather *ad hoc*, and best viewed as *enrichment* methods, distilling down a reduced set of markers that is likely enriched for selected sites. The critical missing element in these methods is the expected distribution of F_{ST} values for a random marker, allowing p values to be placed on outliers. Formal distribution-based tests were introduced by Lewontin and Krakauer (1973), who considered the distribution of F_{ST} values for a random biallelic locus sampled over n populations under an island model (Figure 2.11). If we assume that the distribution (over populations) of the frequency of an allele is roughly normal, the expected large-sample distribution of F_{ST} values approximately follows a $\lambda\chi_{n-1}^2$ distribution, with a scaling factor of $\lambda = E(F_{ST})/(n-1)$. Given Cavalli-Sforza's assumption that, on average, population structure influences all neutral loci equally, Lewontin and Krakauer estimated $E(F_{ST})$ from the average \bar{F}_{ST} over all scored loci, giving the distribution for a random realization F_{ST} as

$$\frac{1}{\lambda}F_{ST} = \frac{(n-1)F_{ST}}{\bar{F}_{ST}} \sim \chi_{n-1}^2 \quad (9.10a)$$

In other words, scaled individual F_{ST} values follow a chi-square distribution with $n-1$ degrees of freedom. This is a large-sample approximation, as the sampling error in estimating the true realization of the F_{ST} value for a given marker is ignored. Because the variance of a χ_n^2 random variable is $2n$ (LW Equation A5.15b), the variance among realizations of F_{ST} values is approximately

$$\sigma^2(F_{ST}) \simeq \sigma^2(\lambda\chi_{n-1}^2) = 2(n-1)\lambda^2 = 2(n-1)\left(\frac{E[F_{ST}]}{n-1}\right)^2 \simeq 2\frac{\bar{F}_{ST}^2}{n-1} \quad (9.10b)$$

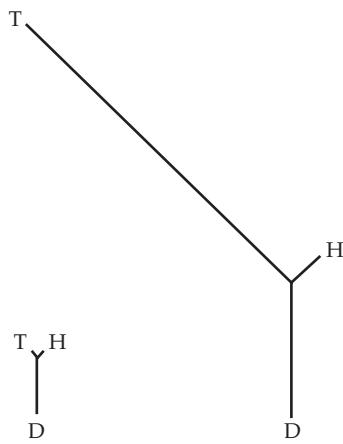

Figure 9.2 F_{ST} -based branch lengths for Tibetan (T), Han (H), and Danish (D) populations. (**Left**) Lengths based on the average F_{ST} values for all sampled markers. (**Right**) The tree for the *EPAS1* gene. While the D and H branches show increased divergence relative to the average F_{ST} , the divergence along the T lineage is far more dramatic. This is consistent with excessive allelic divergence due to selection for living at high altitude (or perhaps other features, such as allelic surfing). (After Yi et al. 2010.)

Baer (1999) empirically showed that the variance of a wide range of fish F_{ST} values is more accurately given by replacing the 2 in Equation 9.10b by a value between 5 and 7. As mentioned in the previous section, the fractal structure of many fish populations (Fourcade et al. 2013), and hence a significant departure from the assumed island-model underlying Equation 8.10b, likely account for at least part of this inflated variance.

There are a number of additional potential problems with this approach of using \bar{F}_{ST} to provide an estimator of λ . First, this estimate can be biased by skew resulting from a few excessive F_{ST} values. Specifically, if $F \sim \lambda \chi^2_{n-1}$, estimating λ by comparing means yields the method-of-moments estimator, $\hat{\lambda} = \bar{F}/(n-1)$, as $E[\chi^2_n] = n$. However, even just a few loci that are under selection—and hence with extreme large values of F_{ST} —inflate \bar{F} and bias the estimate of λ under the null. A more robust approach is to replace the usage of the means with **medians**, the 50% values of the two distributions (Devlin and Roeder 1999). Specifically, $\text{med}(F) = \text{med}(\lambda \chi^2_{n-1})$, or

$$\hat{\lambda} = \frac{\text{med}(F)}{\text{med}(\chi^2_{n-1})} \quad (9.10c)$$

For example, suppose the median for single-locus F_{ST} values among a collection of loci sampled over five populations is 0.127. Because $\Pr(\chi^2_4 \leq 3.357) = 0.5$, the median value of a χ^2_4 is 3.357, yielding

$$\hat{\lambda} = \frac{\text{med}(F)}{\text{med}(\chi^2_{n-1})} = \frac{0.127}{3.357} = 0.038$$

as a more robust estimate of λ under the null (drift) relative to that based on the mean, \bar{F}_{ST} , because the median-based estimate is not biased by the presence of a modest number of loci under selection.

Second, Equation 9.10a depends on the validity of the χ^2 approximation for the distribution of F_{ST} values. This approximation fails when too many alleles (more than five) are

present at a locus, the minor-allele frequency is small (< 0.1), or the divergence time is too large (Goldringer and Bataillon 2004). Indeed, Whitlock and Lotterhos (2015) recommended that loci with low heterozygosities be excluded in estimates of \bar{F}_{ST} .

A third, and deeper, problem is the implicit assumption of Lewontin and Krakauer that neutral allele frequencies are *independent among demes*. This is correct under the standard island model (Figure 2.11), which yields equal expected divergence among any pair of demes, and the same amount of variation within any deme (assuming no among-deme differences in N_e). However, this assumption fails under more complex population structures, such as unequal migration between demes (e.g., the **isolation by distance** model, wherein closer demes exchange migrants at higher rates) or hierarchical structure among demes generated by their founding. These population-structure issues create correlations among allele frequencies from different demes, inflating the variance of F_{ST} relative to the expectations under the island model, which impacts the χ^2 assumption (Nei and Maruyama 1975; Robertson 1975a, 1975b; Tsakas and Krimbas 1976).

As a result of these concerns (and others; see Nicholas and Robertson 1976), the original version of the Lewontin-Krakauer test quickly languished. However, its basic simplicity, coupled with its requirement of only the type of data routinely gathered by ecological geneticists (estimates of locus-specific F_{ST} values), fueled the search for ways to correct these initial flaws.

Whitlock and Lotterhos (2015) recently suggested a potentially simple work-around for many of these issues, going by the name of **OutFLANK**. They noted through extensive simulations of very different population structures that the distribution for F_{ST} values (provided heterozygosity levels were not too small) was very close to χ^2 , but with different degrees of freedom from the Lewontin-Krakauer value of $(n - 1)$. This difference in the degrees of freedom makes sense, given a lack of independence among demes, and they recommended a two-step approach for obtaining approximate p values. First, the upper and lower 5% of the empirical F_{ST} values are trimmed. The logic being that loci under uniform selection (generating excessive low values) and under divergent selection (generating expressive high values) are expected to be only a tiny fraction of all tested sites. The remaining trimmed distribution, representing the core 90% of the values, is then used in a ML setting to estimate the appropriate degrees of freedom for such a doubly truncated χ^2 . (More generally, Table A2.1 shows that the χ^2 distribution is a special case of the gamma distribution, and fitting the latter allows for what amounts to fractional degrees of freedom, which might further improve the fit.) With the corresponding null density now estimated, appropriate p values for outliers can be obtained. Their simulations showed that this approach worked well for excessively high values (i.e., the right-hand tail of the distribution), but very poorly for the left-hand tail (those loci showing small F_{ST} values than expected).

Second-generation Lewontin-Krakauer Tests: Model-based Adjustments

One proposed strategy to resuscitate the Lewontin-Krakauer test was to use knowledge of the population structure as the basis for simulations of the distribution of F_{ST} under the null hypothesis of no selection. Such an analysis was first performed by Bowcock et al. (1991), who had a rough idea of this structure for the five human populations they surveyed. Vigouroux et al. (2002) used coalescent simulations incorporating a founding bottleneck in a screen of 501 maize genes to find those with excessive F_{ST} values. Similarly, Ross-Ibarra et al. (2008) estimated the parameters of a complex model of the population structure of *Arabidopsis lyrata*, and then used simulations based on their estimated demography to detect outliers. The concern with any null distribution generated by simulations is robustness to assumptions about the population structure, as even the most careful simulations can be misleading (e.g., Carret et al. 2006; Excoffier et al. 2009a, 2009b). For example, most analyses of robustness to different demographic models fail to consider the effects of spatial expansion, and hence ignore concerns raised by allelic surfing.

An alternative strategy involves a more careful examination of outliers detected from simulation results. Beaumont and Nichols (1996) suggested that outliers on a two-

dimensional plot of a gene's F_{ST} value versus its (population-wide) heterozygosity value (H) offered a more robust signal of selection. Their logic was that the sampling variance in F_{ST} becomes more sensitive when allele frequencies are skewed over populations, implying that sites with low-frequency alleles can generate an excess of extreme values simply by chance. Further, H constrains the possible range of F_{ST} . Given an estimate of the average neutral F_{ST} , coalescent simulations are performed to generate a joint distribution of F_{ST} versus H values under an island model (the Beaumont-Nichols *FDIST* and *FDIST2* tests). Excoffier et al. (2009b) used a similar approach but with simulations assuming a hierarchical island model (Figure 2.11).

A more robust approach is to move away from the island model as the basis for tests (Meirmans 2012). Because the potential underlying population structure is arbitrary and unknown, successively more complex models have been proposed in the attempt to capture at least some of the true covariance structure among demes. The most common model, from Beaumont and Balding (2004), is to assume that demes are formed as independent draws from the same common ancestral base population (potentially with different N_e values in each of the resulting demes). Once formed, no subsequent migration occurs among demes, resulting in a star phylogeny (all branches radiate from a single ancestral population). Under this model, the vector, \mathbf{p} , of the deme-specific allelic frequencies (under the null) is assumed to have been drawn from a Dirichlet distribution (Equation A2.37) with an ancestral allele frequency of p_0 . Beaumont and Balding modeled the divergence associated with locus i in population j as

$$\ln \left(\frac{F_{ST,ij}}{1 - F_{ST,ij}} \right) = 1 + \beta_j + \alpha_i + \epsilon \quad (9.11)$$

where the locus-specific (α_i) and population-specific (β_j) values are estimated using a Bayesian hierarchical model (Appendix 3). Here, all loci in population j contribute to the estimation of β_j , while the values for locus i over all populations contribute to the estimation of its specific effect, α_i . Beaumont and Balding's *BayesFST* approach flags loci of interest when their α_i values fall significantly below zero (with F_{ST} below the population expectation, suggesting balancing selection) or significantly above zero (with F_{ST} above the population expectation, suggesting divergence selection). A number of investigators have refined this approach (Foll and Gaggiotti 2008; Riebler et al. 2008; Bazin et al. 2010; Gautier et al. 2010; Vitalis et al. 2014; de Villemereuil and Gaggiotti 2015).

The power of these model-based approaches has been examined by a number of authors (Pérez-Figueroa et al. 2010; Narum and Hess 2011; Vilas et al. 2012; de Mita et al. 2013; Lotterhos and Whitlock 2014, 2015; de Villemereuil et al. 2014), albeit usually under a modest range of simulated population structures. The conclusion is that these methods, and in particular Foll and Gaggiotti's (2008) *Bayescan* method, can perform well when the populations are either independent draws from a common ancestral population or are well described by an island model. In other settings, such as a spatial migration structure (e.g., alleles from closer demes are more correlated than those from more distant demes) or nonequilibrium conditions (e.g., expansion out of a refugium, and hence the potential for allelic surfing), these approaches have a high false-positive rate. This is true for both apparent signatures of divergent selection (with excessively high F_{ST} values) and balancing selection (with excessively low F_{ST} values). The presence of selfing within demes further exacerbates these issues (de Mita et al. 2013).

Third-generation Lewontin-Krakauer Tests: Correcting for Population Structure

If we refer to the above model-based approaches as **second-generation** Lewontin-Krakauer (LK) tests, **third-generation** LK tests attempt to estimate the covariance structure among the neutral alleles without using a formal model, and then use this to detect outliers. Their motivation traces back to Felsenstein's (2002) extension of his method for independent contrasts among taxa in a phylogeny (Felsenstein 1985) to within-population comparisons, and to the mixed-model approach of Yu et al. (2006) to correct for population structure under association mapping. These third-generation approaches were first used in methods

(discussed below) that were intended to detect correlations between allele frequencies and environmental factors (Hancock et al. 2008; Coop et al. 2010; Eckert et al. 2010; Günther and Coop 2013), and then subsequently applied to Lewontin-Krakauer tests (i.e., F_{ST} data) by Bonhomme et al. (2010), Fariello et al. (2013), Günther and Coop (2013), Duforet-Frebourg et al. (2014), and Gautier (2015). Their basic structure (outlined in Example 9.5) is to first use all (or a part) of the data to estimate either a kinship or covariance matrix of correlations among neutral allele frequencies between demes, and then use this correlation structure to provide adjusted F_{ST} values.

The ***FLK test*** (for F -matrix LK test; see Example 9.5) of Bonhomme et al. (2010) starts with a set of assumed neutral alleles, together with an outgroup (to root the estimated phylogenetic tree of relatedness between demes). Genetic distances are computed for all pairwise combinations of the sampled populations, and a standard neighbor-joining tree is constructed, whose pattern and branch lengths determine the between-deme correlations. This approach is a significant extension from either the star phylogeny (independent draws from an ancestral population) or equal branch length (island model) assumptions of second-generation approaches, allowing for arbitrary historical relationships among the demes (but no migration between them). The ***hapFLK test*** (Fariello et al. 2013) extends the Bonhomme approach to haplotypes. Fariello et al. (2014) applied both the *FLK* and *hapFLK* tests in a genome scan of worldwide sheep populations. The ***Bayenv/Bayenv2*** method of Coop et al. (2010) and Günther and Coop (2013) does not build the correlation matrix from a phylogeny (and hence does not require an outgroup), but rather constructs a covariance matrix for allelic correlations (within and between demes) directly from a set of assumed neutral alleles. As detailed in Example 9.5, it handles migration and also accommodates at least some local inbreeding, making it a slightly more robust approach. The ***PCAdapt*** approach of Duforet-Frebourg et al. (2014) accounts for population structure through the use of latent factors (Example 9.5). While the *Bayenv* approach is population-based (using average allele frequencies within a deme), *PCAdapt* is individual-based, using data from individuals, and hence does not require first structuring sampled individuals into groups.

Simulation studies find that these third-generation approaches perform significantly better than their second-generation counterparts in terms of controlling false positives and are much more robust to different population structures (Bonhomme et al. 2010; Günther and Coop 2013; de Mita et al. 2013; Lotterhos and Whitlock 2014, 2015; de Villemereuil et al. 2014). As succinctly noted by Lotterhos and Whitlock (2014), third-generation approaches “show great promise for accurately identifying loci under spatially divergent selection.” However, they can still generate false positives when allelic surfing occurs, or when there is substantial genomic variance in the impact of background selection, as all of these methods assume all neutral markers in a genome experience a common population-structure effect. They are also biased when selectively influenced loci are included in the markers that are used to estimate the correlation structure.

Despite these numerous issues, F_{ST} -based methods remain popular and have strong supporters (e.g., Beaumont 2005; Novembre and Di Rienzo 2009) as well as detractors (Hermisson 2009). There is no question that they can provide a very useful tool for finding potential *regions of interest*, but great care should be exercised in making anything other than cautious statements about the *statistical significance* of such regions. Whenever possible, third-generation methods should be used.

ALLELE-FREQUENCY CORRELATIONS WITH ENVIRONMENTAL VARIABLES

A final approach for comparing allele frequencies over a set of populations was introduced in Chapter 8, namely to search for correlations between allele frequencies and environmental factors. This approach is often referred to as **environmental association analysis (EAA)** or **genetic-environmental analysis (GEA)**, although our preference is for the former to avoid confusion of the latter with the analysis of genotype \times environment interactions. In such studies, typically, a large number of potential factors are initially considered, and

then the method of principal components (Appendix 5) is used to extract a smaller set of environmental features. If polygenic adaptation is the norm, classic hard-sweep (Table 8.2) or even soft-sweep signals will be unlikely, as the response is driven by modest allele-frequency changes over a number of small-effect loci. Hancock et al. (2010a, 2010b) suggested that such polygenic sweeps might be detected through subtle allele-frequency shifts that are concordant in populations experiencing similar environments but in different geographic regions.

Searching for correlations between environmental factors (such as locations along some environmental gradient) and the frequency of alleles is a time-honored tradition in population genetics, tracing back to Dobzhansky's work on clines in *Drosophila* chromosome inversions (Lewontin et al. 1981). Historically, these approaches have assumed the presence of a candidate gene and some specific environmental factor or surrogate (such as latitude or altitude). A number of complications arise when moving from testing the association of a single gene with a single environmental variable to scanning a large number of genes and a set of environmental factors. First, all frequency-environmental correlation tests must deal with lack of power (the limiting feature is the number of sampled locations). This limited power is exacerbated by multiple comparisons (Appendix 4), as with n_g biallelic loci and n_e environmental factors, there are $n_g n_e$ comparisons. To accommodate this concern, results are often reported using Storey's q values (Equation A4.24), a measure of the false-discovery rate given the significance of a test. Appendix 4 details how a list of p values for a collection of tests is translated into a list of associated q values, whose interpretation is as follows. Suppose $q \leq 0.025$ for a specific comparison in a collection of tests. This implies that the false-discovery rate for that association is no greater than 2.5%. It further implies that the false-discovery rate for *any* other test in this collection with the same, or a smaller, p value (as our focal test) also has a false-discovery rate of no greater than 2.5%.

Many factors conspire to reduce the power of such association approaches by decreasing the correlation between present environmental values and current allele frequencies. Even when allele-frequency change has been shaped by the environment, the currently measured environment may be rather different from the historical values that generated the present frequency of an allele. There is also an assumption that the same allele is acted on by selection, and with the same LD pattern at nearby markers, over a majority of the demes where the selection pressure is present. If different alleles (perhaps at different loci) accomplish the same adaptation to an environmental feature or if the LD structure between markers and selected alleles varies over demes, this will further erode any signal. Finally, false-positives can be introduced when gene-flow correlates with environmental features. Consider a population expanding from a southerly glacial refugium. As individuals migrate out, the result is a north-south cline in neutral allele frequencies. Such a north-south gradient can also occur in environmental variables (e.g., temperature or hours of sunlight), creating a correlation between such features and allele frequencies. Despite these concerns, EAA approaches have the potential to detect effects that would be missed by standard F_{ST} outlier approaches that are "blind" with respect to any environmental information.

Joost's Spatial Analysis Method (SAM)

The extension of testing for an association between a specified candidate gene and a single environmental factor to a more general genome scan over a set of environmental features starts with Joost et al. (2007). Their **spatial analysis method (SAM)** computes separate logistic regressions for each allele-environment combination. As discussed in Chapter 14, logistic regressions are commonly used to model how the probability of an event varies with some other variable, in this case predicting allele frequency as function of the environmental value. As with second-generation LK tests, SAM has a critical limitation in assuming that neutral alleles from different populations are uncorrelated. Failing to account for the natural correlation in neutral allele frequencies shaped by shared migrations and/or history will yield incorrect sampling errors. Further, populations in geographic proximity are expected to have both correlated allele frequencies (due to migration) *and* correlated environmental

values, generating many false positives. While Poncet et al. (2010) extended *SAM* by allowing for small-scale correlations in allele frequencies within spatially proximate demes, their approach does not adjust for larger-scale correlations.

Accounting for Population Structure: Coop's *Bayenv* and Frichot's *LFMM*

Coop et al. (2010; Eckert et al. 2010; Günther and Coop 2013; also see Gautier 2015) attacked the problem of adjusting for unknown population structure by using marker data to estimate the expected correlation pattern among neutral alleles for the sampled populations. This is akin to the kinship matrix approach used by Bonhomme et al. (2010) to adjust for correlations among allele-frequency values from different demes. Example 9.5 sketches the basic structure of their *Bayenv* approach, which uses Bayes factors (Appendix 2) to gauge the support for an allele-environmental correlation after the effects of population structure have been removed. Formally, however, this is still an outlier method, as it generates an empirical distribution of Bayes factors for each SNP and uses this to assess the strength of association for a given locus. An alternative implementation to adjust for population structure, which is very closely related to Coop's method (as well as to Duforet-Frebourg et al.'s previously mentioned *PCAdapt* approach), is the **latent factor mixed model (LFMM)** approach of Frichot et al. (2013), which is also outlined in Example 9.5.

Simulations by Frichot et al. (2013) and de Villemereuil et al. (2014) found that the *LFMM* approach, along with *Bayenv*, is more powerful and less prone to false positives than methods that do not account for allelic correlations. These authors further found that *LFMM* tends to be slightly less biased than *Bayenv*, perhaps because, under this approach, both the locus-specific environmental effects and the latent population structure are estimated simultaneously, while in *Bayenv* the latter is estimated first and then used to estimate environmental effects. One further advantage of *LFMM* is that the lower-dimensional representation of the covariance structure can result in less bias than using the full structure, whose minor components are generally estimated with error (we return to this issue in Volume 3 when examining the structure of the genetic variance-covariance matrix, \mathbf{G} , associated with multivariate selection; Equation 13.23b).

De Mita et al. (2013), de Villemereuil et al. (2013), and Lotterhos and Whitlock (2015) compared the power of divergence-based (F_{ST}) and correlation-based (EAA) approaches for detecting selection under a number of population structures and assumed selection strengths. The results were somewhat mixed. For example, EAA can outperform divergence-based approaches under an island model, but tended to do poorly under an isolation-by-distance structure. Lotterhos and Whitlock (2015) made the critical point that the sampling design has a major impact. They contrasted three different designs: random sampling over a metapopulation, paired-sampling, and transect-sampling. Under paired sampling, one specifically chooses pairs of populations that are proximally close but that differ substantially in the target environmental variables, and Lotterhos and Whitlock found that this tended to be the most powerful design.

We close this section to noting that EAA is an extremely active research area, with new methods appearing frequently. Recent reviews of some of the evolving issues are given by Rellstab et al. (2015), François et al. (2016), and Hoban et al. (2016).

Example 9.5. Here we sketch out the basic structure of four extensions (*FLK*, *Bayenv*, *LFMM*, and *PCAdapt*) of LK and allele-environment correlation tests that attempt to account for among-deme correlations in allele frequencies. The details are fairly technical, but the basic idea is very similar to that for the Fisher-Ford test (Example 9.2). There, under the assumption of drift, a vector, \mathbf{y} , of allele-frequency changes is turned into a test statistic that is in the form of a quadratic product (Equation 9.6c), $\mathbf{y}^T \mathbf{V}^{-1} \mathbf{y}$, where \mathbf{V} is the covariance for these expected changes under drift alone. This is simply the generalization of a test based on the squared difference between two allele frequencies to a vector of allele frequencies. If \mathbf{y} is multivariate normal, this test statistic follows a χ^2 distribution and excessive values indicate a departure

from the pure-drift model. This basic idea, and structure, also follows here. The extensions follow from an adjustment of the vector of changes to account for environmental influences on allele frequencies and more generalized covariance matrices, given the population structure.

The F_{ST} extension (*FLK*) of Bonhomme et al. (2010) uses a set of neutral loci together with an outgroup to construct a kinship matrix, \mathcal{F} , of populations, based on branch lengths of the estimated phylogenetic tree among the sampled populations. The assumption is that some pattern of evolution (described by \mathcal{F}) unfolds from an ancestral population with an allele frequency of p_0 , but with no further migration between subpopulations. For n populations, the *FLK* test statistic is given by

$$T_{FLK} = \frac{(\mathbf{p} - \hat{p}_0 \mathbf{1})^T \mathcal{F}^{-1} (\mathbf{p} - \hat{p}_0 \mathbf{1})}{\hat{p}_0(1 - \hat{p}_0)}, \quad \text{with } \hat{p}_0 = \frac{\mathbf{1}^T \mathcal{F}^{-1} \mathbf{p}}{\mathbf{1}^T \mathcal{F}^{-1} \mathbf{1}} \quad (9.12)$$

where \mathbf{p} is a vector of the allele frequencies for one particular locus over the n sampled demes and $\mathbf{1}$ is a column vector of n ones. Bonhomme et al. showed that T_{FLK} follows a χ^2 distribution under the null model of no selection, provided allele frequencies are not too extreme, with outliers deemed to be candidates for loci under selection. Note that \hat{p}_0 is of the same form as the GLS estimators for the initial frequency (Equations 9.4 and 9.6a), and that T_{FLK} has the same general form as the test statistic for the Fisher-Ford test for excessive allele-frequency change (Equation 9.6c).

The *Bayenv* test for allele-frequency and environmental correlation (Coop et al. 2010; Eckert et al. 2010; Günther and Coop 2013) starts with a clever latent-variable approach (from Nicholson et al. 2002) to model the allele frequencies, which allows us to work with an (approximately) multivariate-normal vector. The motivation for this approach is the constraint that allele frequencies be confined to the interval [0,1], while the multivariate normal can generate values outside this region. To avoid this issue, assume there is some underlying latent (unseen) variable, θ , that is normally distributed and maps into the deme allele frequency p as follows

$$p = \begin{cases} 0 & \text{if } \theta \leq 0 \\ \theta & \text{for } 0 < \theta < 1 \\ 1 & \text{if } \theta \geq 1 \end{cases} \quad (9.13a)$$

This truncated normal transformation allows for nonzero probabilities that p is at zero or one, corresponding to loss or fixation of the allele, respectively. This transformation allows us to work with a normally distributed random variable, θ , which is mapped into allelic loss ($\theta < 0$) or fixation ($\theta > 1$) if it is too extreme, and otherwise maps into the frequency of a segregating allele. As with most F_{ST} -based methods, the assumption here is that there is very little probability mass at zero or one (i.e., there is modest divergence at most loci), so p is essentially θ .

Following Nicholson et al. (2002), Coop et al. (2010) assumed that the vector, Θ , of θ values for the n sampled populations is multivariate normal (approximating drift by Brownian motion; Appendix 1), with some ancestral frequency (p_0) and correlation structure given by Ω , so that

$$\Theta \sim \text{MVN}_n [p_0 \mathbf{1}, p_0(1 - p_0) \Omega] \quad (9.13b)$$

where Ω is the empirical estimate of the covariance matrix of the underlying θ (and hence of the allele frequencies), based on a set of presumed neutral markers (for details see Coop et al. 2010 and Gautier 2015). This is their base model. Note that standardizing the observed vector of frequencies, \mathbf{p} , by centering it around the mean and adjusting for the covariance structure yields a χ_{n-1}^2 random variable (as the quadratic product is the sum of squared unit normals). This recovers the T_{FLK} test statistic, but with Ω and Θ in place of \mathcal{F} and \mathbf{p} . Operationally, if all elements of \mathbf{p} fall within the range (0, 1), then \mathbf{p} replaces Θ , yielding the test statistic as

$$\frac{(\mathbf{p} - \hat{p}_0 \mathbf{1})^T \Omega^{-1} (\mathbf{p} - \hat{p}_0 \mathbf{1})}{\hat{p}_0(1 - \hat{p}_0)} \quad \text{where } \hat{p}_0 = \frac{\mathbf{1}^T \Omega^{-1} \mathbf{p}}{\mathbf{1}^T \Omega^{-1} \mathbf{1}} \quad (9.13c)$$

which is identical in form to Equation 9.12, except that the covariance matrix Ω replaces \mathcal{F} . Günther and Coop (2013) denoted this test statistic for extreme divergence at a specific locus by $\mathbf{X}^T \mathbf{X}$, which some authors refer to as the *XtX statistic*.

Some comment on Ω versus \mathcal{F} is in order. Ω is the empirical estimate of the allelic-covariance matrix, while \mathcal{F} is based on the estimated branching pattern of deme formation (assuming there is no between-deme migration). Hence, Ω is expected to perform better in situations where the correlations induced by population structure are poorly approximated by a phylogenetic tree, as can be the case with migration between demes (Günther and Coop 2013). Further, because Ω also contains the within-deme variance, it should be slightly more robust to within-deme inbreeding relative to \mathcal{F} , which only considers the covariances between demes. Finally, it should be stressed that the χ^2 distribution only formally arises when Ω is known without error. When Ω is replaced by some estimate, $\hat{\Omega}$, of its true value, this distribution no longer holds.

Coop's base model (Equation 9.13c) is extended to account for environmental factors that influence the allele frequencies as follows. Consider a vector, β , of potential regression coefficients for the impact of environmental factors on allele frequencies, and a matrix, X , whose values in row i correspond to the environmental parameters measured for the i th population (this is simply a GLS linear model; see LW Chapter 8). The null mean p_0 for an allele (Equation 9.13c) is augmented by the environmental effect to give

$$\Theta \sim \text{MVN}_n [p_0 \mathbf{1}_n + X\beta, p_0(1 - p_0)\Omega] \quad (9.13d)$$

where $\mathbf{1}_n$ is an n -dimensional vectors of ones. This model assumes that any relationships between allele frequencies and the environmental variables have some linear component. The addition of the vector $X\beta$ to account for environmental effects is an example of a **factorial regression** (e.g., Baril et al. 1992), which is discussed at length in Volume 3 in the context of analyzing genotype-by-environment interactions.

Coop et al. (2010) couched their model in a Bayesian framework, which involves a different logic for hypothesis testing than the standard likelihood-ratio approach. As reviewed in Appendix 2, hypothesis testing in a Bayesian framework uses **Bayes factors**, which account for how much the data shift any prior belief in favor of a hypothesis (Equations A2.10a and A2.10b; Example A2.3). Coop et al. cautioned that hypothesis testing with their model (Equation 9.13d) is not as straightforward as simply asking whether the inclusion of a nonzero β (meaning that environmental factors influence at least some allele frequencies) significantly improves the fit (a large Bayes factor in favor of $\beta \neq 0$ over the null $\beta = 0$), as their model is only an approximation of the population structure. They noticed that the inclusion of environmental variables strongly influenced the distribution of Bayes factors among their set of control (and presumably neutral) loci used to estimate Ω . As a result, they recommend an outlier approach, in which the Bayes factor for a given locus is compared with the empirical distribution of Bayes factors for control loci that include that environmental variable. This is easiest to handle by using principal components to transform the environment variables to a new and independent set (e.g., Equation A5.15a), and then testing these one at a time. Test-statistic values are computed by adjusting the base-model quadratic product (Equation 9.13c) to account for environmental variables, which shifts the vector of means from $p_0\mathbf{1}$ to $p_0\mathbf{1} + X\beta$ (Equation 9.13d), yielding

$$\frac{(\mathbf{p} - \hat{p}_0\mathbf{1} - X\hat{\beta})^T \Omega^{-1} (\mathbf{p} - \hat{p}_0\mathbf{1} - X\hat{\beta})}{\hat{p}_0(1 - \hat{p}_0)} \quad (9.13e)$$

The *Bayenv* method of Coop et al. is a two-step approach: (i) Ω is estimated from a presumed set of neutral markers, and (ii) the model is run with this matrix (or in a Bayesian framework, with draws of this matrix to generate a posterior accounting for the uncertainty in its estimation; Appendix 2).

Finally, the *LFMM* approach of Frichot et al. (2013) is a one-step model, which jointly fits β along with a series of random vectors (latent factors) to account for the population structure. In essence, this model approximates the allelic covariance structure by a matrix of lower rank (the rank given by the number of latent factors included in the model), by using what in essence are the first k principal components of Ω . These lower-rank approximations are discussed extensively in Volume 3, both in terms of estimating the rank of a multivariate selection covariance matrix, G , and in computing additive main effects and multiplicative interaction (AMMI) models for genotype-by-environment interactions. Frichot et al. claimed

slightly better results are obtained with *LFMM* than with *Bayenv* as a result of using a one-step approach. As mentioned, however, this could simply be due to a less-than-full rank estimate of the covariance matrix being better behaved, as the imprecise estimation of eigenvectors associated with minor eigenvalues may slightly bias the results. The *PCAdapt* approach of Duforet-Frebbourg et al. (2014) is essentially the same as *LFMM*, except with $\beta = 0$ (i.e., environmental associations are not considered).

CHANGES IN THE CHROMOSOMAL PATTERN OF NEUTRAL VARIATION

The classic signature of a recent hard sweep is a chromosomal region of depressed variation, while a site under long-term balancing selection displays enhanced variation, albeit over an ever-shrinking region (Chapter 8). This section develops methods based on the expected spatial pattern of variation on a chromosome around a selected site following a hard sweep. We start with simple graphical methods for suggesting interesting regions before considering a number of approaches based on maximum likelihood (ML) (LW Appendix 4). The details of some ML-based positional models can be challenging, but there is little question that using genomic positional information can significantly improve our ability to detect a recent hard sweep and provide estimates of its strength of selection. We present much of the technical detail to the examples, which the casual reader may prefer to skip.

Simple Visual Scans for Changes in Nucleotide and STR Diversity

The most basic approach is a simple plot of variation as a function of genomic location, looking for either peaks (long-term balancing selection) or valleys (a recent sweep); see, for example, Figures 8.1 and 8.2. With SNP data, variation is typically scored as average nucleotide diversity, π (Chapter 4), within a sliding window to smooth out the inherent noisiness from individual sites. With simple sequence repeats or microsatellite markers (also known as simple tandem repeats, or STRs, and simple sequence repeats, or SSRs), several different metrics of variation are available, such as copy-number variance, number of alleles, and probability of heterozygosity. With their large number of alleles per marker and high mutation rates, STRs provide a more consistent signal and are usually plotted on a per-marker basis (as opposed to a sliding-window analysis); see Figure 9.3 and Example 9.6. A point of caution is that mutation rates at STRs can be length dependent, with smaller arrays often expected to show less variation.

Example 9.6. Domesticated breeds of dogs are ideal candidates for the detection of regions influenced by selective sweeps (Schlamp et al. 2016). Most breeds are rather recent (~ 200 generations or less) and often exhibit large phenotypic effects (and hence harbor the potential of strong selection on just a few genes). Simulation studies by Pollinger et al. (2005) found that a few moderately linked, highly polymorphic loci can give a strong sweep signal under realistic conditions for the formation of dog breeds. They tested their idea using a scan of microsatellites around candidate genes in two different breeds. The Large Munsterlander is a recent breed (originating around 1910) and categorized by a black coat color, with the pigment gene *TYRP1* being suggested as a candidate for this trait. As Figure 9.3A shows, there is a roughly 50 Mb region of depressed microsatellite variation around *TYRP1* relative to the control (neither black or brown) and brown-coated populations. Note that the region under the sweep is rather large, and if indeed *TYRP1* was the actual target, this region is asymmetric, showing more reduced variation to the right of *TYRP1* than at the locus itself. (Recall from Chapter 8 that such asymmetries around a selected site are not uncommon.) A more striking example is offered by dachshunds (Figure 9.3B), which showed no variation at three microsatellites surrounding the *FGFR3* candidate gene that is involved in achondroplasia (limb-shortening).

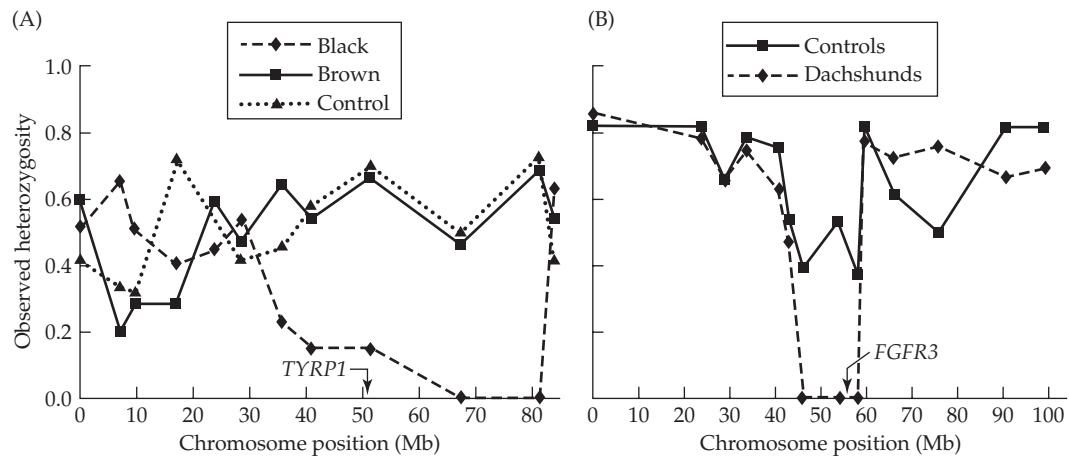

Figure 9.3 Using microsatellites in the search for dog domestication genes. (A) Large Munsterlanders have a black coat, suggesting the pigment gene *TYRP1* on chromosome 11 may be a possible domestication gene. A plot of variation for this breed (black) relative to both control (neither black or brown) and brown individuals shows depressed variation spanning this gene. (B) Dachshunds are characterized by shortened limbs, suggesting the *FGFR3* gene on chromosome 3 as a candidate. Dachshunds have an absence of variation at three microsatellites spanning this gene, while variation is present in controls (normal-limbed breeds). (After Pollinger et al. 2005.)

Both Munsterlanders and dachshunds went through strong bottlenecks during their formation, so sampling noise that was overlaid on the general reduction in variation from the bottleneck may have generated these depressions. To test for this, Pollinger et al. simulated the founding process (akin to what was done in Example 9.3). Assuming the loci are highly polymorphic (STR heterozygosity in excess of 30% prior to the bottleneck), simulations showed a less than 5% chance of finding three adjacent STR loci with no variation under a simple model of a genome-wide population bottleneck during founding (conditioned on the average levels of heterozygosity seen throughout the genome).

These examples in dogs show the power (strong signal with only modestly dense markers) but also the pitfalls (poor localization) when a strong sweep occurs. Because a sweep depresses variation throughout a region, additional sweep-based fine-mapping within this region would be futile. Ironically, localization is easier under a weak sweep than a strong one, as the region of depressed variation is smaller. Because the same traits often appear in independent dog breeds, one potential solution is that if the same gene (or genes) were the targets of selection in each breed there is the potential for improved resolution by searching for overlapping intervals in the detected sweep regions. Chan et al. (2012) used a variant of this approach by comparing the results of seven independent mouse lines selected for increased weight, finding ~70 parallel selected regions (PSRs), where most of the high-weight selected lines shared alleles rarely found in the controls.

While such plots of the spatial structure of genome variation are visually appealing, they are not formal tests of selection and can indeed be rather misleading. A change in the background level of variation can arise for several reasons besides selection, such as variation in the local mutation rate. This is especially true for STR markers, whose mutation rates are expected to vary considerably, reflecting differences in the composition (size and sequence) of their repeat units. Second, the inherent stochasticity of recombination and drift can generate considerable variation in the coalescent process across a genome, so that even with a sliding window analysis for a set of markers with the same mutation rate, strong peaks and valleys are routinely found in neutral simulations (Kim and Stephan 2002; Jensen

at al. 2005).

Two different strategies can address these complications. The first is to use information from the same (and other) regions in several populations. If a region has a low (or high) mutation rate relative to the rest of the genome, presumably this will also be true in other populations or closely related species. For example, a large reduction in STR variation was seen around the *pfCRT* gene, which has been implicated in chloroquine resistance in the malaria parasite *Plasmodium falciparum* (Wootton et al. 2002). This reduction was seen in resistant lines from both South America and Asia and Africa, but was absent in sensitive lines from Asia and Africa, strongly suggesting that the reduction is not due to genomic differences in mutation rates.

However, if one compares *just* a narrow region of interest between two populations, one might (incorrectly) infer a sweep-like signal if one of the populations has experienced a bottleneck (as might occur in the domestication process). Ideally, one would compare k different regions in $n \geq 2$ populations. As detailed below, this can be done with a simple ANOVA approach or through more formal ML-based **bottleneck models**. These approaches examine if some loci appear to have experienced a more severe bottleneck than others in the same genome, which would be consistent with hard sweeps in those regions.

Second, in the absence of information from other populations, **explicit chromosomal spatial-structure models** can be applied. These use ML to compare the genomic positional pattern of variation as a function of recombination fraction over a region of interest, testing whether the fit is consistent with the pattern expected from a sweep (e.g., Equation 8.8a). This approach is both the most powerful (when modeling assumptions hold), and potentially the most fragile (when they do not), and we will address some of these concerns and their potential corrections.

Tests Based on STR Variation Across Populations

Schlötterer and colleagues (Schlötterer et al. 1997; Harr et al. 2002; Schlötterer et al. 2002; Kauer et al. 2003; Schöfl and Schlötterer 2004) proposed several straightforward tests using k unlinked markers sampled from n populations. While their tests used STR/SSR data, this same approach can be applied to SNP data in nonoverlapping windows. ANOVA is used to obtain site- and population-specific values to correct (respectively) for variation in mutation rates over loci and variation in N_e over populations, and then test if a specific locus-population combination is unusual.

Consider a set of STRs, and let V_{ij} denote the variance in repeat copy number at locus i in population j . Because variances typically have a skewed distribution, we work instead with $v_{ij} = \ln(V_{ij})$, as a log transform reduces the effects of skew. The effects of locus-specific mutation rates are accounted for by averaging locus i over all populations ($v_{i\cdot}$), while population-specific effects are accommodated by using the average ($v_{\cdot j}$) of population j over all loci. Under the assumption of no locus \times population effects and no LD between scored markers, the expected log-variance can be written as a simple ANOVA model

$$v_{ij} = v_{i\cdot} + v_{\cdot j} - v_{\cdot\cdot} + e_{ij} \quad \text{for } 1 \leq i \leq k, 1 \leq j \leq n \quad (9.14)$$

A sweep in population j near the i th STR is indicated by a significant deficiency relative to the predicted value, $\hat{v}_{ij} = v_{i\cdot} + v_{\cdot j} - v_{\cdot\cdot}$, which can be tested using a *t*-like statistic (Schlötterer et al. 1997).

A related approach is the **Log RV** statistic of Schlötterer (2002). For a single-step mutation model (meaning that STR repeat length is equally likely to change by plus or minus one following a mutation), the expected variance is $\sim 4N_e\mu$ where μ is the locus-specific mutation rate (Slakkin 1995b). Thus, the locus-specific mutation rate cancels out in the ratio $RV = V_{ij}/V_{i\ell} = 4N_{j,e}\mu_i/4N_{\ell,e}\mu_i = N_{j,e}/N_{\ell,e}$ for the same locus (i) in two different populations (j and ℓ), leaving only the ratio of effective population sizes. (The related **Log RH** statistic of Kauer et al. 2003 uses the ratio of heterozygosities, as opposed to copy-number variance.) Simulation studies showed that the distribution for the logs of these two ratios is approximately a normal under many demographic scenarios, with the exception of extreme

bottlenecks. While similar in spirit to Equation 9.14, the *Log RV* and *Log RH* statistics are outlier approaches, computing all pairwise values and using outliers as potential sites of selection. Modifications have been proposed for two linked STRs (Harr et al. 2002), while Wiehe et al. (2007) proposed a follow-up statistic as an additional test for an STR showing signs of selection.

Tests of Sweeps Using Bottleneck Models

In domesticated species, one can imagine a founding bottleneck that reduced variation across all loci relative to the ancestral source population. However, *in addition* to this common bottleneck, a *further* reduction will likely be associated with genes selected during domestication (assuming these generate hard sweeps), which can be thought of as an additional bottleneck beyond the genome-wide founding bottleneck. This idea leads to a more formal ML-based test. Data for multiple loci from two (or more) populations are first used to estimate a common bottleneck value for loci in one population (relative to another). One then tests whether the model fit is improved by allowing a subset of these loci to experience an additional bottleneck (as would happen with a sweep following the initial domestication bottleneck). One potential weakness of this approach is background selection (BGS). If there is significant variance over the genome in the ratio of gene density to recombination rate, a model assuming an additional bottleneck may provide an improved fit (even in the absence of sweeps), simply by capturing some of the genomic heterogeneity in loss of variation from BGS.

The bottleneck approach was first considered by Galtier et al. (2000). They assumed the existence of a population in mutation-drift equilibrium at some ancestral time, where $\theta_i = 4N_e\mu_i$ measures variation at the i th locus (Chapter 2). At some time, T , in the past (scaled in terms of $2N_e$ generations), a bottleneck occurred, and after some passage of time in the bottleneck, the population quickly expanded back to its previous size. The authors made the clever observation that while a bottleneck is a reduction in population size, the net result is that the number of distinct lineages going into a bottleneck is far greater than the number that escape it. Motivated by this observation, they introduced a measure of bottleneck strength, B , which is the expected amount of time required to lose the same number of lineages as in a model of constant population size. They then assumed for some time, 0, until T , a standard neutral coalescent process is occurring, with mutations and coalescent events (Chapter 2). From time $T < t < T + B$, only coalescences are allowed (mutation is effectively turned off), reducing the number of surviving lineages. Finally, from time $t > T + B$, mutation is turned back on again. Given a population sample of segregating sites over k loci, the method of Griffiths and Tavaré (1994a, 1994b) can be used to obtain maximum likelihood estimates of T , B , and θ_i for $1 \leq i \leq k$. Galtier et al. then constructed a model where the bottleneck is potentially different for each locus, in which case T and B are now locus specific, and one estimates T_i , B_i , and θ_i for $1 \leq i \leq k$. A standard likelihood ratio test (LW Appendix 4) determines if the second model provides a better fit.

Example 9.7. Wright et al. (2005) used a multiple bottleneck model in their search for genes under selection in maize. The authors used SNP data on 774 genes from 14 maize and 16 teosinte inbred lines. Collectively, the sampled maize lines had roughly 60% of the heterozygosity found in teosinte lines, showing a strong bottleneck signal across the entire maize genome (as expected from the initial domestication process). The authors quantified the strength of this bottleneck using the parameter $b = N_b/d$, the size of the population in the bottleneck divided by its duration. Smaller values of b imply stronger bottlenecks. Using simulations with different values of b , the maximum likelihood given the numbers of segregating sites at a given locus in maize and teosinte occurred at a value of $\hat{b} = 2.45$.

The authors then fit a second model that assumed two classes of loci: a fraction, $(1 - q)$, experiencing a bottleneck of strength b_1 and a fraction, q , experiencing a much stronger

bottleneck of strength, $b_2 < b_1$, giving the resulting likelihood for locus i as

$$L(q, b_1, b_2 | S_i) = (1 - q)L(b_1 | S_i) + q L(b_2 | S_i) \quad (9.15a)$$

where $L(b_j | S_i)$ is the likelihood function for b_j ($j = 1, 2$), given the number, S_i , of segregating sites in maize at locus i . Assuming loci are independent, the full likelihood is the product over all loci. This is a mixture model (LW Chapter 13), with parameters of q , b_1 , and b_2 , and again, the model can be searched by simulation to locate the ML estimates (MLEs). The resulting MLEs using all 774 genes were $\hat{b}_1 = 2.45$, $\hat{b}_2 = 0.15$, and $\hat{q} = 0.02$. However, many of the loci had low variation even in teosinte and offered little information on b . Using a set of 275 genes with high variation (10 or more segregating sites in teosinte) returned MLEs of $\hat{b}_1 = 2.45$, $\hat{b}_2 = 0.01$, and $\hat{q} = 0.036$. This sample of $\sim 4\%$ of maize genes potentially experienced a much greater bottleneck (smaller b) than the rest of the genome, and hence this set contains strong candidates for sites influenced by a sweep.

With these estimates in hand, one can use Bayes' theorem (Equation A2.2) to obtain the posterior probability of a locus being in this selected (stronger bottleneck) class, and hence localize genes that potentially were under past selection. Recall that Bayes' theorem allows one to "flip" the conditional, as we can easily compute $\Pr(S_i | b_j)$ —indeed, this is just the likelihood, $L(b_j | S_i)$ —but we are much more interested in $\Pr(b_j | S_i)$. Bayes' theorem connects these as

$$\Pr(b_2 | S_i) = \frac{q L(b_2 | S_i)}{(1 - q)L(b_1 | S_i) + q L(b_2 | S_i)} \quad (9.15b)$$

This gives a posterior probability for a particular locus (i) being in the strong bottleneck class (b_2), given that it has S_i segregating sites in maize. This same approach for posterior prediction reappears in Example 10.15 in the context of predicting which sites in a protein have been under positive selection.

Tests of Sweeps Using Genomic Positional Information: CLRT-GOF

While bottleneck approaches are elegant, they ignore any information from the expected spatial pattern of variation across a chromosomal region, for example, the functional form of the expected decrease in variation as one moves closer to the site of selection. Further, they require samples from two (or more) populations, which may be impractical. Kim and Stephan (2002) proposed a likelihood-based test using the positional pattern of variation from a single population, which not only detects a sweep, but also localizes its position and estimates its strength of selection. A similar regression-based approach was suggested by Wiener and Pong-Wong (2011).

The basic structure of their test (and several extensions) is as follows. Suppose m linked segregating sites from a local chromosomal region of interest are scored in a sample of n chromosomes. Using an outgroup, we can polarize any segregating alleles, determining which are derived. The resulting data are the number, k_i , of copies of the derived alleles at a segregating site, i , where $1 \leq k_i \leq n - 1$. Building on Equation 2.36c, the probability of observing k_i given the sample size n and the vector Θ of model parameters is simply

$$\Pr(k_i | n, \Theta) = \binom{n}{k_i} \int_{1/(2N)}^{1-1/(2N)} x^{k_i} (1-x)^{n-k_i} \phi_i(x | \Theta) dx \quad (9.16a)$$

where $\phi_i(x | \Theta)$ is the frequency spectrum for site i under the model (specified by the distribution parameter vector, Θ) of interest. Equation 9.16a is also the likelihood for Θ given the data, $L(\Theta | k_i, n)$. Under the equilibrium neutral model, the Watterson distribution (Equation 2.34a) is used for ϕ_i , where the vector of distribution parameters, Θ , is just a scalar, as $\Theta = (\theta_i) = (4N_e \mu_i)$, the scaled mutation rate for site i . If one starts with a Watterson distribution and then has a sweep at a linked site, ϕ_i is now given by Equation 8.13, with parameters $\Theta = (\theta_i, f_{s,i})$, where $f_{s,i}$ measures the strength of the sweep at site i . From Table 8.1

$$f_{s,i} = (4N_e s)^{-c_i/(2hs)} = e^{-c_i \lambda} \quad (9.16b)$$

with $\lambda = (1/2hs) \ln(4N_e s)$, and c_i representing the recombination fraction between site i and the site of the sweep. Usually one assumes that $\theta_i = \theta$ is the same for all sites, in which case, under the null model, all sites follow the same Watterson distribution (with no expected position-specific genomic pattern).

Because Equation 9.16a gives a proper likelihood for each site, one might imagine that the total likelihood $L(\Theta | \mathbf{k}, n)$, given the vector \mathbf{k} of the k_i values for each site, is simply the product of the site-specific likelihoods over all m sites

$$L(\Theta | \mathbf{k}, n) = \prod_{i=1}^m L(\Theta | k_i, n) \quad (9.16c)$$

with the MLE for Θ being the value that maximizes $L(\Theta | \mathbf{k}, n)$. However, this product is *not* a proper likelihood, as adjacent sites are *correlated* (due to shared history). The product of the site likelihoods (Equation 9.16c) is thus a **composite likelihood** (also called a **quasi-maximum likelihood** or **pseudo-likelihood**), which is an approximation of the total likelihood. Wiuf (2006) showed that the composite and true likelihoods are usually consistent for many population-genetic problems. Kim and Stephan (2002) contrasted the maximum value of this composite likelihood under the Watterson distribution (using Equation 2.34a for ϕ) with the maximum obtained under a sweep model (using Equation 8.13 for ϕ). Because f_s changes with distance c_i from any particular site (Equation 9.16b), the location giving the maximum value of f_s corresponds with the estimated position of the selected site. Kim and Stephan compared the ratio of the two composite likelihoods, $L_{\text{sweep}}/L_{\text{neutral}}$, corresponding to

$$\Lambda_{CLR} = \frac{\max L(\theta, f_s(\lambda, c_i) | \mathbf{k})}{\max L(\theta, f_s = 0 | \mathbf{k})} \quad (9.16d)$$

and called this approach the **CLR test** (or **CLRT**), for **composite-likelihood ratio test**. Because this is *not* a strict likelihood ratio, large-sample approximations (LW Appendix 4) for its distribution are *not* valid, and the critical values must be obtained by simulation. Boitard et al. (2009; also see Kern and Haussler 2010) proposed the use of hidden Markov models to account for the correlations among markers that are ignored under a composite-likelihood framework. Li and Stephan (2005, 2006) developed a true maximum-likelihood method that uses only a subset of the frequency spectrum (the **compact frequency spectrum**, recording the number of singletons, doubletons, and sites greater than two) to estimate the position of the sweep.

Jensen et al. (2005) found that the CLR test is *not* robust to population structure or recent bottlenecks. While neither of these demographic features is expected to generate the same spatial pattern as seen under a sweep, they *can* generate an excess of sites segregating rare derived alleles, so that some aspects of the frequency spectrum can be similar to a sweep, and this in turn could improve the fit relative to a model assuming the equilibrium Watterson distribution. To distinguish sweeps from false signals generated by demography and population structure, Jensen et al. proposed that any significant CLR result be subjected to an additional goodness-of-fit (**GOF**) test to see how well it fits a sweep model (Example 9.8). Again, the key is that a sweep is expected to generate a specific *spatial pattern* of variation, which will be absent under neutrality even if the site-frequency spectrum is shifted because the population is not at equilibrium.

Kim and Nielsen (2004) extended the CLRT to include information on linkage disequilibrium using their ω statistic (Equation 9.37), which contrasts measures of LD among all pairs of loci on the same side of a putative sweep with those for pairs of loci on opposite sides of the sweep. While incorporation of this LD information did improve estimation, the gain was rather modest. Finally, Meiklejohn et al (2004) and Vy and Kim (2015) have extended the CLRT for detecting incomplete sweeps. The basic logic is as above, but with only a partial shift in the frequency of the selected allele (as it is still on its sojourn to fixation).

Example 9.8. The *GOF* test of Jensen et al. (2005) starts by comparing the maximum of the composite-likelihood function under the sweep model (as the null) against the maximum of the likelihood under a more general model, L_A , where the population frequency of the derived allele is unique for each site, but *uncorrelated between sites*. This latter assumption is the key, as a sweep is expected to generate a specific correlated pattern of variation (runs of extreme frequencies) near the selected site. The likelihood function for site i under the L_A model—namely, an unknown, but arbitrary, frequency p_i at site i —follows from the binomial distribution. Given the observation of k_i copies of the derived allele (out of n sampled)

$$L_A(p_i | k_i) = \binom{n}{k_i} p_i^{k_i} (1 - p_i)^{n-k_i} \quad (9.17a)$$

The resulting maximum-likelihood estimate (MLE) for p_i is simply $\hat{p}_i = k_i/n$ (LW Appendix 4), giving the value of the likelihood function evaluated at the MLE as

$$L_A(\hat{p}_i | k_i) = \binom{n}{k_i} (\hat{p}_i)^{k_i} (1 - \hat{p}_i)^{n-k_i} = \binom{n}{k_i} \left(\frac{k_i}{n} \right)^{k_i} \left(1 - \frac{k_i}{n} \right)^{n-k_i} \quad (9.17b)$$

Assuming that the site-specific p values are uncorrelated, the total composite likelihood is the product of Equation 9.17a over all sites. If there are n_i sites, each with i copies of the derived allele, their contribution to the total likelihood is the n_i th power of Equation 9.17b, with the maximum of the composite likelihood being the product of the individual maximum likelihoods (Equation 9.17b) across all levels of polymorphisms

$$\max(CL_A) = \prod_{i=1}^{n-1} \left[\binom{n}{i} \left(\frac{i}{n} \right)^i \left(1 - \frac{i}{n} \right)^{n-i} \right]^{n_i} \quad (9.17c)$$

The *GOF* test is the log of the ratio of the maxima of the two different likelihoods

$$\Lambda_{GOF} = \ln \left(\frac{\max(CL_A)}{\max(CL_0)} \right) \quad (9.17d)$$

where $\max(CL_0)$ is the value of the sweep composite-likelihood function evaluated at the MLEs for the sweep parameters. Again, because these are not true likelihoods, large-sample distribution theory cannot be used to assess their significance. Instead, Jensen et al. used the MLEs for the sweep parameters to generate a large number of data sets under the null (which is the sweep model under the *GOF* test), using these to compute $\max(CL_A)$, and hence a distribution of Λ_{GOF} under the null. Support for a sweep is indicated when: (i) the *CLR* test gives a significant result, and (ii) the *GOF* test is *not* significant. If both the *CLR* and *GOF* tests are significant, support for a sweep is questionable, as demographic features are likely the cause of departures from the neutral equilibrium model. Jensen et al. found that this two-step approach was much more robust to population structure and demography issues than the *CLR* test alone, giving false positives only when very severe bottlenecks occurred. However, the improved control over the false-positive rate comes at the cost of decreased power (Jensen et al. 2006; Boitard et al. 2009).

Tests of Sweeps Using Genomic Positional Information: “*SweepFinder*”

Nielsen et al. (2005b) proposed a modification of the *CLRT* approach, replacing the Watterson distribution by an empirical site-frequency spectrum, $\mathbf{p} = (\hat{p}_1, \dots, \hat{p}_{n-1})$, where \mathbf{p} is estimated by using a reference sample of m segregating, and presumed neutral, sites. Here $\hat{p}_k = n_k/m$ is the fraction of these m sites that contain exactly k copies of the derived allele, where n_k is the number of such sites in the sample. Their idea is that the Watterson

distribution assumes an equilibrium neutral population, while using the actual distribution observed in the population of interest (at presumed neutral sites) to a large extent can accommodate any demographically induced departures. The use of an empirical site-frequency spectrum should also at least partly correct for any SNP ascertainment bias. While an elegant approach, the delicate issue is being able to find an appropriate (and large) set of presumed neutral sites. This approach goes by the name *SweepFinder*, and the resulting likelihood function is derived in Example 9.9. Simulations by Nielsen et al. (2005b) showed that while this approach is more robust than the CLR test, demography can still influence the test statistic. In particular, intermediate bottlenecks (of a size reduced to 5% to 10% of the original N_e) seem to be the most problematic in terms of false positives (Williamson et al. 2007; Stephan 2010a), while the test has little power under strong bottlenecks (Poh et al. 2014). Hence, significance values should be obtained by simulating this procedure under a set of assumed demographic models.

A cautionary tale on the importance of accounting for demography was given by Long et al (2013) and Huber et al. (2014). Long et al. sequenced 180 lines of *Arabidopsis thaliana* from Sweden, with 130 from southern Sweden (a population generally regarded as being continuous with the main European population) and 50 lines from an isolated population in northern Sweden. *Sweepfinder* was run separately on both populations, yielding 22 strong signals from the northern population and only one from the southern population. This disparity was surprising, especially given the much larger sample size for the southern population. Huber et al. reanalyzed these data by first constructing a demographic model for these populations from the sequence data. They found that the resulting CLR distribution under the null was left-shifted by demography, making the cutoffs used by Long et al. too conservative, while it was right-shifted for the northern population, making the cutoffs too liberal. Using these demographic-corrected cutoffs, Huber et al. found that only three of the original 22 northern signals were significant, while they found significant signatures for nine sweeps in the southern population.

While *SweepFinder* uses only sites that show variation within the sample, Huber et al. (2016) expanded the original concept by including sites that show fixed differences with an outgroup. This partly accounts for the variation in mutation rates, and their simulations showed that this improves both power and precision. Finally, if one assumes that background selection is a more appropriate null (as suggested in the introduction to this chapter), the presumed neutral sites must be chosen from genomic regions whose ratio of gene density to recombination rate is similar to that of the target region. Huber et al. (2016) discussed how to replace the empirical p (the observed site-frequency for reference, and presumably neutral, loci) with estimates corrected for background selection.

Example 9.9. While using the same basic logic as the CLR_T, namely, constructing a likelihood model where the frequency spectrum is a function of distance from the site, there is a bit more bookkeeping required to obtain the likelihood function for *SweepFinder*. The task is to translate an empirical site-frequency spectrum, \mathbf{p} (at a set of presumably neutral loci), before a sweep into a pattern, \mathbf{p}_s , after the sweep. Nielsen et al. (2005b) approached this problem by focusing on a site at distance (recombination frequency) c from the target of selection (with c being estimated by the model), and conditioning on the number of lineages (from the preselection population) that are now present in a sample of size n . Suppose ℓ of these represent lineages that have escaped the sweep (and hence will be reflective of the normal background distribution, \mathbf{p}), in which case the remainder, $n - \ell$, will be lineages that did not escape, and hence will either all contain the derived allele (if it was associated with the initial favorable mutation), or all lack it. From Chapter 8, the probability that any sample sequence escaped a sweep is $1 - f_s$, where f_s is a function of the distance, c , from the selected site (Equation 9.16b). The probability that ℓ out of n sample sequences are lineages that escaped

the sweep is binomial, with a success probability of $1 - f_s$, yielding

$$P_e(\ell) = \binom{n}{\ell} (1 - f_s)^\ell f_s^{n-\ell} = \binom{n}{\ell} (1 - e^{-c\lambda})^\ell (e^{-c\lambda})^{n-\ell} \quad (9.18a)$$

where $\lambda = (1/2hs) \ln(4N_e s)$ measures the strength of selection (Equation 9.16b) and is constant over all linked sites, while c varies with the distance of our focal marker from the target of selection. There are $M = \min(\ell + 1, n)$ lineages (the ℓ distinct lineages and the single lineage associated with the sweep). Conditioned on ℓ , we need to compute $p_{s,i}$, the probability of seeing i/n derived alleles in our sample. We then average this over $P_e(\ell)$ to obtain the likelihood for a site. The probability of finding i derived alleles in a sample of the M lineages following the sweep is

$$\Pr(i | M) = \sum_{j=i}^{n-1} p_j \frac{\binom{j}{i} \binom{n-j}{M-i}}{\binom{n}{M}}, \quad \text{for } 0 \leq i \leq M \quad (9.18b)$$

where the combinatorial term in the sum is from the hypergeometric distribution. Assuming there are j copies of the derived allele in a sample of n initial lineages before the sweep, this term gives the probability that M draws (without replacement) will yield i copies in our sample. Averaging over the probability, p_j , that j copies of the derived allele (the j th element in \mathbf{p}) were in this ancestral sample yields $\Pr(i | M)$. Given that there are i lineages of the M carrying the derived allele, the probability that the derived allele is in the lineage that did not escape is simply i/M .

For a derived allele to have i copies at a site following the sweep means that it either was linked to the favorable allele, and hence was present in $(i + \ell + 1 - n)$ of the $\ell + 1$ lineages at the start of the sweep, leading to i copies in the sample, or it was not associated with the favorable mutation, so that i copies in the initial $\ell + 1$ lineages results in i copies in the sample. Putting these together gives the likelihood as

$$p_{S,i} = P_e(n) p_i + \sum_{\ell=0}^{n-1} P_e(\ell) \left[\Pr\left(i + 1 + \ell - n | \ell + 1\right) \frac{i + 1 + \ell - n}{\ell + 1} + \Pr\left(i | \ell + 1\right) \frac{\ell + 1 - i}{\ell + 1} \right] \quad (9.18c)$$

The first term is the probability that all of the sampled lineages escaped the sweep, simply recovering the background spectrum (p_i). The values given by Equation 9.18c replace those given by Equation 9.16a to construct the likelihood under a sweep. It is useful to note where parameters appear. The sweep strength (λ) and location (c) appear through f_s in the $P_e(\ell)$ term (Equation 9.18a), the number of lineages that escaped the sweep. The empirical background spectrum, \mathbf{p} , appears in the $\Pr(i | M)$ terms (Equation 9.18b) that populate the original sample of lineages at the start of the sweep. Improvements to the original *SweepFinder* have been suggested, such as the computationally more efficient version *SweeD* (Pavlidis et al. 2013).

Tests of Sweeps Using Genomic Positional Information: XP-CLR

Chen et al. (2010) introduced a test that is similar in spirit to the CLRT but uses the genomic positional pattern of *allele-frequency differences* between two populations (a reference and a candidate), as opposed to heterozygosity data from a single population. Their **cross-population composite-likelihood ratio test**, or **XP-CLR**, is constructed as follows. They assumed a biallelic marker, such as a SNP, and scored the frequency of an allele in the reference and candidate populations, with selection assumed to have occurred in the latter (but not the former). First, they modeled the neutral divergence in allele frequency between two isolated populations that originally shared a common ancestor. To simplify matters, they

used a Brownian motion (or Wiener process) approximation for drift (Appendix 1), using a normal for the expected distribution of allele frequencies. This approximation assumes that alleles are segregating and hence frequencies are in the $(0, 1)$ range. For pure drift, the expected change, $m(x)$, in an allele at frequency x is zero, while the expected variance of the change is $v(x) = x(1 - x)/(2N_e)$. If we build the Wiener process by using Equation A1.31a, the expected frequency, x , of an allele at generation t , given that it started at a frequency of p_0 , is approximately normally distributed, with

$$x(t) \sim N\left(p_0, t \frac{p_0(1 - p_0)}{2N_e}\right) \quad (9.19a)$$

More generally, we can write the variance as $\beta p_0(1 - p_0)$, where the β term accounts for the population history (allowing for variation in population size, etc.), so that if p_r is the allele frequency in some reference population, then under a pure drift model, the distribution of frequencies in the candidate population should follow

$$x \sim N(p_r, \sigma^2) \quad \text{where} \quad \sigma^2 = \beta p_r(1 - p_r) \ll 1 \quad (9.19b)$$

The last condition follows because this approximation only works well for σ^2 small. Due to the shared population history, all neutral genes should have (roughly) the same β value, which one can estimate directly from the data. If k out of n sampled chromosomes in the control population contain the allele, the likelihood (for β) for this site is given by using Equation 9.16a, but with $\phi(x)$ now replaced by the normal density function, with parameters given by Equation 9.19b. Chen et al. (2010) introduced an additional refinement. Instead of simply multiplying all individual likelihoods together, they formed their composite likelihood by multiplying the *weighted* product of the likelihoods, downweighting SNPs that are in LD in the reference population.

Now consider the effect of a sweep in the candidate population. Chen et al.'s argument follows the same logic leading to the shift in the frequency spectrum under a sweep (Equation 8.13), but now the focus is the shift in the distribution of the allele frequency in the candidate population. Suppose a single mutation immediately under selection arises that is linked to the SNP being followed. If the SNP allele frequency is x , then with a probability of x , the new favorable allele occurs on this background, and the resulting sweep changes the SNP allele frequency to $f_s + x[1 - f_s]$ (Equation 8.1e). Conversely, with a probability of $1 - x$, its frequency decreases to $x(1 - f_s)$, where f_s is again given by Equation 9.16b. Using the same logic and changes-of-variables employed in Example 8.4, Chen et al. showed that the distribution of x in the candidate population shifts to a mixture of two normals, the first representing SNP alleles not initially associated with the new favorable mutation, and hence driven toward a frequency of 0, and the second, where they were associated with the mutation and driven toward a frequency of 1, yielding

$$x \sim \left(\frac{f_s - x}{f_s^2}\right) I_{[0, f_s]} N(f_s p_r, f_s^2 \sigma^2) + \left(\frac{x + f_s - 1}{f_s^2}\right) I_{[1 - f_s, 1]} N(f_s p_r + 1 - f_s, f_s^2 \sigma^2) \quad (9.20)$$

where $I_{[a,b]}$ denotes an indicator function that is 1 when x is in the interval (a, b) and zero otherwise. This distribution now replaces $\phi(x)$ in Equation 9.16a to give the likelihood under selection for this site. The formal test consists of the ratio of the maximum of the composite likelihood under the sweep model (Equation 9.20) to the maximum of the composite likelihood under the neutral model (Equation 9.19b).

What makes Chen et al.'s method compelling is that the empirical null distributions of their test statistic over a wide range of demographic models were essentially identical. Further, their approach had greater power than the CLRT in their simulation studies and showed robustness to variation in recombination rates. Peng et al. (2011) presented an interesting application of this model, locating candidate genes for the adaptation of humans to high altitudes by contrasting a Himalayan Tibetan population (as the candidate) with Han

Chinese from Beijing (as the reference). Finally, an alternative (nonparametric) test using between-population divergence and chromosomal positional information was suggested by Oleksyk et al. (2008).

Ascertainment Issues

Because many of these likelihood models exploiting genomic positional information are computationally demanding, they are typically employed *following* a general scan of a genome for some signature of selection, such as regions of depressed variation, or showing unusual site-frequency spectra (such as those with a negative Tajima's D or positive Fay and Wu's H values, which are discussed in the next section). Choosing the region or regions in which to perform the likelihood tests based on the appearance of these special features creates a strong ascertainment bias that dramatically shifts the null distribution. (Note that this is different from SNP ascertainment bias arising from the nonrandom choice of SNPs at the start of the analysis.) The coalescent process can be noisy, and regions with unusual underlying genealogies (such as strong compression of the nodes) can occur by chance even under the equilibrium neutral model. This is especially true when a large number of sites are sampled, presenting more draws from the same underlying process, some of which will be realizations that are extreme values.

Thornton and Jensen (2007) outlined an approach to adjust for both ascertainment and nonequilibrium population structure when simulating the neutral null distribution. First, genome-scan data are used to estimate the parameters for an appropriate demographic model (such as the time and duration of a bottleneck). Next, these are used in neutral coalescent simulations. Normally, this would be the null distribution, but we need to also model the ascertainment process itself as well. For example, suppose the lowermost 2% of regions of reduced variation are chosen for follow-up *CLR* tests. The appropriate null would be constructed by also sampling such low-variation regions from the unconditional null, and then using these as the appropriately ascertained null distribution. Thornton and Jensen noted that increasing the length of the region of analysis is a good general strategy for increasing power. Likewise, they and Teshima et al. (2006) both noted that measures of either diversity (such as reduced heterozygosity) or population differentiation (such as F_{ST} values) seem more reliable for identifying outliers than do frequency-spectrum based approaches.

Model Fragility: Demography, Mutation, Recombination, and Gene Conversion

A concern to always keep in mind when using a sophisticated model is its *robustness* to errors in the underlying assumptions. Simple approaches often have modest power but considerable robustness, while highly specialized models can be quite powerful *when the data fit the assumptions* but may be quite fragile when they do not. Given the constant concern about nonequilibrium and structured populations, and hence generation of the appropriate null model, the robustness to demography is critical (Akey et al. 2004).

While sensitivity to demographic assumptions is generally well appreciated, less appreciated are the effects of genomic assumptions, such as constant mutation and recombination rates across the region. We have already stressed that variation in mutation rates can generate peaks and valleys in the background patterns of neutral variation. These patterns can easily be declared as signals of selection by most of the previously mentioned likelihood tests. The exception is *XP-CLR*, which is based on between-population differences, and thus controls for this problem to some extent. Likewise, although the recombination rate, c , between a neutral site and the selected target appears in most of the likelihood models, operationally one assumes a constant rate, c_0 , per nucleotide, with $c = c_0L$, where L is the distance in nucleotides. However (as discussed in Chapter 4), recombination rates can vary dramatically over very fine scales (Coop and Przeworski 2007), and gene conversion also needs to be considered (Andolfatto and Nordborg 1998). As mentioned in Chapter 8, conversion events can disrupt the signal expected from a sweep (Jones and Wakeley 2008). For

example, Glinka et al. (2006) observed a sharp peak of variation in the middle of a valley of depressed variation around the *unc-119* gene in a European population of *Drosophila*. They reasoned that a sweep plus two conversion events generated this unusual pattern.

Finally, background selection, which is expected to be a function of the ratio of gene density to recombination rate, also creates outliers if there is significant genomic variation in this ratio. To some extent, this can be controlled by examining whether significant tests disproportionately fall into such regions.

TESTS BASED ON SITE-FREQUENCY SPECTRUM STATISTICS

Under the infinite-sites model, a sequence is treated as a series of L sites, with each new mutation assumed to occur at a new site (Chapter 4). At mutation-drift equilibrium, most features of this model, including the site-frequency spectrum (SFS), are fully specified by the population-size-scaled mutation rate, $\theta = 4N_e\mu$. Depending on the nature of the data, an observed frequency spectrum is viewed as either folded or unfolded (Chapter 2). An unfolded spectrum considers the frequency of the derived allele (Equation 2.35a), and such data are said to be polarized (typically using an outgroup to distinguish between ancestral and derived, or mutant, alleles). The folded spectrum (Equation 2.35b) uses the minor-allele frequency, ignoring whether the rarer allele is ancestral or derived. To distinguish between these different spectra, we use the notation that ζ_i denotes the number of sites that contain exactly i derived alleles ($1 \leq i \leq n - 1$), yielding the observed unfolded SFS as the vector $(\zeta_1, \dots, \zeta_{n-1})$. Similarly, η_i denotes the number of sites with exactly i copies of the minor allele ($1 \leq i \leq [n/2]$), with $(\eta_1, \dots, \eta_{[n/2]})$ being the observed folded SFS, where

$$[n/2] = \begin{cases} n/2 & \text{for } n \text{ even} \\ (n - 1)/2 & \text{for } n \text{ odd} \end{cases}$$

The η_i and ζ_i are simply related by

$$\eta_i = \zeta_i + \zeta_{n-i} \quad \text{for } 1 \leq i \leq [n/2]$$

For example, both ζ_1 and η_1 denote the number of sites that are **singletons**, with ζ_1 being the number of sites with a single copy of the derived allele and η_1 being the number of sites with a single copy of the minor allele. The latter could be due to *either* a single copy of the derived allele *or* a single copy of the ancestral allele, with $\eta_1 = \zeta_1 + \zeta_{n-1}$.

As detailed in Chapter 8, both a hard sweep and long-term balancing selection are expected to perturb a starting site-frequency spectrum into some new distribution. A hard sweep increases the frequency of sites with rare derived alleles and also sites with high-frequency derived alleles (Figure 8.5). In a folded frequency spectrum, these jointly appear as an increase in the frequency of sites with rare alleles. Conversely, long-term balancing selection is expected to increase the number of sites with intermediate-frequency alleles, albeit over a region that becomes ever-narrower over time (Chapter 8). While they are widely used, a problem with all site-frequency spectrum tests is that nonequilibrium conditions (e.g., during recovery following a bottleneck) or spatial population structure cause the frequency spectrum of neutral alleles to depart from the benchmark Watterson distribution. Thus, a significant amount of the following discussion deals with these concerns.

Summary Statistics Based on Infinite-sites Models

As introduced in Chapter 4, a variety of summary statistics can be used to estimate $\theta = 4N_e\mu$ under the infinite-sites model. For a sample of L sites (generally nucleotides), suppose that there are S segregating sites, with η_1 and ζ_1 sites harboring (folded and unfolded, respectively) singletons, and Π denoting the average number of pairwise differences between two random sequences. If our goal is to estimate θ on a *per-nucleotide* basis, so that μ is the per-nucleotide mutation rate, then (as in Chapter 4), we would

Table 9.1 Summary of the site-frequency tests presented in this chapter, which contrast estimates of θ based on different regions of the site-frequency spectrum. The estimators $\hat{\theta}_S$, $\hat{\theta}_{\Pi}$, $\hat{\theta}_1$, and $\hat{\theta}_{1^*}$ are given by Equation 9.21a; $\hat{\theta}_{S-\eta_1}$ and $\hat{\theta}_{S-\zeta_1}$ are Achaz's (2008) estimators using S but removing unfolded and folded singletons; $\hat{\theta}_{\Pi-\eta_1}$ and $\hat{\theta}_{\Pi-\zeta_1}$ are Achaz's analogous estimators using Π ; and $\hat{\theta}_H$ (Equation 9.27a) and $\hat{\theta}_L$ (Equation 9.28a) are developed below. The column labeled "Spectrum" indicates whether the test requires unfolded data, with alleles designated as ancestral or derived. Further details are given in the text.

Test	Contrast	Spectrum	Signal
Tajima's D	$\hat{\theta}_S$ vs. $\hat{\theta}_{\Pi}$	Folded	< 0: Excess of rare alleles Sweep or population bottleneck > 0: Excess of intermediate-frequency alleles Balancing selection or population structure
Achaz's Y^*	$\hat{\theta}_{S-\eta_1}$ vs. $\hat{\theta}_{\Pi-\eta_1}$	Folded	Same as for Tajima's D
Achaz's Y	$\hat{\theta}_{S-\zeta_1}$ vs. $\hat{\theta}_{\Pi-\zeta_1}$	Unfolded	Same as for Tajima's D
Fu and Li's D	$\hat{\theta}_S$ vs. $\hat{\theta}_1$	Unfolded	Same as for Tajima's D
Fu and Li's D^*	$\hat{\theta}_S$ vs. $\hat{\theta}_{1^*}$	Folded	Same as for Tajima's D
Fu and Li's F	$\hat{\theta}_{\Pi}$ vs. $\hat{\theta}_1$	Unfolded	Same as for Tajima's D
Fu and Li's F^*	$\hat{\theta}_{\Pi}$ vs. $\hat{\theta}_{1^*}$	Folded	Same as for Tajima's D
Fay and Wu's H	$\hat{\theta}_{\Pi}$ vs. $\hat{\theta}_H$	Unfolded	< 0: Excess of high-frequency derived alleles. Sweep or allelic surfing
Zeng et al.'s E	$\hat{\theta}_{\Pi}$ vs. $\hat{\theta}_L$	Unfolded	< 0: Excess of low- vs. high-frequency derived alleles. Signal of a recent <i>past</i> sweep

consider the fraction of segregating sites as S/L ; the nucleotide diversity as $\pi = \Pi/L$; and the fraction of sites that are singletons as S_1/L . When searching for genomic regions under selection, our goal shifts to $\theta_L = 4N_e\mu_L$, the corresponding value for the *region*, where $\mu_L = L\mu$ is the total mutation rate over the L sites. Because the focus in this section is on specific regions, in an effort to keep the notation simple, we suppress the subscript and use θ and μ to denote the region-side values (θ_L, μ_L).

While S and Π have the same values for polarized and unpolarized data, the number of singletons can be slightly different. All of these summary statistics yield estimates of θ for a region of interest, with

$$\hat{\theta}_S = \frac{S}{a_n} \quad \hat{\theta}_{\Pi} = \Pi \quad \hat{\theta}_1 = \zeta_1, \quad \hat{\theta}_{1^*} = \frac{n}{n-1} \eta_1 \quad (9.21a)$$

where $a_n = \sum_{j=1}^{n-1} 1/j$ (Equation 4.3b). These four expressions correspond (respectively) to: the Watterson estimator (Equation 4.3a, which is also commonly denoted by θ_W); Tajima's estimator (Equation 4.1); our previous singleton estimator, $\hat{\theta}_1$, using unfolded data (Equation 4.6a); and the corresponding singleton estimator, $\hat{\theta}_{1^*}$, using folded data. The sampling variances for these estimates are given by Equations 4.4a ($\hat{\theta}_S$), 4.2 ($\hat{\theta}_{\Pi}$), and 4.6b ($\hat{\theta}_1$). These expressions for the variance are functions of both θ and θ^2 , and are typically (e.g., Tajima 1989) computed by replacing

$$\theta \text{ by } S/a_n \quad \text{and} \quad \theta^2 \text{ by } \frac{S(S-1)}{a_n^2 + b_n} \quad (9.21b)$$

where $b_n = \sum_{j=1}^{n-1} 1/j^2$ (Equation 4.4b).

The idea behind site-frequency tests of neutrality is to compare two different estimates of θ based on information from *different regions* of the site-frequency spectrum. When the infinite-sites model holds and the population is at mutation-drift equilibrium, these estimates should be within the sampling error of each other, while they can be significantly different when the neutral equilibrium model does not hold. Table 9.1 summarizes the various site-frequency test statistics discussed here, all of which have the form

$$t = \frac{\hat{\theta}_i - \hat{\theta}_j}{\sigma(\hat{\theta}_i - \hat{\theta}_j)} \quad (9.21c)$$

When applying any of these tests, care must be taken to avoid SNP ascertainment bias. If the process by which SNPs are chosen is biased by their frequency (SNP discovery panels are generally biased in favor of intermediate-frequency sites), this results in a biased estimate of the frequency spectrum, potentially compromising the tests. Likewise, when tests are based on the unfolded SFS, errors introduced by incorrect polarity assignment (incorrectly assigning a derived allele ancestral status, and vice versa) can be very serious (Baudry and Depaulis 2003; Hernandez et al. 2007). Finally, sequencing errors result in an increase in singletons, which can bias tests away from neutrality (Achaz 2008; Johnson and Slatkin 2008), although maximum-likelihood approaches exist that deal with sequencing errors when estimating SNP frequencies (Lynch 2009a; Maruki and Lynch 2013).

Example 9.10. Suppose we sample ten alleles from a population and observe a total of 12 segregating sites ($S = 12$), an average of four differences between alleles ($\Pi = 4$), and three segregating sites that have only a single copy of the minor allele ($\eta_1 = 3$). What are the estimates of θ based on these three summary statistics? Using Equations 9.21a yields

$$\hat{\theta}_S = \frac{S}{a_{10}}, \text{ with } a_{10} = \sum_{i=1}^9 \frac{1}{i} = 2.83 \text{ yielding } \hat{\theta}_S = \frac{12}{2.83} = 4.24$$

$$\hat{\theta}_{\Pi} = \Pi = 4 \quad \hat{\theta}_{1^*} = \frac{n}{n-1} \eta_1 = \frac{10}{9} \cdot 3 = 3.33$$

Example 9.11. As we now illustrate, all of the tests summarized in Table 9.1 follow from a general family of estimators of θ based on the discrete Watterson distribution (Equation 2.35). For a sample of n sequences with L sites, the expected number of segregating sites with i copies of the derived (unfolded, ζ_i) or of the minor (folded, η_i) allele are

$$E(\zeta_i) = \frac{\theta}{i} \quad \text{for} \quad 1 \leq i \leq n-1 \quad (9.22a)$$

$$E(\eta_i) = E(\zeta_i) + E(\zeta_{n-i}) = \frac{\theta}{i} + \frac{\theta}{n-i} = \frac{\theta}{i} \frac{n}{n-i} \quad \text{for} \quad 1 \leq i \leq [n/2]$$

where $\theta = 4N_e\mu$ is the scaled mutation rate for the entire region.

Hence, a method-of-moments estimator for θ using only the number in the i th class from either SFS is simply

$$\hat{\theta}_i = \begin{cases} i \cdot \zeta_i & i \text{ copies of the derived allele} \quad 1 \leq i \leq n-1 \\ \frac{i \cdot (n-i)}{n} \eta_i & i \text{ copies of the minor allele} \quad 1 \leq i \leq [n/2] \end{cases} \quad (9.22b)$$

Nawa and Tajima (2008) suggested that a plot of $\hat{\theta}_i$ versus i can be helpful for visualizing departures from the neutral SFS, although values for large i may be more problematic as the variance of $\hat{\theta}_i$ dramatically increases with i .

Following Zeng et al. (2006), consider any summary statistic, g , of the unfolded site-frequency spectrum of the form

$$g = \sum_{i=1}^{n-1} c_i \zeta_i \quad (9.23a)$$

From Equation 9.22a

$$E(g) = \sum_{i=1}^{n-1} c_i \frac{\theta}{i} = \theta h(n) \quad \text{where} \quad h(n) = \sum_{i=1}^{n-1} \frac{c_i}{i} \quad (9.23b)$$

Thus, a family of estimators for θ based on an arbitrary vector (c_1, \dots, c_{n-1}) of weights is given by

$$\hat{\theta}_g = \frac{g}{h(n)} \quad (9.23c)$$

where $h(n)$ is a function of the sample size n and the chosen weights c_i , and g is the observed value of the statistic.

The choice of weights allows one to tailor statistics to use different parts of the frequency spectrum when estimating θ . Taking $c_i = 1$ yields $g = S$ and $h(n) = a_n$, recovering the Watterson estimator, $\hat{\theta}_S = S/a_n$. Taking $c_i = i(n-i)$

$$h(n) = \sum_{i=1}^{n-1} i(n-i)/i = n(n-1)/2$$

yielding

$$\hat{\theta} = \sum_{i=1}^{n-1} \frac{2i(n-i)}{n(n-1)}$$

which is simply the average pairwise difference, Π . As with S , Π is symmetric with respect to i and $n-i$, so that both folded and unfolded data return the same estimate. Taking $c_1 = 1, c_{i>1} = 0$ yields $g = \zeta_1$ (the number of derived singletons) and $h(n) = 1$, recovering the $\hat{\theta}_1$ estimator.

Similarly, for a folded frequency spectrum,

$$g = \sum_{i=1}^{[n/2]} c_i \eta_i, \quad \hat{\theta}_g = \frac{g}{f(n)}, \quad f(n) = \sum_{i=1}^{[n/2]} c_i \frac{n}{i(n-i)} \quad (9.23d)$$

Consider the estimator using only folded singletons, η_1 . Here, $c_1 = 1, c_i = 0$ for $i > 1$, and hence $f(n) = n/(n-1)$, giving $\eta_1(n-1)/n$ as an estimator of θ , which recovers $\hat{\theta}_{1*}$. Achaz (2009) provided general expressions for the variance of any estimator of the form given by Equations 9.23c or 9.23d, providing all of the machinery to develop general tests in the form of Equation 9.21c using any feature of interest in the SFS.

Tajima's D Test

The first proposed, and most widely used, site-frequency spectrum test is **Tajima's D** (1989), which contrasts θ estimates based on the number of segregating sites (S) and average pairwise difference (Π),

$$D = \frac{\hat{\theta}_{\Pi} - \hat{\theta}_S}{\sqrt{\alpha_D S + \beta_D S^2}} \quad (9.24a)$$

where

$$\alpha_D = \frac{1}{a_n} \left(\frac{n+1}{3(n-1)} - \frac{1}{a_n} \right) - \beta_D \quad (9.24b)$$

$$\beta_D = \frac{1}{a_n^2 + b_n} \left(\frac{2(n^2 + n + 3)}{9n(n-1)} - \frac{n+2}{a_n n} + \frac{b_n}{a_n^2} \right) \quad (9.24c)$$

with a_n and b_n as above (Equations 4.3b and 4.4b). Being based on S and Π , this test does not require unfolded data. Tajima's motivation was that θ_S and θ_Π measure different features of the frequency spectrum. The number of segregating sites, S (and thus θ_S), counts polymorphic sites independent of their frequencies, making it more sensitive to changes in the frequencies of rare alleles (as small changes can cause sites segregating rare alleles to either enter or drop out of the sample). Conversely, the average pairwise difference, Π (and thus θ_Π), is a frequency-weighted measure and more sensitive to changes in intermediate-frequency alleles. A negative value of D indicates that there are too many low-frequency sites, while a positive value of D indicates that there are too many intermediate-frequency sites. Expressed another way, D is a test for whether the amount of heterozygosity per site is consistent with the number of polymorphic sites expected under the equilibrium neutral model. Under selective sweeps (and population expansion), heterozygosity should be significantly less than is predicted from the number of polymorphisms. As with all site-frequency spectrum tests, the distribution of D critically depends on adherence to the neutral equilibrium assumptions.

Tajima obtained upper (D_{max}) and lower (D_{min}) bounds on D , so that

$$(D - D_{min}) / (D_{max} - D_{min})$$

lies in the range (0, 1). Under the equilibrium neutral assumption, Tajima showed that D is well approximated on this modified scale by a Beta distribution (Equation A2.38a), with distribution parameters

$$\alpha = -\frac{(1 + D_{min}D_{max})D_{max}}{D_{max} - D_{min}} \quad \text{and} \quad \beta = \frac{(1 + D_{min}D_{max})D_{min}}{D_{max} - D_{min}} \quad (9.25a)$$

Innan and Stephan (2000) and Živković and Wiehe (2008) showed that the distribution of D in a population of changing size is significantly different from this equilibrium neutral result. Because the minimal value of D varies with the number of segregating sites, S , Schaeffer (2002) proposed a standardized $D' = D/D_{min}$ to adjust for this, allowing for more fair comparisons of D across loci. The minimum value of Π given S was obtained by Tajima (1989) as

$$\Pi_{min} = S \frac{2(n-1)}{n^2} \quad (9.25b)$$

D_{min} is computed from Equation 9.24a, with Π_{min} replacing $\hat{\theta}_\Pi$.

Example 9.12. Two interesting applications of the D test were offered by Tajima (1989). First, he considered Aquadro and Greenberg's (1983) data for 900 base pairs in the mitochondrial DNA of seven humans. They observed 45 segregating sites and an average number of nucleotide differences between all pairs of 15.38. Hence,

$$a_7 = \sum_{i=1}^6 \frac{1}{i} = 2.45, \quad b_7 = \sum_{i=1}^6 \frac{1}{i^2} = 1.49$$

$$\hat{\theta}_S = \frac{S}{a_n} = \frac{45}{2.45} = 18.38, \quad \hat{\theta}_\Pi = \Pi = 15.38$$

$$\beta_D = \frac{1}{2.45^2 + 1.49} \left(\frac{2(7^2 + 7 + 3)}{9 \cdot 7(7 - 1)} - \frac{7 + 2}{7 \cdot 2.45} + \frac{1.49}{2.45^2} \right) = 0.00475$$

$$\alpha_D = \frac{1}{2.45} \left(\frac{7 + 1}{3(7 - 1)} - \frac{1}{2.45} \right) - 0.00475 = 0.01005$$

$$D = \frac{\hat{\theta}_{\Pi} - \hat{\theta}_S}{\sqrt{\alpha_D S + \beta_D S^2}} = \frac{15.38 - 18.38}{\sqrt{0.01005 \cdot 45 + 0.00475 \cdot 45^2}} = -0.945$$

Table 2 of Tajima (1989) gives the 95% confidence interval for D under strict neutrality for $n = 7$ as -1.608 to 1.932 , so that this value is not significantly different from its neutral expectations.

Tajima also applied his test to the data of Miyashita and Langley (1988), who examined 64 samples of a 45-kb region of the *white* locus in *D. melanogaster*. Taking large insertions and deletions as the polymorphic sites, they found $S = 15$ and $\Pi = 0.94$, which yields a value of $D = -2.0709$. Given that the 95% confidence interval under neutrality is -1.795 to 2.055 , the site-frequency spectrum associated with this locus shows evidence (a significantly negative D value) of either directional selection or a population bottleneck.

Achaz's Y and Y^* Tests

Achaz (2008) noted that estimates of both S and π can be biased by sequencing errors, which introduce an excess of singletons, thus skewing D toward more negative values. His **Y and Y^* tests** modify Tajima's D by computing $\hat{\theta}_{\Pi}$ and $\hat{\theta}_S$ after removing singletons. With unfolded data, his Y test replaces these estimates by $\hat{\theta}_{\Pi-\zeta_1}$ and $\hat{\theta}_{S-\zeta_1}$, while with folded data, his Y^* test uses $\hat{\theta}_{\Pi-\eta_1}$ and $\hat{\theta}_{S-\eta_1}$. Expressions for these estimators and the sampling variances of the tests can be found in his paper. While initially proposed as a method to deal with potential sequencing errors (which can now be accounted for by using ML approaches), these tests are still a useful metric, as a comparison of Y and Y^* with D providing information about the impact of singletons.

Fu and Li's D^* and F^* Tests

Fu and Li (1993b) introduced tests based on other contrasts among the infinite-sites θ estimators given by Equation 9.21a. Both proposed tests use the number of singleton sites, with variants using either folded (η_1 sites with a single copy of the minor allele) or unfolded (ζ_1 sites with a single copy of the derived allele) singletons. Using these statistics gives estimates of θ based on the rare-alleles region of the SFS, which are then contrasted with estimates based on either S or Π . Using folded data, this gives rise, respectively, to their D^* and F^* tests. Their exact counterparts for unfolded data (using ζ_1 in place of η_1) are, respectively, their D and F tests, which are not discussed further. Given the widespread use of Tajima's D , when we simply reference a "D test," this always refers to Tajima's test.

Fu and Li's **D^* test** compares the segregating sites (S) versus the folded-singleton (η_1) estimators of θ

$$D^* = \frac{\hat{\theta}_S - \hat{\theta}_{1^*}}{\sqrt{\alpha_* S + \beta_* S^2}} \quad (9.26a)$$

$$\alpha_* = \frac{1}{a_n} \left(\frac{n+1}{n} - \frac{1}{a_n} \right) - \beta_* \quad (9.26b)$$

$$\beta_* = \frac{1}{a_n^2 + b_n} \left[\frac{b_n}{a_n^2} - \frac{2}{n} \left(1 + \frac{1}{a_n} - a_n + \frac{a_n}{n} \right) - \frac{1}{n^2} \right] \quad (9.26c)$$

Their **F^* test** compares the average pairwise divergence (Π) with the folded-singletons (η_1) estimators

$$F^* = \frac{\hat{\theta}_{\Pi} - \hat{\theta}_{1^*}}{\sqrt{\alpha_F S + \beta_F S^2}} \quad (9.26d)$$

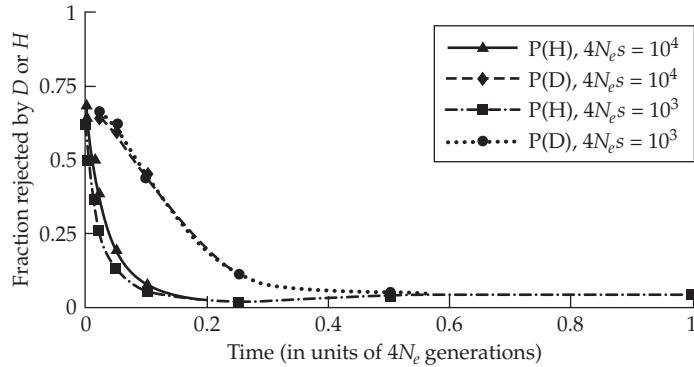

Figure 9.4 The power (P) of the H and D tests to detect signatures of a recent sweep is very fleeting. The power of H (which is based on high-frequency derived alleles) falls off especially rapidly after a sweep (as high-frequency alleles are fixed), essentially having power only within $0.2N_e$ generations following a sweep. D , which is based on an excess of rare alleles, can detect new mutations that enter following the sweep and has power over about $0.5N_e$ generations following a sweep. A value of $c/s = 0.01$ was used and power (for a sample size of 50) was graphed for two different values of $4N_e s$. For D (the upper two curves in the figure, which are essentially superimposed on each other), the power is essentially identical for these two values of $4N_e s$, while for H (the lower two curves), there is a very slight power increase for $4N_e s = 10^4$ when $t < 0.1N_e$. (After Przeworski 2002.)

$$\alpha_F = \frac{1}{a_n} \left(\frac{4n^2 + 19n + 3 - 12(n+1)a_{n+1}}{3n(n-1)} \right) - \beta_F \quad (9.26e)$$

$$\beta_F = \frac{1}{a_n^2 + b_n} \left(\frac{2n^3 + 110n^2 - 255n + 153}{9n^2(n-1)} + \frac{2(n-1)a_n}{n^2} - \frac{8b_n}{n} \right) \quad (9.26f)$$

These expressions are from Simonsen et al. (1995), with Equation 9.26e correcting the original Fu and Li paper. Critical values (assuming no recombination in the region) were tabulated by Fu and Li (1993b). While these tests are fairly widely used, Simonsen et al. (1995) found that they are not as powerful as Tajima's test for detecting a selective sweep or demographic features (bottlenecks or population subdivision).

Fay and Wu's H Test

The first test to use the full power of the unfolded frequency spectrum was proposed by Fay and Wu (2000), who noted that a hard sweep results in an excess of sites with high-frequency derived alleles (Figure 8.5). Although the signature is rather fleeting (Figure 9.4), this excess forms the basis for their **H test**. Their idea is to disproportionately weight sites containing derived alleles at high frequencies, and they chose to do so using the weights $c_i = i^2$. From Equation 9.23b, these weights imply $h(n) = n(n-1)/2$, and Equation 9.23c yields

$$\hat{\theta}_H = \frac{2}{n(n-1)} \sum_{i=1}^{n-1} i^2 \zeta_i \quad (9.27a)$$

The H test is the scaled difference between Fay and Wu's estimator for θ and that based on average pairwise differences,

$$H = \frac{\hat{\theta}_{\Pi} - \hat{\theta}_H}{\sigma(H)} \quad (9.27b)$$

Zeng et al. (2006) obtain the sampling variance as

$$\sigma^2(H) = \left[\frac{n-2}{6(n-1)} \right] \theta + \left[\frac{18n^2(3n+2)b_{n+1} - (88n^3 + 9n^2 - 13n + 6)}{9n(n-1)^2} \right] \theta^2 \quad (9.27c)$$

As above, Equation 9.21b is used for θ and θ^2 when computing Equation 9.27c. Because Π is a measure of the intermediate-frequency sites, H is a contrast between high- and intermediate-frequency variation, with a negative H indicating an excess of sites with a high frequency of derived alleles. Jointly negative (and significant) values of D and H are consistent with a selective sweep, indicating both an excess of rare alleles and an excess of high-frequency derived alleles. One caution when applying the H test is its extreme sensitivity to polarity errors (Baudry and Depaulis 2003).

Przeworski (2002) showed that both the D and H tests have moderate power immediately after a sweep but the power of the H test rapidly dissipates (within $\sim 0.2N_e$ generations) as the high-frequency alleles become fixed (Figure 9.4). The D test retains power a bit longer ($\sim 0.5N_e$ generations), as it is sensitive to the generation of rare alleles by new mutations immediately after the sweep. As a result of using different signatures in the SFS, one can easily encounter situations where, following a sweep, one test is highly significant while the other is not. Even for a strong hard sweep, neither D nor H may be significantly negative, depending on the time since the sweep was completed (Figure 9.4).

Zeng et al.'s E Test

A variant of the H test was proposed by Zeng et al. (2006), who noted that the most powerful contrasts between regions of the unfolded frequency spectrum following selection should involve high- versus low-frequency sites. However, most contrasts involve a comparison with θ_{Π} , which is a measure of intermediate-frequency alleles. To rectify this, Zeng et al. introduced the estimator, θ_L , based on a weight, $c_i = i$, that places more emphasis on high-frequency sites than θ_S (but not as much as θ_H). For these weights, Equation 9.23b implies $h(n) = n - 1$, and hence Equation 9.23c yields

$$\hat{\theta}_L = \frac{1}{n-1} \sum_{i=1}^{n-1} i \zeta_i \quad (9.28a)$$

Zeng et al.'s **E test** contrasts the high- and low-frequency regions of the frequency spectrum,

$$E = \frac{\hat{\theta}_L - \hat{\theta}_S}{\sigma(E)} \quad (9.28b)$$

where

$$\sigma^2(E) = \left[\frac{n}{2(n-1)} - \frac{1}{a_n} \right] \theta + \left[\frac{b_n}{a_n^2} + 2 \left(\frac{n}{n-1} \right)^2 b_n - \frac{2(nb_n - n + 1)}{(n-1)a_n} - \frac{3n+1}{n-1} \right] \theta^2 \quad (9.28c)$$

Again the variance is approximated by replacing θ and θ^2 with their estimates from Equation 9.21b. A negative E indicates an excess of low- versus high-frequency sites relative to expectations of the equilibrium neutral model. This occurs *immediately after* a sweep, as the excess of high-frequency alleles is quickly lost by drift (due to their fixation), while at the same time mutation is generating an excess of low-frequency sites, which have yet to drift up to their neutral equilibrium values. The unique feature of E is its ability to yield a signal *after* a sweep, which can persist up to $2N_e$ generations (and hence much longer than H).

Adjusting the Null to Account for Nonequilibrium Populations

The site-frequency tests summarized in Table 9.1 critically depend on the Watterson distribution as the null model, as do the entire family of θ estimators given by Equation 9.23. As such, they are especially susceptible to false positives when samples come from a population not satisfying the underlying assumptions (a panmictic population in mutation-drift equilibrium). Four strategies have been proposed to address this concern. The first three

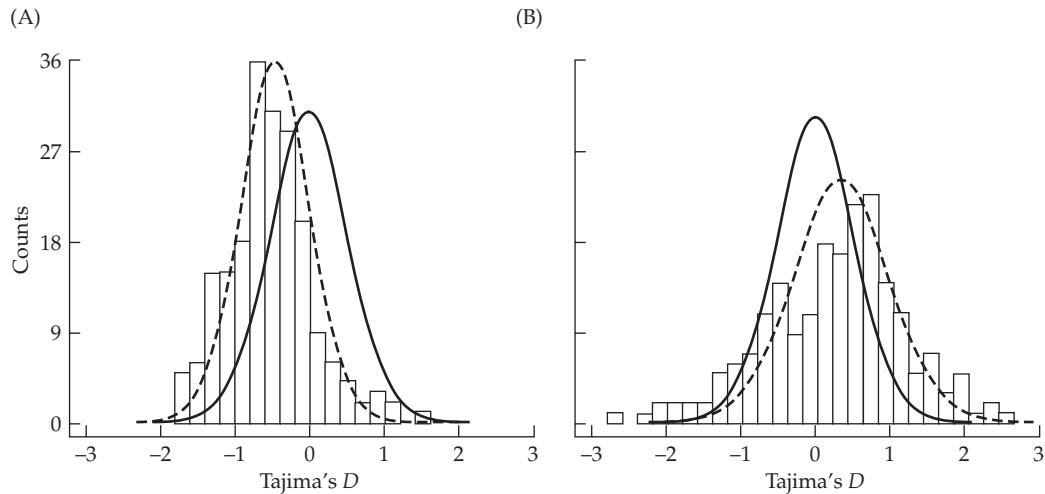

Figure 9.5 Distribution of Tajima's D for 201 genes in African-American (A) and European-American (B) samples. The empirical distribution is represented by the histogram, the solid line represents the simulated values under the equilibrium neutral model, and the dashed line the simulated distribution under the best-fitting demographic model. For (A), this is exponential growth starting 50,000 years ago, while for (B), this is a bottleneck starting 40,000 years ago. (After Ronald and Akey 2005.)

are standard approaches to refine the null to better suit the sampled population: (i) using the empirical distribution of test statistics from a set of genes in the sample (the outlier approach), (ii) using coalescent simulations with marker-based estimates of demographic parameters, and (iii) using the empirical site-frequency spectrum at reference locations as the null. The final strategy, **support via a preponderance of evidence**, considers the joint signatures from a number of different tests and will be discussed separately. While approaches attempting to account for nonequilibrium populations offer improvements over tests based on the standard (i.e., equilibrium) neutral model, they still do not guarantee that significant signatures represent true regions influenced by positive selection. Because of this, the current operational use for many of these tests (such as Tajima's D) are as *convenient summary statistics* for features in a region of interest, such as whether there is an excess of rare alleles.

The first approach assumes that the empirical distribution of a test statistic over a large number of genes sampled from the target population can provide useful information. Under the equilibrium neutral model, the test statistics reviewed in Table 9.1 should have a mean of zero, while the empirical distribution shows whether the tests trend away from this expectation in the target population. Figure 9.5 gives examples of the empirical distribution of D for 201 genes in two different human populations. For African-Americans, the mean D is negative, while it is positive for European-Americans. A gene whose negative D value is significant under the equilibrium neutral model is likely to be even more significant in this European-American population (given this population's trend toward a positive D), but is problematic in this sample of African-Americans (given that random tests in this group trend toward a negative D). While the mean of this distribution can be informative, one cannot simply use it to adjust test statistics for individual genes. This is because departures from the standard neutral model often *inflate the variance* of test statistics (Nielsen 2001). Thus, even when the mean of the empirical distribution is zero, the variance under the

standard model may be too narrow, and hence significance can be overstated. Finally, the empirical distribution is largely shaped by common demographic features that influence all genes. Allelic surfing of neutral alleles does not leave a constant genome-wide signature, and sites experiencing surfing can easily create outliers, mimicking signatures of selection.

The second approach to account for a nonequilibrium population is to use genomic data to infer demographic parameters (such as the size and duration of any past bottleneck), which are then used as the basis for coalescent simulations (Chapter 2). This generates a more appropriate null distribution of the test statistic for the target population (e.g., Figure 9.5). An example of this approach was provided by Schaffner et al. (2005), who used human data to find the best-fitting model over a rather rich parameter space, including population structure, bottleneck times, and variation in recombination rates. Tenaillon et al. (2004) performed a similar analysis on the bottleneck during the formation of maize from teosinte. With estimated demographic parameters in hand, coalescent simulation programs such as MSMS (Ewing and Hermisson 2010), GENOME (Liang et al. 2007), cosi (Schaffner et al. 2005), or MS (Hudson 2002) can be used. Again, this approach only corrects for demographic features that leave a common signal over the entire genome, implying that sites experiencing allelic surfing can still generate false signals of selection even after this correction. As recently summarized by Li et al. (2012), the joint estimation of both demographic and selection parameters is still somewhat problematic.

The final approach is to use the empirical site-frequency spectrum vector, \mathbf{p} , from a reference set—as opposed to the Watterson distribution—as the null (Nielsen et al. 2005b, 2009). Here p_i is the fraction of sites in the reference set with i copies of the allele (derived or minor, for the unfolded and folded spectra, respectively). A standard goodness-of-fit test (such as the G -test; LW Appendix 2) is then used to assess whether the spectrum n_1, \dots, n_{n-1} in a candidate region is consistent with the multinomial probabilities given by \mathbf{p} . One can also compare different parts of the spectrum, such as searching for an excess of low-frequency alleles, or high-frequency derived alleles, relative to this standard. Nielsen et al. (2009) used this approach for their ***MWU-low*** and ***MWU-high*** tests, respectively, where ***MWU*** stands for the Mann-Whitney U test (a common nonparametric test for comparing two groups, e.g., Conover 1999). One major reservation with these nonparametric approaches is the choice of the reference set of sites for the neutral background spectrum. Even if these site are neutral, local effects such as differences in the mutation rates (and hence in θ) and the background recombination rates that influence the levels of standing variation (Chapter 8) can result in the target sites (even if strictly neutral) differing from the distribution at reference sites. If one assumes background selection as the appropriate null, the sites used in constructing \mathbf{p} should (at a minimum) come from genomic regions with very similar values of gene density to recombination rates as the tested region.

Support via a Preponderance of Evidence

A common strategy in the literature to support a claim for selection is to show that a number of different tests are all highly significant. To this aim, a number of authors have proposed compound tests based on the joint distribution of two (or more) summary statistics of selection. Zeng et al (2006) proposed their ***DH test***, which combines signals from Tajima's D and Fay and Wu's H tests. Zeng et al. (2007b) extended this approach with their ***HEW*** and ***DHEW tests***, which combine either Fay and Wu's H statistic or Zeng et al.'s *DH* test (respectively) with the Ewens-Watterson test (introduced shortly as Equation 9.30b). Pavlidis et al. (2010) and Lin et al. (2011) also suggested approaches that combine multiple signals. This approach was taken to the extreme by Grossman et al. (2010, 2013), who combined test statistics based on both population differentiation and haplotype information to construct a likelihood based on the values of multiple test statistics (their **composite of multiple signals**, or **CMS**, approach). While composite tests likely do not return proper significance values (due to a lack of independence between tests), they can still have considerable utility. Grossman et al. noted that *CMS* often yields a substantially narrower region for a selected site, increasing resolution up to 100-fold. Further, given that different tests are optimal over

different time scales during a sweep (Table 8.2), a composite test offers the possibility of having power over a larger time span.

Others have advocated **meta-analysis** approaches, combining the significance values over multiple tests (Appendix 4). This can be accomplished in several ways. Utsumomiya et al. (2013) proposed ***meta-SS***, using Stouffer's *Z* score (Equation A4.2) to combine *p* values for different tests applied in a particular region to obtain a single overall *p* value for that region. Randhawa et al. (2014) used a slightly different approach, their **composite selection signals** or **CSS**. Here, for a given test, a standardized rank score, $R_k/(n+1)$, is computed for each of the n SNPs (R_k is the rank, from lowest to highest, of the *p* value of the test). The resulting scores (for a given test) for each SNP range from $1/(n+1)$ to $1 - 1/(n+1)$, which are then probit-transformed (Equation 14.2) and averaged over all of the tests to obtain a *Z* score for each particular SNP. Again, such meta-analysis *p* values are only approximations, as they assume the *p* values for different tests are uncorrelated, which is usually not true. Their utility is largely as a convenient summary statistic for evidence of selection in a particular region, rather than as a definitive probability statement.

Ma et al. (2015) proposed a simple measure to deal with test correlations, their **de-correlated composite of multiple signals**, or **DCMS** statistic. Let $p_{i,k}$ denote the *p* value for test k for site i , and let r_{kj} be the empirical correlation among the values of the test statistics for tests k and j over all of the scored sites, so that $r_{kk} = 1$ and $r_{kj} = 0$ when tests k and j are uncorrelated. Ma's *DCMS* statistic for site i is given by

$$DCMS_i = \left(\frac{1}{W} \right) \sum_{k=1}^t \ln \left(\frac{1 - p_{i,k}}{p_{i,k}} \right), \quad \text{where } W = \sum_{k=1}^t |r_{kt}| \quad (9.29a)$$

The terms in the sum are the odds ratio for each test (which Ma et al. used in place of Bayes factors with equal prior weight on the null and alternative; see Equation A2.10b). The weighting term (W) ranges from 1 (none of the tests are correlated, so that $W = r_{tt} + 0 = 1$), to the case where all of the tests are perfectly correlated, so that $W = t$. In the former case, the composite measure is simply the sum of the odds ratios, while in the latter it is the average of the odds ratio. Ma et al. found in their simulations that *DCMS* had higher power than either *meta-SS* or *CSS* under most settings.

A final class of composite measures are **multivariate outlier metrics**. Just as the outlier approach is widely used to highlight sites that have exceptional values in a given single test statistics, one can also consider outliers from a *collection* of test statistics. Assuming all the tests have a mean of zero under the null, the total Euclidean distance of a vector of test statistics from the mean value under the null (0) would be one approach. However, different test statistics have different variances, and further they are correlated. One standard approach in such cases is to transform all of the test statistics to have the same variance and to be uncorrelated, which leads to the **Mahalanobis distance** (Equation A5.19),

$$D_i^2 = \mathbf{t}_i^T \boldsymbol{\Sigma}_{\mathbf{t}}^{-1} \mathbf{t}_i \quad (9.29b)$$

where \mathbf{t} is the vector of test statistics for site i and $\boldsymbol{\Sigma}_{\mathbf{t}}$ is the empirical variance-covariance matrix for the vector of test scores over all of the sites. Lotterhos et al. (2017) used this metric and a variant replacing the vector (\mathbf{t}) of test statistics with a vector whose elements were based on the ranks of the *p* values for a given site (along the lines of Randhawa et al. 2014). They then took the negative log of these rank-based *p* values as the elements of \mathbf{t} for the Mahalanobis distance. This approach goes by the compact name of **Mahalanobis distance based on negative-log rank-based p-values**, or **Md-rank-P**. They found that this approach worked the best of the composite measures they tested, followed by *DCMS*.

While seemingly logical, there are a number of subtle concerns with these composite approaches. First, although the tests reviewed in Table 9.1 highlight different features of the site-frequency spectrum, they are generally still correlated (Fu 1997; Achaz 2009). Hence, when choosing a region because of an abnormal *D* value, one might expect to find other abnormal site-frequency values as well, even if the region is neutral. This also holds for

other types of tests, such as parametric sweep-based approaches (*CLR*, *Sweepfinder*) and haplotype-based tests (discussed below). When a region is ascertained by having an unusual test statistic value, this skews the distribution of other tests as well. For example, a region of low recombination can amplify random departures from the neutral equilibrium model. This point was stressed by O'Reilly et al. (2008), who noted that loci with significant selection tests scores in humans are disproportionately found in regions of low recombination. On the one hand, this makes sense, as regions with low c values are expected to have stronger signals from sweeps (Chapter 8). However, on the other hand, regions of low recombination create longer correlations among adjacent sites as well, so that an extreme discordance of a local coalescence from the neutral equilibrium model extends over a larger region. This is one reason to be very cautious of tests that look for localized runs of a particular statistic. For example, consider the **continuous regions of Tajima's D reduction** (or *CRTR*) test (Carlson et al. 2005). While a run of sites with negative D values is expected under a sweep, it is also expected around an unlikely—but not exceptional—neutral genealogy in a region of low recombination.

The strongest preponderance of evidentiary support comes from *completely independent* tests, such as site-frequency data from one population coupled with an abnormal F_{ST} value for that site between populations. Even in these cases, the skeptic can suggest that most of the signal is coming from an unusual event in a single population, but an event that could be an outlier from a neutral drift process. For example, if one catches a surfing allele in one population, it has the potential for generating a number of selection-like signals and will also give a large F_{ST} value relative to other populations where it has not surfed.

Recombination Makes Site-frequency Tests Conservative

A final comment on frequency-spectrum tests is that, ignoring demographic concerns, they are likely conservative in many settings. In particular, Wall (1999) noted that site-frequency spectrum tests all assume that there is no recombination within the region of interest. While recombination does not bias the expected values for various statistics, it does *reduce* their variances (Rozas et al. 1999; Wall 1999), as the observed values represent the average across several genealogies (Depaulis et al. 2003). As a result, when recombination *does* occur within a region, tests are *conservative*, with the true p value being smaller than the zero-recombination values tabulated by the original authors of the various tests. As a result of this conservative nature of SFS tests under recombination, they are often significantly *underpowered*, using more stringent critical values than necessary. Wall found this effect to be significant when the rate of recombination is on the order of the total regional mutation rate, as is often the case (Table 4.1). Coalescent simulations allowing for recombination can significantly improve the power of tests by obtaining more accurate p values. As discussed in Chapter 4, the four-gamete test (Hudson and Kaplan 1985) can be used to detect recombination in the coalescence history of the sample, and the R_M statistic suggested by these authors estimates the minimal number of recombinants in the sample, which can then be incorporated into an appropriate coalescent simulation (e.g., Depaulis et al. 2005).

HAPLOTYPE-BASED TESTS

While powerful in some settings, the site-frequency spectrum does not contain all the information in a sample of sequences, as it ignores their **haplotype structure**—the nature of the association (linkage disequilibrium, or LD), among segregating sites. Treating distinct haplotypes as distinct alleles moves us from an infinite-sites model of sequence analysis to an infinite-alleles framework (Chapter 2, especially Figure 2.9). It is important to note that tests based on haplotype information tend to be among the most powerful means of detecting an ongoing sweep. Before examining such tests, we first address the central question of just how one defines a haplotype.

Defining and Inferring Haplotypes

If one considers a sufficiently long stretch of DNA, every sequence is a unique haplotype, so just how are haplotypes defined? The answer depends on both the test being used and the features of LD that are of interest. If we are interested in number and diversity of haplotypes in an infinite-alleles framework, the unit of analysis is a sufficiently small region, ideally with no recombination observed in the sample. The four-gamete test of Hudson and Kaplan (1985) can be used to detect recombination in the sample (Chapter 4), helping to define the size of a region (for example, by setting the size of a sliding window moving through a larger region). Practically, one may be constrained to find regions with sufficient haplotype diversity for analysis given either the marker density or background levels of variation, so that small amounts of recombination within the defined region may appear in the sample. For tests based on the average pairwise disequilibrium among all sites within a region, one actually wants some (but not too much) recombination. Finally, tests based on long haplotypes require a **core haplotype** (either a single SNP or a set of a few tightly linked SNPs) to define distinct allelic classes, with the disequilibrium patterns within each class (i.e., as one moves away from the core) forming the basis of tests. Again, recombination (outside of the core) is critical to these tests.

Determining haplotypes requires *phased genotypes*, which are not required for analysis under an infinite-sites model. For example, an *AaBb* individual is segregating at both sites in an infinite-sites analysis and no data on phase are needed. Conversely, for a haplotype (infinite-alleles) analysis, we need to determine if this individual is composed of either *AB*, *ab* or *Ab*, *aB* chromosomes. How, then, are haplotypes inferred? In the simplest case, one has haploid sequence data, which can include *X* chromosome data from males (and *Z* chromosome data from species with heterogametic females), or mitochondrial or chloroplast sequences. One can also have effectively haploid data, such as sequences from fully inbred lines (Example 9.13). Often, however, haplotypes have to be *inferred* from sequence data. The ideal setting for phasing genotypes is **trio** data—both parents and their offspring—but such data are not independent, giving an effective number of sequences in the analysis that is less than the actual number of sequences. More generally, haplotypes for unrelated individuals are inferred from unphased data by a variety of methods (reviewed in Stephens and Scheet 2005), the most popular being PHASE and its descendants (Stephens et al. 2001; Stephens and Scheet 2005). Surprisingly little discussion or analysis appears in the literature as to whether these reconstructions are biased by selection or other demographic departures. Given this concern, it is reasonable for one to feel a little uneasy when using inferred haplotypes in tests of selection.

Overview of Haplotype-based Tests

As reviewed in Table 9.2, a number of haplotype features can be used as the basis for tests of ongoing selection. **Strong haplotype structure** occurs when there are fewer haplotypes than expected given the number, S , of segregating sites within a region. This *underdispersion* of haplotypes is a signature of excessive LD within a region. Strong haplotype structure also results in a deficiency in **haplotype diversity**, H (the probability that two random haplotypes from the sample are different, analogous to Π under the infinite-sites model), and an excess of high-frequency haplotypes (roughly analogous to Fay and Wu's H test; Equation 9.27b). Such signatures are created by any process generating a coalescent with long internal branches (relative to the equilibrium neutral model; see Figure 8.3), such as a partial sweep (the favorable allele is not yet fixed), recovery from a moderate bottleneck, balancing selection, or population structure. Conversely, we can have the opposite pattern (*overdispersion* of haplotypes), with an excess of haplotypes, excess haplotype diversity, and an excess of rare-frequency haplotypes. Such signals are generated by a star-like coalescent genealogy, as would occur near the conclusion of a hard sweep, or the recovery from an extreme population bottleneck. However, in these overdispersed settings, LD summary statistics typically have low power, as S is small (most of the variation is removed), so that while haplotype overdispersion occurs, its signal is often weak.

Table 9.2 Haplotype-based signals of positive selection under different types of sweeps.

Completed or Nearly Completed Hard Sweep	
Overdispersion of haplotype structure relative to S	
Excess number of haplotypes	
Excess haplotype diversity	
Excess of high-frequency haplotypes	
LD structure	
High LD on either side of selected site, little across site	
Partial Sweep or Recent Balancing Selection	
Strong haplotype structure	
Deficiency in number of haplotypes	
Deficiency in haplotype diversity	
Excess of low-frequency haplotypes	
LD structure	
Alleles with long haplotypes at excessive frequencies	
Allele age	
Alleles with long haplotypes at excessive frequencies	
Soft Sweep	
Moderate haplotype structure	
A few dominant haplotypes	
LD structure	
High pairwise LD across entire region	

Another classic LD signature of ongoing selection involves **long haplotypes**, regions of LD far longer than expected given the observed frequency of an allele. High-frequency alleles are (on average) *older* alleles under neutrality (Figure 2.3), and hence have experienced more recombination, resulting in shorter haplotypes. Finally, as developed in Chapter 8, there is a characteristic LD structure around a selected site following a completed sweep. For a soft sweep, an excess of pairwise LD is expected *throughout* this region, even when the site-frequency spectrum shows little change (Pennings and Hermisson 2006b). For a hard sweep, a different pattern is seen with strong LD between sites on the same side of the sweep, but no LD *across* the site (Figure 8.6).

Based on these different possible signatures (summarized in Table 9.2), we place haplotype-based tests into three loose categories. The first are based on the infinite-alleles model, such as the number of unique haplotypes and their frequency distribution within a sample. These are the analogs of site-frequency tests but now under an infinite-alleles framework, focusing on haplotypes instead of sites. The second class of tests utilizes summary statistics of all pairwise linkage disequilibria over sites within a region. The final class essentially uses linkage information to determine the age of an allele, either by looking at sequence variation within a haplotype (such as variability at tightly linked STRs) or by the decay of LD as one moves away from a core sequence. Table 9.3 (at the end of this section) summarizes the rather large number of tests based on these different strategies.

It bears emphasizing that haplotype (and LD) structure can provide signals of selection that are missed by site-frequency and ML-based hard-sweep tests, and thus offer more power in some settings, especially for the detection of partial and soft sweeps (Zeng 2007a; Ferrer-Admetlla et al. 2014). Age-of-allele tests (particularly in the form of detecting long haplotypes) are perhaps the most powerful approach for detecting an *ongoing* sweep, but usually have little to no power once the sweep is close to completion. Conversely, tests based on pairwise LD summary statistics offer significant power (albeit over a very short time window) for the detection of just-completed sweeps.

Example 9.13. Hudson et al. (1994) used a sample of 41 homozygous lines (making haplotypes

easy to infer) of *Drosophila melanogaster* from California and Spain to survey variation at the superoxide dismutase (*Sod*) gene. For these data, neither Tajima's *D* or Fu and Li's *D** (both defined in Table 9.1) were significant. However, the haplotype data told a very different story. The authors classified the 41 sampled chromosomes into two classes: 19 slow and 22 fast, as judged by a fast/slow polymorphism for isozyme mobility. They found that all 19 slow chromosomes were identical in sequence through a 1410-bp region surrounding the fast/slow site, while the 22 fast chromosomes consisted of 10 different haplotypes within this region. They used coalescence simulations (with no recombination), conditional on the observed number of segregating sites and the sample size, to show that this is a significant decrease in variation of slow haplotypes relative to their frequency. This suggested that the slow allele experienced a recent, and rapid, expansion, as might occur under positive selection.

Other *Drosophila* examples where haplotype-based tests gave a strong signal, but site-frequency tests were not significant, include the work of Kirby and Stephan (1995), who found very strong haplotype structure at the *white* locus, but nonsignificant *D* and *D** tests. Andolfatto et al. (1999) examined a 1.4 kb region spanning the breakpoint of a naturally occurring chromosome inversion, also finding highly significant haplotype structure but a nonsignificant *D* value. Finally, Rozas et al. (2001) examined a 1.3 kb region around the ribosomal protein 49 (*rp49*) gene in *D. simulans*. Tajima's *D*, Fu and Li's *D* and *F*, and Fay and Wu's *H* (Table 9.1) were all nonsignificant, while a number of measures of haplotype structure (diversity, number of haplotypes, and the frequency of the most common haplotype) were all significantly different from neutral expectations in most populations.

The Ewens-Watterson Test

The first formal tests of selection in the molecular era were based on haplotypes (i.e., number of alleles), and their development proceeds as follows. Assuming that the region of analysis is sufficiently small such that no recombinants are expected in the sample, the simplest approach is to treat each distinct haplotype as a distinct allele. Following the notation from Chapter 2, let k be the number of alleles (distinct haplotypes) in a sample of size n sequences, and n_i be the number of alleles in the sample present in exactly i copies. For example, if one allele is present as five copies, three alleles are each present as two copies, and four alleles are present as singletons, then $k = 8$, and the allele-frequency spectrum becomes $n_5 = 1, n_2 = 3, n_1 = 4$ (with all other $n_i = 0$), and $n = \sum i \cdot n_i = 15$. Equation 2.33b gives $\Pr(n_1, n_2, \dots, n_k | n, k)$, namely, the expected frequency spectrum under neutrality given n and k . Ewens (1972) and Watterson (1977, 1978) proposed comparing the fit of the observed allele-frequency spectrum to the conditional distribution given the observed number of alleles, k .

Ewens suggested using the following summary statistic of the frequency spectrum,

$$I = - \sum_{i=1}^n n_i \left(\frac{i}{n} \right) \ln \left(\frac{i}{n} \right) \quad (9.30a)$$

His motivation for this statistic was its use as a general measure of dispersion (information) in the data. Watterson (1977, 1978) showed that the sample homozygosity

$$h = \sum_{i=1}^n n_i \left(\frac{i}{n} \right)^2 \quad (9.30b)$$

was a better choice for improved power to detect departures under weak overdominance (the selection model du jour of the time). Comparing the statistic given by Equation 9.30b with its value under the equilibrium neutral model is known as the **Ewens-Watterson test** (also the **Watterson test** or **homozygosity test**). Watterson proposed to assess significance by taking a large number of draws from Equation 2.33b (using the observed number, k , of

alleles in the sample) to generate a null distribution of h values to compare against its value in the original sample. The same approach can also be used for the Ewens statistic (Equation 9.30a).

Advances in computational speed led Slatkin (1994, 1996) to propose an **exact Watterson test**, wherein one computes all possible h values over the set for a given value of n , as opposed to randomly sampling some number of draws from Equation 2.33b. This same approach is the basis for Fisher's exact test for contingency tables, and hence the name. The resulting value P_h is computed as

$$P_h = \sum_{\mathbf{n}^* \text{ such that } h(\mathbf{n}^*) \leq h} \Pr(n_1, n_2, \dots, n_k | n, k) \quad (9.31a)$$

namely, the sum over all *configurations* $\mathbf{n}^* = (n_1, \dots, n_k)$, constrained by $\sum i n_i = n$ (Equation 2.32), that give a value of h (Equation 9.30a) that is the same, or smaller than, the observed sample value of h .

Slatkin also suggested a second exact test, wherein one computes the probability over all possible configurations *directly*, as opposed to using the less informative summary statistic h , with

$$P_e = \sum_{\substack{\mathbf{n}^* \text{ such that} \\ \Pr(\mathbf{n}^* | n, k) \leq \Pr(\mathbf{n} | n, k)}} \Pr(n_1, n_2, \dots, n_k | n, k) \quad (9.31b)$$

where the vector, \mathbf{n} , is the observed allele-frequency spectrum. The difference between P_e and P_h is that the sum is over a different set of \mathbf{n}^* . In Equation 9.31a, the sum is over those \mathbf{n}^* that give smaller h values than observed in the sample, while in Equation 9.31b the sum is over those \mathbf{n}^* values that give a smaller probability of a particular configuration than in the original sample. Slatkin found that the resulting p values for both tests are very similar for small n , but can be rather different for large n .

Zeng et al. (2007a) found that the Ewens-Watterson (EW) test was among the most powerful for detecting selection during the sweep phase, but Zhai et al. (2009) found that its power quickly falls off near fixation. Because the classic infinite-alleles model assumes the sequence has no recombination (at least in the sample), a reasonable concern is how robust the EW test is to recombination. Zeng et al. found that it is remarkably so, in part because the number of distinct alleles, k , contains information on local recombination rates, so that conditioning on k partly accommodates the impact from recombination.

Other Infinite-alleles Tests: Conditioning on $\hat{\theta}$

Watterson-type tests use the *conditional* allele-frequency spectrum, where the observed number of alleles, k , is used in Equation 2.33b to generate the null distribution. What about tests based on k itself, such as whether there are too many, or too few, alleles based on some other diversity measure? Such tests use the sampling distributions given by either Equation 2.30a or Equation 2.33a, and require an estimate of θ . Fu (1996, 1997) used this approach to test whether a sample contains too many, or too few, alleles (haplotypes) relative to the neutral equilibrium model. His **W test** (1996) used the Ewens sampling formula (Equation 2.30a) with θ replaced by the Watterson estimator, $\hat{\theta}_S$ (Equation 4.3a), and it returns the probability of seeing k (or fewer) alleles in the sample as

$$W = \Pr(K \leq k) = \sum_{i=1}^k \Pr(K = i | \hat{\theta}_S, n) = \sum_{i=1}^k \frac{S_n^i \cdot [\hat{\theta}_S]^i}{S_n(\hat{\theta}_S)} \quad (9.32)$$

where S_n^i is the coefficient on $(\hat{\theta}_S)^i$ in the polynomial

$$S_n(\hat{\theta}_S) = \hat{\theta}_S (\hat{\theta}_S + 1) (\hat{\theta}_S + 2) \cdots (\hat{\theta}_S + n - 1)$$

These coefficients are called **Stirling numbers**, hence the S_n^i notation. This is a test for a deficiency of rare alleles/haplotypes, and hence is *one-sided*. Fu showed that the W test is more

powerful than Tajima's D or Fu and Li's D^* and F^* tests (Table 9.1) for detecting signals of balancing selection or a structured population. Indeed, Strobeck (1987) proposed essentially the same test (using $\hat{\theta}_{\Pi}$ in place of $\hat{\theta}_S$) as a method for detecting population structure, rather than selection.

Fu's F_S **test** (1997) is the compliment of W , as it tests for an *excess of rare alleles/haplotypes*. It starts by computing the probability of seeing k or more alleles/haplotypes in a sample,

$$S' = \Pr(K \geq k) = \sum_{i=k}^n \frac{S_n^i \cdot [\hat{\theta}_{\Pi}]^i}{S_n(\hat{\theta}_{\Pi})} \quad (9.33a)$$

but now using $\hat{\theta}_{\Pi}$, the estimator of θ based on average number of pairwise differences (which is more sensitive to sites with intermediate allele frequencies). Fu noted that S' is not an optimal test statistic because its critical values are often too close to zero. Because of this, the test uses the transformation

$$F_S = \ln \left(\frac{S'}{1 - S'} \right) \quad (9.33b)$$

As with W , this is also a one-sided test. F_S is negative when there is an excess of rare alleles/haplotypes (as would occur with a selective sweep or population expansion), with a sufficiently large negative value serving as evidence for selection or population expansion. Fu (1997) showed that F_S is more powerful than Tajima's D and the Fu-Li D^* and F^* tests (Table 9.1) for detecting selective sweeps or population expansion following a bottleneck.

Other Infinite-alleles Tests: Conditioning on S

While elegant in using exact results from the allele-frequency sampling distributions, these tests for excessive k values *do not* return exact p values, as using an estimate, $\hat{\theta}$, in place of the true value, θ , makes both Equation 2.30a and Equation 2.33a only approximations. Hudson et al. (1994) and Depaulis and Veuille (1998) noted that while θ is unknown, the number of segregating sites, S , is directly observed. Hence, one can generate coalescence genealogies (via simulation) and then randomly place the S segregating sites over them (at a rate proportional to the branch lengths within the coalescent), generating a distribution of haplotypes in the final sample. This procedure generates draws under the neutral equilibrium model conditioned on the observed number of segregating sites. In effect, these tests examine the sequence data from *both* the infinite-alleles and infinite-sites perspectives. While the number of alleles, k , is a sufficient statistic under the infinite-alleles model, S is *not*. Conditioning on S , the distribution still has a dependency on θ , although this is often weak (Griffiths 1982; Depaulis et al. 2001, 2005; Markovtsova et al. 2001; Wall and Hudson 2001; Innan et al. 2005).

A detailed analysis by Ramos-Onsins et al. (2007) examined the distributions associated with nine haplotype-based tests and compared those generated by conditioning on an observed S with those using a known value of θ . All distributions based on conditioning on S departed significantly from their corresponding distributions using a known θ . More critically, the departure was usually in the tails, where p values are obtained. As a result, Ramos-Onsins et al. recommended against using infinite-alleles methods that condition on S . Further, Zeng et al. (2007a) found that tests that are conditional on S suffer from low power (being overly conservative) in the presence of recombination and concluded that tests conditioning on the number of alleles, k , are more powerful than those conditioning on the number of segregating sites, S . Tests conditioned on k are more robust to recombination, because k includes some information on recombination (being a function of haplotypes), while S does not (being a function of individual sites). Despite these concerns, infinite-alleles tests based on conditioning on S appear widely in the literature.

Hudson et al. (1995) pioneered this approach of conditioning on S with their **haplotype test**, also referred to as the **haplotype partition (HP)** or Hudson's haplotype test (**HHT**). Its

initial form (motivated by the observations discussed in Example 9.13) was a rather open-ended test: given a sample of n sequences with S segregating sites, what is the probability of observing j sequences with i or fewer alleles (for example, what is the chance of observing $j = 3$ alleles present as $i = 2$ copies or less, i.e., $n_2 + n_1 = 3$). This is akin to Slatkin's exact test (Equation 9.31b), concerning the likelihood of a given allele-frequency configuration. The difference is that Slatkin's test conditions on the observed number of alleles, k , while Hudson's test conditions on S . Hudson's test is typically implemented by asking if there is an excess of the most frequent haplotype (Depaulis et al. 2005; Innan et al. 2005). Suppose there are n sequences and the highest-frequency haplotype occurs j times. Hudson's test is

$$\Pr(n_i \geq 1 \text{ for } i \geq j | S)$$

where, as above, n_i is the number of alleles present as exactly i copies in the sample. Andolfatto et al. (1999) extended Hudson's test using a sliding window of variable size to scan the region of interest and developed a correction for multiple tests (the different windows). Again, hypothesis testing is done using the null generated from a coalescent with S segregating sites.

Depaulis and Veuille (1998) also used conditioning on S and developed two tests. Their **haplotype number, or K , test** is essentially Fu's W test (Equation 9.32), but using $\hat{\theta}_S$ (and hence conditioning on S) rather than $\hat{\theta}_{\Pi}$. Their **haplotype diversity, or H , test**, uses the statistic

$$H = 1 - \sum_{i=1}^k p_i^2 \quad \text{with } p_i = \text{frequency of the } i\text{th haplotype} \quad (9.34a)$$

namely, the haplotype heterozygosity, which is compared to its expected neutral equilibrium value given S . A comparison with Equation 9.30b shows that the H test is essentially the Ewens-Watterson test, but with its significance assessed by conditioning on S rather than k . Note that the range on H is

$$\frac{2(n-1)}{n^2} \leq H \leq 1 - \frac{1}{n} \quad (9.34b)$$

with the lower bound set by the sample consisting of just two haplotypes, one with $n-1$ copies and the other a singleton ($n_{n-1} = 1, n_1 = 1$), while the upper range is set by all of the haplotypes being present as singletons ($n_1 = n$). Critical values for these statistics (conditioned on n and S) generated from coalescent simulations were tabulated by Depaulis and Veuille (1998).

Finally, Innan et al. (2005) proposed a **haplotype configuration test (HCT)**, based on the configuration of the haplotype (allele) frequency spectrum. Again, this is a version of Slatkin's exact test (Equation 9.31b), but now the conditioning is on S (as opposed to k),

$$P_E = \sum_{\substack{\mathbf{n}^* \text{ such that} \\ \Pr(\eta^* | n, k) \leq \Pr(\eta | n, S)}} \Pr(n_1, n_2, \dots, n_k | S) \quad (9.34c)$$

These probabilities can easily be generated using the constant- S coalescent simulation approach discussed above. Depaulis et al. (2005) and Innan et al. (2005) discussed haplotype-frequency spectrum approaches in greater detail, while power and bias issues were examined by Ramos-Onsins and Rozas (2002), Depaulis et al. (2003, 2005), and Ramos-Onsins et al. (2007).

Other approaches based on haplotype number have also been suggested, although more as heuristics and summary statistics than as formal tests. Przeworski (2002) suggested standardizing the number of haplotypes by the number of segregating sites, using $k' = k/(S+1)$. A smaller k' implies higher LD, as specific combinations of segregating sites are locked into a small number of haplotypes. Przeworski noted that while k' tends to decrease as one approaches a selected site during an ongoing hard sweep, k' can actually be greater

than its expectation under the equilibrium neutral model *after* a sweep is completed. This occurs because high-frequency variants are fixed and new mutations arise, most of which are singletons and hence form a large collection of unique haplotypes. She noted that excluding singletons when computing both k and S gives k' much more stability, with the adjusted k' sharply decreased at the completion of a hard sweep and then increasing back to its neutral expectation in $\sim N_e$ generations after the sweep.

Garud et al.'s H_{12} and H_2 Tests

A number of tests are built around **haplotype homozygosity (HH)**, the probability that two randomly chosen haplotypes are identical. This is given by the complement of the Depaulis-Veuille H (haplotype heterozygosity) statistic (Equation 9.34a),

$$H_1 = 1 - H = \sum_{i=1}^k p_i^2 \quad (9.35a)$$

where p_i is the frequency of the i th haplotype in the sample. To adjust for sampling, some variants of this statistic replace p_i^2 with $[p_i + (1/k)]^2$, where k is the number of haplotypes (e.g., Kemper et al. 2014). As mentioned in Chapter 8, Garud et al. (2015) showed that a simple modification of this statistic results in a test that can detect *both* hard and soft sweeps. Their H_{12} test statistic combines the two largest haplotype classes into a single one,

$$H_{12} = (p_1 + p_2)^2 + \sum_{i>3} p_i^2 = H_1 + 2p_1 p_2 \quad (9.35b)$$

The logic is that a soft sweep results in not one, but several, dominant haplotypes. If the sweep is not too soft, then the first two haplotypes, both presumably harboring the favored allele, will together comprise most of the haplotype variation. In the case of a hard sweep, the second-most frequent haplotype will be sufficiently rare that $H_{12} \simeq H_1$. The authors applied this approach to *Drosophila*, looking at windows with a fixed number of SNPs and adjusting for the local recombination rate and then used coalescent simulations to generate values under the null of neutrality.

Garud et al. considered a second modified HH statistic, namely, the homozygosity with the largest class removed

$$H_2 = \sum_{i>1} p_i^2 \quad (9.35c)$$

Under a hard sweep with its single dominant haplotype, H_2 should be considerably smaller than H_1 , while under a soft sweep the drop-off in value from H_1 to H_2 should be much less dramatic. Based on this observation, the ratio H_2/H_1 forms the basis of a test as to whether a detected sweep is hard or soft, with moderate values suggesting soft sweeps and very small values suggesting hard sweeps (Garud et al. 2015; Garud and Rosenberg 2015).

Recombination and Infinite-alleles-based Tests

What is the effect of recombination on these various infinite-alleles-based tests? Recall that recombination had a uniform effect on the interpretation of site-frequency spectrum tests, making all SFS tests conservative, and hence underpowered. This is *not* the case for haplotype-based tests. Recombination creates new alleles, which inflates the number of haplotypes, the diversity of haplotypes, and the number of rare haplotypes, while decreasing the frequencies of the most common haplotypes. Thus, depending on the test, recombination can either make a test conservative, with p values being too large, or anticonservative, with p values being too small (Depaulis et al. 2001; Rozas et al. 2001; Wall and Hudson 2001; Depaulis et al. 2005; Ramos-Onsins et al. 2007; Zeng et al. 2007a). Tests for a low number of haplotypes, low haplotype diversity, and excessive high frequency of the most common haplotype are all conservative under recombination. Tests for excess rare haplotypes, excess haplotype diversity, and excess haplotype number all have their p values reduced

by recombination (making these tests anticonservative). Finally (as mentioned above), the Ewens-Watterson test (Equation 9.30b) is relatively robust to recombination, as conditioning on the number of alleles, k , partly accounts for recombination.

Incorporating recombination into coalescent simulations significantly improves the power for conservative tests and creates more accurate p values for anticonservative tests. However, using incorrect recombination values can significantly bias a test. Under the coalescent framework, recombination is measured by $4N_e c$, the population-scaled rate (Chapter 4), with c as the recombination frequency for the size of haplotypes being considered. Depaulis et al. (2005) offered the following suggestion. First, estimate Hudson's minimal number of recombinants, R_M , in the sample from the four-gamete test (Chapter 4), and then choose $4N_e c$ in the coalescent simulations as the value that gives 5% (or less) of the samples showing R_M or more recombinations.

Pairwise Disequilibrium Tests: Kelly's Z_{nS} and Kim and Nielsen's ω_{max}

Positive selection can produce two very different patterns of disequilibrium around a site. For soft and partial sweeps, there is an excess of LD *throughout* a region, while for completed hard sweeps, LD is found on *either side* of the selected region, but not *through it* (Chapter 8). To test for these patterns, two different averages of pairwise disequilibrium within a region have been proposed. Both start with Hill and Robertson's (1968) scaled measure of the disequilibrium, which is expressed as a correlation coefficient

$$r_{ij}^2 = \frac{D_{ij}^2}{p_i(1-p_i)q_i(1-q_i)} \quad (9.36a)$$

where D_{ij} is the disequilibrium between sites i and j , and p_i and q_i are the frequencies of leading alleles at the two sites. For a general measure of the average amount of LD throughout a region with S segregating sites, Kelly (1997) proposed using the average over all of the pairwise squared correlations

$$Z_{nS} = \frac{2}{S(S-1)} \sum_{i=1}^{S-1} \sum_{j=i+1}^S r_{ij}^2 \quad (9.36b)$$

This is often computed over windows of various sizes, so that (for example) Z_{n5} and Z_{n8} denote values for windows with five and eight segregating sites, respectively. Kelly showed that values of Z_{nS} are largely determined by the final coalescent time in the sample (the time for the last two lineages to coalesce into the ancestral lineage for the entire sample). The longer this time, the larger the value of Z_{nS} . This statistic is smallest under a star genealogy, as most of the coalescence events will have occurred at roughly the same time (i.e., the nodes of the genealogical tree are extremely compressed).

Thus, a small value of Z_{nS} is consistent with a hard sweep or an extreme bottleneck. In such cases, there is usually a reduced amount of site polymorphism, which in turn reduces the power of Z_{nS} . Conversely, with a partial or soft sweep, Z_{nS} increases. Critical values of Z_{nS} are determined by coalescent simulations that are conditional on S (as discussed above). When recombination is ignored, the one-sided test of excessive Z_{nS} values is conservative (as recombination lowers Z_{nS}), while the test of reduced Z_{nS} values is anticonservative. Pennings and Hermisson (2006b) suggested that LD-based tests, such as Z_{nS} , may have the most power to detect a *very recent* soft sweep.

Kim and Nielsen (2004) proposed a different measure of pairwise disequilibrium designed for the expected pattern of LD following a hard sweep (Figure 8.6). Here, there is LD on either side, but not *across* the site (this LD signal dissipates rather quickly, roughly on the order $\sim 0.1N_e$ generations immediately following a sweep; Przeworski 2002; Jensen et al. 2007). Based on this disjoint LD pattern, Kim and Nielsen proposed a test statistic, ω , comparing LD within, versus across, the left and right sides of a sliding window. Suppose there are ℓ sites $(1, \dots, \ell)$ on the left (L) side of the putative selected region and $S - \ell$ (sites

$\ell + 1, \dots, S$ on the right (R). Define

$$\omega = C_{S,\ell} \frac{\sum_{i,j \in L} r_{ij}^2 + \sum_{i,j \in R} r_{ij}^2}{\sum_{i \in L, j \in R} r_{ij}^2}, \quad C_{S,\ell} = \frac{\ell(S-\ell)}{\binom{\ell}{2} + \binom{S-\ell}{2}} \quad (9.37)$$

where the combinatorial term, $C_{S,\ell}$, is a function of the number of sites contrasted over the three comparisons (within L , within R , and between L and R). Under the distinct signal of LD from a completed hard sweep, one expects a large value for the numerator (strong LD within either side) and small denominator value (little LD across sides) around a sweep, giving a large value of ω . Because r^2 is sensitive to small allele frequencies, polymorphic sites showing singletons are best ignored when computing ω . Kim and Nielsen's test statistic ω_{max} (which gives rise to the name of their test) is the maximum value of Equation 9.37, a function of both window size and window position, with critical values determined via a coalescent simulation. Pavlidis et al. (2010) offered improvements that allow this test to be scaled up to scan an entire genome efficiently, which are implemented in their **OmegaPlus** package (Alachiotis et al. 2012).

Jensen et al. (2007) found that this approach had promise for a very vexing situation: detecting sweeps that start in nonequilibrium populations (i.e., those having experienced a recent change in population size). Indeed, Crisci et al. (2013) found that OmegaPlus outperformed SFS-based (*SweepFinder*, *SweepD*) and long-haplotype (*iHS*; see below) tests under both equilibrium and nonequilibrium settings in detecting an ongoing sweep.

Jensen et al. found that population structure does not cause the distinctive hard-sweep LD pattern detected by ω , but that a very strong bottleneck (1% of the population surviving) can give modest ω_{max} scores, and hence some chance of a false-sweep signal. The effects of recombination on this test (i.e., recombination within the test window) are a bit unclear. On the one hand, by reducing r_{ij}^2 values within each side, recombination should be conservative. Conversely, by also reducing r_{ij}^2 values between sides under the null, this can inflate p values, making the test anticonservative. Kim and Nielsen found that while assuming the incorrect value for the scaled recombination rate, $4N_e c$, in coalescent simulations for the null decreases power, ω_{max} is more robust to incorrect $4N_e c$ values than Z_{nS} .

To summarize these two LD-based test statistics, Z_{nS} has the power to detect partial sweeps and recently completed soft sweeps, but poor power to detect recently completed hard sweeps. Conversely, ω_{max} has good power to detect a recently completed hard sweep and also has robustness against many demographic concerns, although a severe bottleneck can also generate modest genome-wide ω_{max} scores. While most LD/haplotype tests have more power *during* a sweep, these two statistics have power only during a very short time window ($\sim 0.1 N_e$ generations) immediately *following* a successful sweep. A final concern is that even rare amounts of gene conversion involving the selected site can significantly distort any disequilibrium-based signature (Andolfatto and Nordborg 1998; Jones and Wakeley 2008).

Contrasting Allele-frequency vs. Intra-allelic Variation Estimates of Haplotype Age

As discussed above, we define an allele by either a single SNP or a set of SNPs sufficiently close together that no recombination has occurred between them in our sample. Moving outward from this core, we can examine the structure of haplotypes for a given allele in progressively longer regions, which we loosely refer to as the haplotypes for a given allele. The pattern of variation among the haplotypes associated with a single allele provides information on its age.

Assuming that an allele arose as a single mutation, it initially was on a single haplotype background in complete LD with tightly linked markers. As the allele ages, the fraction of copies associated with the original background decays through recombination. Likewise, new mutations at tightly linked sites arise, with the number of segregating SNPs (and copy-number variation at STRs) both increasing with age. Hence, the diversity of haplotypes associated with that allele provides information about its age (reviewed by Slatkin

and Rannala 1997, 2000). A common approach (especially in human genetics) is to contrast one (or more) of these **intra-allelic variation** estimates of age with the estimate of age based on allele frequency (e.g., Example 2.3). Figure 2.3 shows that, under the equilibrium neutral model, *a common allele is an old allele*. As such, there is time for mutation and recombination to act, generating a more diverse collection of haplotypes associated with a particular SNP variant. While a few formal tests have been proposed to determine whether there is too little (directional selection) or too much (balancing selection) intra-allelic variation (Slatkin 2000, 2008; Slatkin and Bertorelle 2001), our goal here is to review the different age estimators, as discrepancies between them are often offered as evidence supporting selection. As with many tests, allelic surfing can result in neutral alleles of a young age that are common at the edges of an expanding population, generating false positives in allelic-age tests.

While Equation 2.12 gave a simple expression for the expected age of an allele as a function of its frequency, it is a bit misleading, due to its very large variance. A better estimator follows from Slatkin and Rannala (2000), based on their approximation for the probability distribution of age as a function of frequency under the equilibrium neutral model (also see Watterson 1976; Griffiths and Tavaré 1998; Griffiths 2003). Letting T denote time scaled in $2N_e$ generations, then for an allele whose frequency is p in a sample of size n , the probability that the true age, T , is less than τ (namely, no older than $2N_e\tau$ generations) is given by

$$\Pr(T \leq \tau) \simeq (1 - p)^{-1+n/(1+n\tau/2)} \quad (9.38a)$$

This is simply Equation 2.13, now expressed in units of $2N_e$ generations, which is a more natural time scale for drift (being the expected coalescent time for two neutral alleles). Taking the derivative with respect to τ recovers the probability density function, and hence the likelihood function (LW Appendix 4). The resulting distribution is very skewed, with a long heavy tail toward increased age. As a result, the mode of the distribution (the maximum likelihood estimator or MLE; LW Appendix 4) is less, and usually substantially so, than the mean. In particular, the MLE (in units of $2N_e$ generations) for T becomes

$$\text{MLE}(T) = -\ln(1 - p) - \frac{2}{n} \quad (9.38b)$$

Unlike Equation 2.12, the MLE accounts for the sample size, n , used to estimate p . A $100(1 - \alpha)\%$ confidence interval for age is given by $(\tau_{\alpha/2}, \tau_{1-\alpha/2})$, where τ_x is the solution in Equation 9.38a of

$$\Pr(T \leq \tau_x) = x \quad (9.38c)$$

For large n , $n/(1 + n\tau_x/2) \simeq 2/\tau_x$, reducing Equation 9.38a to

$$x \simeq (1 - p)^{-1+2/\tau_x}$$

which yields a solution to Equation 9.38c as

$$\tau_x \simeq \frac{2}{1 + \ln(x)/\ln(1 - p)} \quad (9.38d)$$

This equation can be used to approximate confidence intervals when n is large. When n or x are small, it serves as a starting value for numerically solving Equation 9.38c (for example, one can plot Equation 9.38a as a function of τ around the value give by Equation 9.38d to visually search where it equals x). The weakness of this estimator is that it is *extremely* sensitive to demography (Slaktin 2000; Slaktin and Rannala 2000).

Example 9.14. Recall Example 2.3, where we showed (following Stephens et al. 1998) that the estimated age of the HIV-resistant *CCR5-Δ32* mutation (roughly 5100 generations from Equation 2.12) was incompatible with an independent estimate of its age based on intra-allelic

variation (roughly 28 generations). Is this conclusion changed if Equation 9.38b and 9.38d are used instead of Equation 2.12 to estimate age from frequency? In Example 2.3, we used $p = 0.10$ and $N_e = 5000$. Taking $n = 4000$ as the approximate sample size of Europeans used to estimate the allele frequency, Equation 9.38b gives the MLE as

$$\text{MLE}(t) = -2N_e \left(\ln(1 - p) + \frac{2}{n} \right) = -10,000 \left(\ln(0.9) + \frac{2}{4000} \right) = 1048 \text{ generations}$$

One reason for this discrepancy relative to the estimate of 5100 generations from Equation 2.12 is that the latter uses the mean, while Equation 9.38b uses the mode, of the allelic-age distribution. The long tail of the age distribution significantly skews the mean to much higher values, due to rare events associated with very large ages.

While the MLE-based estimator is much smaller than that given by Equation 2.12, does its 95% confidence interval still exclude the variation-based estimate of ~ 30 generations? Values of $\tau_{0.025}$ and $\tau_{0.975}$ are obtained by solving Equation 9.38c. Using the approximation offered by Equation 9.38d yields starting values (in units of $2N_e$ generations) of 0.055 and 1.61. Plotting Equation 9.38c around these values gives the exact answers, $\tau_{0.025} = 0.067$ and $\tau_{0.975} = 1.61$, which translates into 670 to 16,100 generations ($2N_e\tau_{0.025}$ and $2N_e\tau_{0.975}$, respectively). Despite this very wide range, the lower value still greatly exceeds 28 generations, meaning that the frequency of this allele is not consistent with an equilibrium neutral model.

Novembre et al. (2005) examined spatial models of the spread of this allele in Europe, showing that both strong selection and long-distance dispersal are required to account for its current geographic distribution. The agent of selection is thought to be smallpox (reviewed by de Silva and Stumpf 2004; Stumpf and Wilkinson-Herbots 2004; Galvani and Novembre 2005). However, as is often the case with claims of selection, the evidence may not be as definitive as the previous analysis suggests. Sabeti et al. (2005), using refined recombination estimates, obtained an allelic-age estimate of around 280 generations with a 95% confidence interval of 116 to 630. This is consistent with the observation that this allele is found in 2900-year-old skeletal remains (roughly 120 generations ago) from different locations in southern Europe. The lower end of our previous confidence interval (670) comes fairly close to Sabeti et al.'s (2005) upper estimate of 630 generations. Hence, the CCR5- $\delta 32$ mutation may be significantly older than suggested from the Stephens et al. (1998) analysis. Further, Sabeti et al. found that this allele exhibited none of the classic long-haplotype, or other, features expected from a partial sweep (as would be generated by a selected allele increasing in frequency).

As Example 9.14 shows, potential evidence for selection is offered when a frequency-based estimator of age (which assumes a pure-drift model) is too large relative to an estimate based on within-haplotype variation. Because these comparisons involve *segregating* alleles, they are designed to detect sweeps that are currently underway (ongoing selection) as well as recent partial sweeps (where selection in the past has swept an allele up to near its current frequency, but is either now much weaker or no longer occurring). Intra-allelic age estimators are also important in their own right, as the age of an allele currently under selection, or the time since a sweep has completed, is of interest. We briefly consider three haplotype-based estimators of allelic age here: (i) the persistence of disequilibrium with a marker at a known recombination fraction, c ; (ii) the number of segregating sites within a very closely linked region; and (iii) the variance at STRs. The last two measures are assumed to be scored in a sufficiently close region around the allele that recombination can be ignored. The major caveat with any of these approaches is that intra-allelic age estimates generally tend to have a downward bias, making alleles appear too young (Slatkin and Rannala 2000). Given that most contrasts of frequency and intra-allelic variation invoke selection when the frequency estimate is much older than the variation-based estimator, *caution is always in order when using this approach*.

The technique of estimating age from the persistence of LD between an allele and a linked marker (Example 2.3) was first proposed by Serre et al. (1990). Again, we assume there is no selection. Let A denote a marker allele at a site closely linked to the target allele, B , that we are trying to age. The marker allele is typically chosen because the target allele is

overrepresented on A -bearing haplotypes (relative to its population frequency), suggesting that the initial mutation arose on such a background (i.e., an AB haplotype). Let $x(t)$ denote the current frequency of B -bearing haplotypes that also contain the marker allele A . If we assume there is a single-origin mutation that occurred on an A background, then $x(0) = 1$. If we let y be the frequency of haplotypes carrying A in the ancestral population, we further assume that this ancestral value is close to the present-day value (i.e., we assume that $t \ll 1/[2N_e]$). The resulting decay in LD by recombination is

$$x(t) - y = (1 - c)^t [x(0) - y] = (1 - c)^t (1 - y) \quad (9.39a)$$

This follows because $x(0) - y$ is the initial disequilibrium, which decays at a rate of $(1 - c)$ per generation (note that this is just a modification of Equation 8.2a). Solving for t yields

$$t = \frac{1}{\ln(1 - c)} \ln \left(\frac{x - y}{1 - y} \right) \quad (9.39b)$$

where x is the current frequency of AB haplotypes. This approach is very closely related to LD mapping (LW Chapter 14), where in the latter, one assumes that t is known and solves for c via Equation 9.39a. Equation 9.39b is a slightly more accurate approach for estimating age than was used in Example 2.3, as it accounts for the population-wide frequency, y , of the marker allele. A. Risch et al. (1995) and McPeek and Strahs (1999) discussed how information from multiple marker loci linked to the target site can be simultaneously used to estimate t . The delicate issue in applying Equation 9.39b is that it is sensitive to c . Using a value of c less than the true value overestimates the age, while the age will be underestimated if too large a c value is used.

A second approach to estimate the age of an allele using intra-allelic diversity is based on the number of segregating sites in a tightly linked region around the target allele (Example 8.5). This approach is typically used to estimate the age of a sweep (as opposed to, e.g., Equation 9.39b, which provides an age estimate for a contrast to a frequency-based age estimator). Under a hard selective sweep (and hence an approximate star genealogy for the sampled sequences), Equation 8.14 provides a rough estimate of age as $t = S/\mu n$, where n is the sample size, S is the number of segregating sites, and μ is the total mutation rate for the region being considered. Alternatively, one could use the fact that S follows a Poisson distribution to obtain both an ML estimator and confidence intervals (Example 9.15). Examples 8.5 and 9.15 both assume there is a very defined genealogy, which in reality is unknown, introducing considerable noise (and possible bias) into these estimators. In particular, the assumption of a star genealogy creates a process with too little variation, and hence confidence intervals that are too narrow. As emphasized by Slatkin and Rannala (2000), there is considerable variation in a particular genealogy *even* under an equilibrium neutral model.

Example 9.15. Meiklejohn et al. (2004) observed three segregating sites ($S = 3$) in a population sample of $n = 26$ sequences from a region spanning the *janB* locus in *Drosophila simulans*. They assumed that the total mutation rate for this region was $\mu = 1.73 \times 10^{-5}$ per year. For a mutation arising t years ago, the expected number of mutations on a single sampled allele is μt . Under the approximation that the coalescence has a star-shaped structure (very little shared coalescence time among sampled alleles, as would be expected in a sweep or partial sweep), each of the n lineages in the sample is essentially independent of the others, giving the expected number of segregating sites in a sample of n alleles as $\lambda = n\mu t$, with the distribution of observed S values within the sample following a Poisson distribution with a parameter of λ . The resulting MLE for t given these data is simply the value that maximizes the likelihood, given $S = 3$,

$$\Pr(S = 3 | t \mu) = \frac{\lambda^3}{3!} \exp(-\lambda) \quad \text{where} \quad \lambda = n\mu t = 0.0004498 t$$

Plotting this expression as a function of t shows that the maximum of this expression (and hence the MLE) occurs at $t = 6667$ years (which is essentially identical to the simpler estimate given by Equation 8.14). The 95% confidence interval follows from the Poisson distribution, by finding those values of $t_{0.025}$ and $t_{0.975}$ such that $\Pr(S \leq 3 | t_{0.025} \mu) = 0.025$ and $\Pr(S \leq 3 | t_{0.975} \mu) = 0.975$, where (from the Poisson)

$$\Pr(S \leq 3 | \lambda) = \exp(-\lambda) \left(1 + \lambda + \frac{\lambda^2}{2!} + \frac{\lambda^3}{3!} \right)$$

Numerically solving this equation yields $\Pr(S \leq 3 | \lambda = 8.77) = 0.025$ and $\Pr(S \leq 3 | \lambda = 1.09) = 0.975$. Because $\lambda = 8.77 = 26 \cdot (1.73 \times 10^{-5}) \cdot t$, the upper limit of t becomes $8.77/[26 \cdot (1.73 \times 10^{-5})] \sim 19,500$ years. Similarly, the lower limit is ~ 1400 years.

The copy-number variance at an STR also provides an estimator of age. As above, a new mutation arises on a haplotype carrying a specific allele (whose state is defined by repeat copy length) at a linked STR. As that haplotype spreads and ages, variants arise at the STR, generating variance in copy number at the STR for the haplotype carrying the mutation. As noted previously, using copy-number variance to estimate the age is very model dependent, especially given the unknown structure of STR mutation. Assuming a simple stepwise mutation scheme with a mutation rate that is constant over array size, Thomas et al. (1998) noted that the average squared difference between copy number over all sampled haplotypes and the ancestral haplotype has an expectation of μt , where μ is the microsatellite mutation rate. Much more sophisticated analyses can also be used (e.g., Wilson et al. 2003). Given their high mutation rates, STR variation can allow for more precise estimation of younger alleles than approaches using segregating sites or recombination with very tightly linked sites. The major caveat is that using the wrong mutational model can yield biased estimates (as rates can change with copy number and single mutations may result in copy-number changes greater than one).

Finally, we have seen examples in Chapter 8 where the insertion of a mobile element generated an adaptive mutation (most likely due to regulatory changes). Mobile elements provide a unique age-based test for adaptation, as one can date the insertion (and hence the age of the new mutation it creates). A typical element is several kilobases long, and its age of insertion can be estimated by looking at two features. Some elements generate direct or inverted flanking repeats of known length. While typically just a few bases long, divergence between these short repeat segments can be used to date an insertion. Much more information is provided by the sequence divergence of the inserted element itself, which has a mutational target size of several kb. One approach is to compare the insertion against a consensus sequence for active elements. While not fool-proof (there can be existing divergence in active elements and the insertion event itself might be error-prone, such as in retrotransposons), this does provide an approach to age the insertion. See Blumenstiel et al. (2014) for details.

Long-haplotype Tests Using Within-population Data: *rEHH, LDD, iHS, nS_L, SDS, and DIND*

The currently most popular class of allele-age-based tests are those that search for alleles that are at moderate to high frequency and with long haplotypes. Under the neutral model, a common allele is an old allele and hence has experienced many generations of recombination. Long haplotypes for strictly neutral alleles are only expected when either the allele is very young or when the recombination rate is greatly suppressed.

Recall our previous discussion on the definition of an allele, namely a core SNP or set of very tightly linked SNPs that define alternate classes. For alleles defined by a single biallelic SNP, this generates two classes (sequences carrying the alternative SNP alleles). The haplotype structure within each allelic class is examined by looking at shared variants

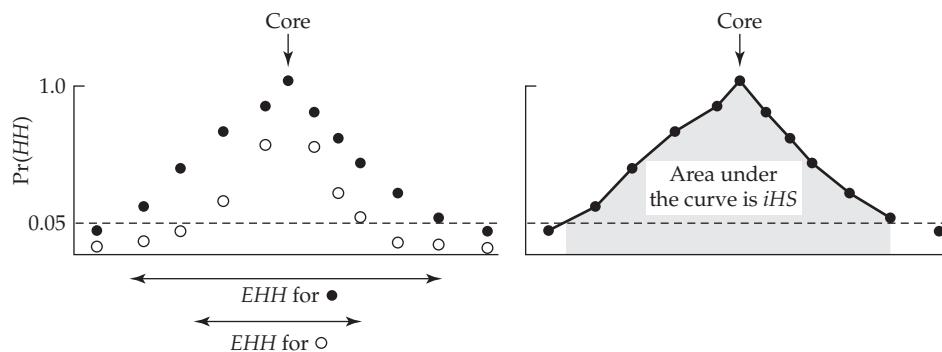

Figure 9.6 Haplotype homozygosity (HH) is defined as the probability that two randomly chosen chromosomes containing the same core SNP variant (used to define allelic classes) are identical (homozygous) at all markers within a defined window. In the figure, HH is computed at a series of SNP markers moving away from the core (allelic-defining) SNP. The open and filled circles correspond to the HH values at a given SNP in the two allelic classes, namely, the probability that random draws of chromosomes from the same allelic class are identical within the region between the core SNP and the marker SNP. The relationship between HH and distance from the core is usually summarized using one of two statistics. (Left) The extended haplotype homozygosity (EHH) for an allelic class is the length of the region around the core where the HH value is $\geq 5\%$ (above the dashed line). The allele corresponding to the filled circles has a larger EHH value, and thus a longer haplotype. (Right) A potentially more informative measure is given by the **integrated EHH score**, iHS , the total area under the HH curve over the region spanned by the EHH for that allele. For ease of presentation, only the values corresponding to the allele with the larger EHH value (filled circles) are plotted.

as one moves away from the core. The standard metric for the length of an allele is based on its haplotype homozygosity (HH), the probability that two randomly chosen chromosomes containing the same SNP variant (or core set of SNPs) are identical (homozygous) for *all* markers within a specified region. Sabeti et al. (2002) defined **extended haplotype homozygosity (EHH)** as the length of a region around the core allele (SNP) where HH has a value of 5% or greater, namely, the length around the core where there is a 5% or greater chance that any two random haplotypes of that allele are identical at all markers (Figure 9.6).

While alleles with excessive values of EHH are produced by partial sweeps, simply scanning for sites with large EHH values will not serve as a sufficient indicator of selection, as a localized decrease in the recombination rate inflates the EHH value. The formal use of EHH as a selection-detecting statistic thus requires an internal control. Sabeti et al. (2002) proposed considering the **relative extended haplotype homozygosity (rEHH)** of a particular allele (SNP variant), defined as the ratio of the EHH value for that allele divided by the average EHH value for all other core alleles at the focal locus. For allele i , this is given by

$$rEHH_i = \frac{EHH_i}{\text{ave}(EHH_j) \text{ for } j \neq i} \quad (9.40)$$

where $\text{ave}(EHH_j)$ denotes the average EHH values for all SNPs at the allelic-defining site. For the biallelic case (an allele defined by a single SNP, as opposed to a collection of tightly linked SNPs), $rEHH$ is simply the ratio of the EHH values for the two alleles. By contrasting different alleles at the same site, most concerns about local variation in the recombination rates are ameliorated. However, if there are haplotype-specific recombination rates (e.g., the insertion of a mobile element reducing local recombination rates; Macpherson et al. 2008), then this test may be compromised. One consequence of comparing different alleles at a site is that as one allele approaches fixation, the power of the test disappears, as there are too few individuals in the comparison class to produce a meaningful statistic. As a result, the $rEHH$ test has a rather narrow time window for the detection of a sweep: a rough rule is

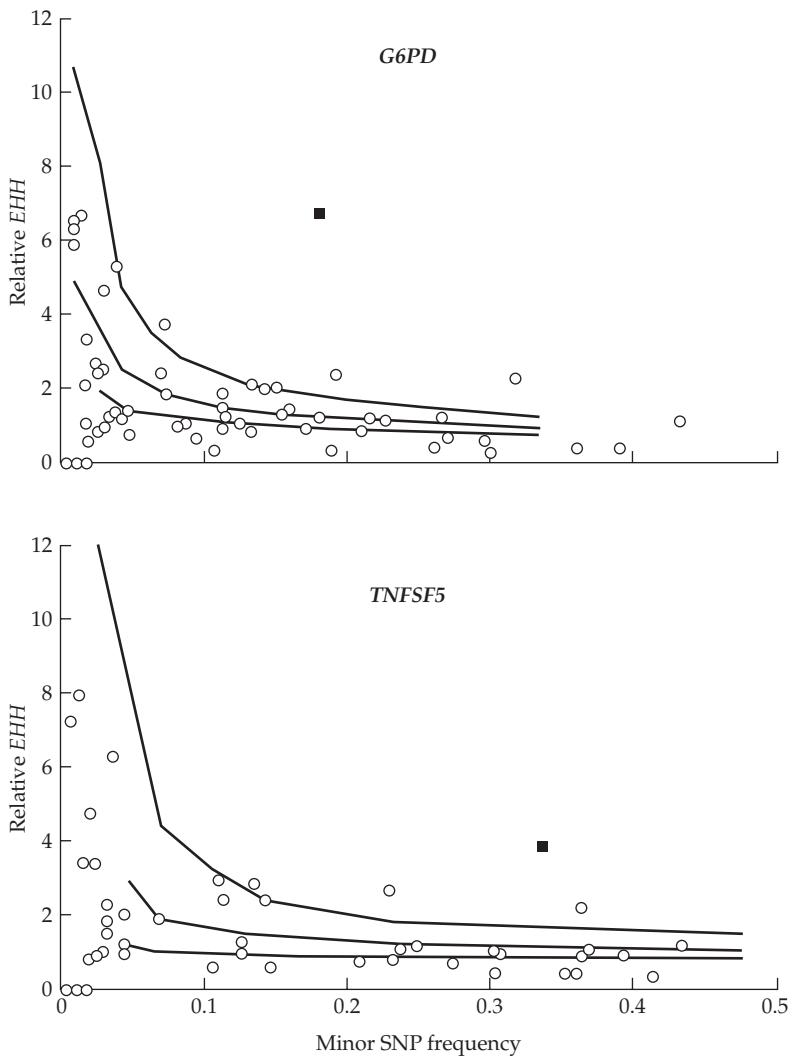

Figure 9.7 As a proof-of-concept of the $rEHH$ method, Sabeti et al. (2002) looked for signatures of selection at two loci, *G6PD* and the *CD40* ligand gene (*TNFSF5*), that carry segregating alleles that are strongly suspected of increasing resistance to malaria. Standard site-frequency tests (Tajima's D , Fu and Li's D^* , and Fay and Wu's H ; see Table 9.1) were all nonsignificant. However, recall from Chapter 8 that site-frequency spectrum signals are weak when the favored allele is at a modest frequency. The figure displays $rEHH$ versus allele frequency for the candidate alleles (solid squares) along with values for alleles at other randomly chosen autosomal loci (open circles). The curves (from top to bottom) correspond to the empirical 95th, 75th, and 50th percentiles, respectively, of the cumulative distribution. (After Sabeti et al. 2002.)

that the frequency of the favored allele must be 0.7 or less. Within such a time window, this test is among the most powerful for detecting selection. Nonetheless, a large $rEHH$ value is not sufficient for suggesting selection, as some rare alleles (potentially being very young, and hence with reduced time for recombination) are expected to have large $rEHH$ values. To detect selection, Sabeti et al. (2002) plotted the $rEHH$ value versus frequency for each allele and looked for outliers (Figure 9.7). Coalescent simulations were then performed under

different neutral models (with different demographic assumptions) to assess significance. Wang et al.'s (2006) **linkage disequilibrium decay (LDD)** test is a modification of *EHH* that does not require phasing.

Variant tests based on the length of shared haplotypes have been proposed by a number of researchers (e.g., Toomajian et al. 2003, 2006; Hanchard et al. 2006; Wang et al. 2006); see Table 9.3. Perhaps the most powerful modification is from Voight et al. (2006), who extracted more LD information than simply the size of the *EHH* and corrected for differences in the local recombination rate and the target-allele frequency. One potential advantage of this approach is that while the *EHH* test has high power when the correct SNP is chosen to define alleles for the haplotype-length comparisons, its power falls off dramatically if the choice is off by even one polymorphic site (Zeng et al. 2007a). Voight et al.'s more comprehensive statistic may avoid this problem. Their approach used polarized data, with p denoting the frequency of the derived (D) SNP and $1 - p$ denoting the frequency of the ancestral (A) SNP. To extract more information, they computed an **integrated EHH score (iHS)**, the area under the curve drawn by connecting the adjacent values for the SNPs within the *EHH* (Figure 9.6). They defined the (unstandarized) integrated *EHH* score (iHS_{us}) as the log of the ratio of the iHS score for the ancestral allele to that for the derived allele

$$iHS_{us} = \ln \left(\frac{iHS_A}{iHS_D} \right) \quad (9.41a)$$

A negative score occurs when the iHS value for the derived allele exceeds that of the ancestral allele, whereas the converse occurs when the ancestral allele has the larger iHS score. One can either keep the sign or use the absolute iHS score, $|iHS|$. Voight et al. standardized the (signed) iHS_{us} score by defining the statistic

$$iHS = \frac{\ln \left(\frac{iHS_A}{iHS_D} \right) - E_p \left[\ln \left(\frac{iHS_A}{iHS_D} \right) \right]}{SD_p \left[\ln \left(\frac{iHS_A}{iHS_D} \right) \right]} \quad (9.41b)$$

The expectation (E_p) and standard deviation (SD_p) are subscripted by p to highlight that these statistics are computed over all iHS_{us} values in the genome for SNPs whose derived allele frequency is p . Standardizing the score with respect to p automatically incorporates any relationship between the iHS_{us} score and the allele frequency (and hence the age for a neutral allele). The authors noted that this approach seems fairly robust to demographic departures from the equilibrium neutral model, especially at extreme values of the standarized score. Despite this, Voight et al. correctly did not assign significance values to individual iHS values, but rather used large (absolute) scores as a screening method for potential sites under selection.

Ferrer-Admetlla et al. (2014) proposed a statistic that is very similar in form to iHS but counts length variation differently. Their **number of segregating sites by length (nS_L)** statistic replaces the average area under the iHS curve by the average number of consecutive segregating sites shared by two randomly sampled chromosomes around a specific SNP variant. This average statistic for the ancestral and derived alleles replaces iHS_A and iHS_D (respectively) in Equation 9.41b. Ferrer-Admetlla et al. noted that this simple change in the metric results in a test that is significantly more robust to recombination and slightly more robust to nonequilibrium departures than the iHS statistic. When applied in a human genome scan, the method did not yield the large enrichment of significant scores in regions of low recombination typically seen when other (more recombination-sensitive) tests are used (e.g., O'Reilly et al. 2008). Further, their simulations found that nS_L has reasonable power to detect ongoing sweeps, even those from standing variation.

Another variant of this basic idea was recently suggested by Field et al (2016). Their **singleton density score (SDS)** measures the length of haplotypes by calculating the distance to the nearest singleton from a candidate site (looking on either sides). This distance can be turned into an estimate of the mean branch length in the coalescent tree for that allele, and

the estimates for the ancestral and deviate allele at a target site are contrasted. Specially, the test statistic is

$$SDS = \ln \left(\frac{\hat{t}_A}{\hat{t}_D} \right) \quad (9.42)$$

where \hat{t} are the estimated coalescent times from the singleton distance. As with several of the above test, the contrast the two alleles at a site controls for local variation in recombination and mutation rates. Under recent selection, the average branch lengths for an allelic class should be much shorter, resulting in longer distances to singletons. As with other haplotype-based approaches, comparisons are made over classes with the same derived allele frequencies. Field et al found that their *SDS* test had power to detect very recent selective events (within the last ~100 generations), a time scale usually too short for other haplotype-based methods (e.g., *iHS*) to show a strong signal. Further, they showed that with a sample size of 3000 individuals (and a derived allele frequency of 0.7), that they could detect ongoing events with a 2% selective advantage.

Finally, Barreiro et al. (2009) proposed a hybrid between long-range haplotype tests and diversity tests. Their **derived intra-allelic nucleotide diversity (*DIND*) test** compares the nucleotide diversities associated with the ancestral ($i\pi_A$) and derived ($i\pi_D$) alleles ($i\pi$ is used to denote that these are intra-allelic nucleotide diversities). A core SNP is used to define the two allelic classes, and the diversity, π , within some specified length around each core variant is computed in the same fashion as an estimate of pairwise diversity from a sample (Equation 4.1)). The logic is that derived alleles, being more recent, should show little diversity relative to their ancestral (and thus older) counterparts. The *DIND* test uses an approach very similar to that of the *rEHH* test, plotting $i\pi_D/i\pi_A$ versus the frequency of the derived allele and then looking for outliers. Both the *SDS* and *DIND* tests were designed to fully leverage extensive resequencing data. Fagny et al. (2014) found that both the *DIND* and *iHS* tests were powerful in detecting recent selection, and also robust over demography. However, the *DIND* was more powerful than the *iHS* when the resequencing data had either poor coverage or low-quality genotype calling.

Long-haplotype Tests Using Between-population Data: *XP-EHH*, *Rsb*, *rHH*, *rMHH*, and χ_{MD}

Tests based on comparing the haplotype lengths of alternative alleles lose all power as a favorable allele approaches fixation. However, if the favored allele is only fixed in a single population, a *between-population* comparison of haplotype length still has power immediately following fixation. This approach was proposed by both Tang et al. (2007) and Sabeti et al. (2007), and it follows the same logic leading Equation 9.41a and 9.41b. However, instead of contrasting the *EHH* or *iHS* score for alternate alleles in the same population, they contrast values for the *same* allele in *different* populations. Sabeti et al. referred to this as the **cross-population extended haplotype homozygosity** (or ***XP-EHH***) test. A similar test (with a few subtle differences) was proposed by Tang et al., who defined the analog of Equation 9.41b as their ***In(Rsb)*** statistic.

A second cross-population comparison test was suggested by Kimura et al. (2007), who considered two ratios of haplotype homozygosity in a control versus test population. The first, *rHH*, is the ratio of haplotype homozygosities in the two populations. The second, *rMHH*, is the ratio of haplotype homozygosities, but computed using just the most frequent haplotype in the control population (i.e., the probability that two random draws of sequences are both the most common haplotype). For a recently fixed allele, the expectation is a low *rMHH* value (a high population divergence), but a high *rHH* value (a population-specific decrease in haplotype diversity). Simulation studies with neutral models (under limited demographic conditions) suggested that the combination of low *rMHH* and high *rHH* values is rather unusual. Again, this is an outlier-based approach, with outliers on an *rMHH*-by-*rHH* plot of the genomic data suggesting potential targets of selection.

Table 9.3 Summary of tests reviewed in this chapter that use haplotype and LD information to indicate positive selection. AFS(k) denotes the equilibrium neutral distribution for the allele-frequency spectrum (the distribution of the number of haplotype classes within a sample), conditioned on the number of alleles/haplotypes, k (Equation 2.33b). S denotes the number of segregating sites, HH denotes the haplotype homozygosity (the probability that two randomly chosen sequences are identical over some defined region), and EHH is the extended haplotype homozygosity (the length of the region for a given allele over which $HH > 0.05$). See text for specific references.

Tests based on the allele-frequency spectrum AFS(k):

- Ewens-Watterson Test:** Observed allelic homozygosity vs. expected homozygosity under AFS(k)
- Slatkin's Exact Test:** Observed AFS(k) vs. expected AFS(k)
- Innan et al.'s HCT:** Observed AFS(k) vs. expected AFS(k) conditioned on observed S
- Hudson's HP Test:** Frequency of most common haplotype given S
- Fu's W :** Test for deficiency of rare haplotypes given S
- Fu's F_s :** Test for excess of rare haplotypes given $\hat{\theta}_{\Pi}$ (average pairwise difference estimator)
- Depaulis & Veuille's K :** Observed number of haplotypes given S
- Depaulis & Veuille's H :** Observed haplotype diversity given S
- Garud et al.'s H_{12} :** Observed haplotype diversity combining the two most frequent classes
- Garud et al.'s H_2 :** Observed haplotype diversity ignoring the most frequent class

Tests based on averages of pairwise disequilibria:

- Kelly's $Z_{n,S}$:** Average of all pairwise disequilibria between all sites in a region
- Kim and Nielson's ω_{max} :** Pairwise LD among sites within vs. between sides of a region

Tests based on frequency estimates of age vs. allelic-diversity estimates of age:

- Age estimated by decay of LD between allele and a linked marker
- Age estimated by number of segregating sites S within an allelic haplotype class
- Age estimated by copy-number variance at tightly linked STRs in the allelic class
- Age of a mobile element insertion estimated by divergence from its consensus sequence

Tests contrasting haplotype lengths of alternative alleles in the same population:

- Sabeti et al.'s $rEHH$:** Ratio of the haplotype lengths (EHH) of two alternative alleles
- Wang et al.'s LDD:** Rate of linkage disequilibrium decay, modification of EHH
- Hanchard et al.'s nHS :** Haplotype diversity of the derived allele relative to the ancestral allele
- Voight et al.'s iHS :** Ratio of area under the EHH curve for ancestral vs. derived alleles
- Ferrer-Admetlla et al.'s nS_L :** Very similar to iHS , with the number of consecutive shared polymorphic sites replacing the area under the EHH curve
- Field et al.'s SDS:** Distance to nearest singleton, yielding an estimated mean allelic branch length
- Barreiro et al.'s DIND:** Ratio of nucleotide diversity in derived vs. ancestral allele

Tests contrasting haplotype lengths of the same allele in two populations:

- Sabeti et al.'s XP-EHH , Tang et al.'s $\ln(R_{sb})$:** Ratio of area under the EHH curve in different populations
 - Kimura et al.'s rHH vs. $rMHH$ plot:** Ratios of overall HH to MHH based on most frequency haplotype
 - Lange and Poll's χ_{MD} test:** Contrast of pairwise haplotype sharing between populations
-

A final cross-population test was proposed by Lange and Pool (2006). Their **comparative haplotype identity** method (χ_{MD}) examines whether the average length of pairwise sharing of haplotypes is large in a target population relative to a control (as would be expected if the target was under selection). For a given window around a target site, they first set a threshold value, then in each population compute the total lengths of haplotypes for a given pairwise comparison (i.e., between two members from the same population). Their χ statistic is this sum over all pairwise comparisons within a population, and then contrasts this value (for a given window) between the target and control populations. They found

that this approach had good power and outperformed *XP-EHH* in many cases of either partial and/or soft sweeps.

Summary: Tests Based on Haplotype/LD Information

As summarized in Table 9.2, different kinds of sweeps (hard, partial, and soft) leave different haplotype signals. Given the diversity of such signals, it is not surprising that there are a number of haplotype-based tests to detect these different features (Table 9.3). LD-based tests are generally regarded as the *most powerful for sweeps that are currently underway*. Site-frequency spectrum tests often perform poorly under a partial sweep, as the distortion in the frequency spectrum is often not sufficiently powerful. Signatures from both a recently completed partial sweep, and a currently ongoing hard sweep, include long haplotypes at excessive frequencies, alleles that are at too high a frequency given other estimates of their age, an excess of one or a few haplotypes, and a reduction in haplotype diversity.

In addition to their unique role in detecting partial sweeps, LD summary statistics can also offer significant power to detect *just-completed sweeps*. Under a hard sweep, the unusual pattern of high LD on either side of, but not across, a selected site can be detected using Kim and Nielson's ω statistic (Equation 9.37). However, this statistic has no power to detect a soft sweep. Conversely, Kelly's Z_{ns} statistic (measuring average pairwise LD throughout a region; Equation 9.36b) can detect a recently completed soft sweep but has no power to detect a just-completed hard sweep.

As with almost all the tests discussed in earlier sections, haplotype-based tests can also generate false positives for neutral alleles in nonequilibrium populations. The standard approach of using outlier analysis to suggest regions of interest and coalescent simulations (using marker-based demographic estimates) can also be used here, with the same caveats. As mentioned, both outlier analysis and coalescent simulations use corrections based on genome-wide patterns and thus do not adjust for allelic surfing. This is especially troublesome, for as outlined below, the species most surveyed for recent selection—humans, the cosmopolitan human commensal *Drosophila (melanogaster and simulans)*, and *Arabidopsis*—are all known to have undergone massive spatial expansions over the last 100,000 years, making them prime candidates for surfing.

SEARCHES FOR SELECTION: HUMANS

Given the huge array of tests introduced in this chapter, we end on a purely empirical note, examining what their applications to both natural and domesticated populations have told us about the nature of selection. Chapter 8 examined the theory and data for the impact of *recurrent* sweeps on a genome (a topic further examined in Chapter 10), while our focus here is on what is known about *particular* sweeps. The search for selection is motivated by both gene-specific and genome-wide questions. At the level of an individual gene, we would like to understand how an ecological challenge is met by a molecular solution: is it highly idiosyncratic or do some general patterns emerge? On a genomic scale, we are interested in general trends of adaptation. What is the relative importance of regulatory versus structural changes? Are genes of major effect more important than genes of minor effect? A growing consensus, at least in multicellular species, on the former question is that regulatory changes may be the predominant route for adaptation (e.g., Grossman et al. 2013), but whether their contribution is just roughly equal to, or significantly greater than, structural changes remains an open question. Our current understanding is certainly based on a nonrandom sample of loci, as methods for detecting sweeps are strongly biased toward genes of major effect that are under strong selection. We stress that our brief discussion is not meant to be comprehensive, as any review in this area will be out of date by the time it is published. Rather, we highlight a few case studies to illustrate the issues facing an investigator when trying to understand the results of a study for molecular signatures of selection.

Table 9.4 Overlap in sweep detection in three early scans (Carlson et al. 2005; Voight et al. 2006; Wang et al. 2006) that used different statistics to infer positive selection in humans. Diagonal elements represent the number of sites declared to be under positive selection in each given study, and off-diagonal elements represent the number shared between studies. See the text for further details. (After Biswas and Akey 2006.)

	Wang (LDD)	Voight (<i>iHS</i>)	Carlson (<i>D</i>)
Wang	1799	125	47
Voight		455	11
Carlson			176

At present, genome-wide scans for genes under recent, or ongoing, selection have been performed on only a modest (but growing) number of species. For natural populations, the most extensive work has been done on humans, *Drosophila*, and *Arabidopsis thaliana*. Given that we know a great deal about the genetics, genomics, and molecular biology of these species, this choice is not surprising. All three groups have undergone major expansions into a wide range of new habitats over the last 100,000 years, and hence harbor the potential for a significant response to evolutionary challenges. For humans, the movement out of Africa into more temperate climates, coupled with the transition from hunting and gathering to agriculture and the resulting increase in population density, generated novel environmental pressures. The commensal *D. melanogaster* and *D. simulans* followed humans into these new environments, while in the northern hemisphere, *Arabidopsis* underwent significant range expansion following the end of the ice age. The environmental challenges faced by these species, as well as demographic changes (such as massive population expansions), leads us to expect a history of recent selection.

Recent and Current Selection in Humans

Early searches in humans looked for molecular signals at candidate genes either believed, or very strongly suspected, to be under selection in particular environments. Examples include disease-resistance genes such as *Duffy* (*FY*) and *G6PD*, dietary genes such as lactase (*LCT*), and climate-related genes such as *MC1R* (influencing skin color). Ronald and Akey (2005) and Harris and Meyer (2006) reviewed these and other candidate genes, and found strong signals (such as skewed site-frequency spectra, long haplotypes, and/or excessive F_{ST}), adding support to the belief that they have experienced recent selection. Signals of recent hard sweeps should persist for no more than $2N_e$ generations (Table 8.1), or roughly covering no longer than the past 250,000 years (assuming 25 years per generation and $N_e \sim 5,000$).

Starting with the advent of dense-SNP maps and continuing as whole-genome sequencing became economically feasible, candidate-gene studies were replaced by **genomic scans**, searching the genome without any preconception of what sites might be under selection. Biswas and Akey (2006) reviewed six early scans that used different statistics to infer positive selection. In total, roughly 2300 genes were found with signals of selection in at least one of these studies, but the overlap between studies was quite small. For example, consider the overlap between the findings of Wang et al. (2006) and Voight et al. (2006), who used long-range haplotype tests (*LDD* and *iHS*, respectively; Table 9.3), and Carlson et al. (2005), who used outliers in Tajima's *D* (Table 9.1). As shown in Table 9.4, of the 455 sites detected by Voight, 125 (27%) were also seen by Wang. Conversely, of the 176 sites with outliers in *D*, only 6% (11) of these were also detected by Voight, while 27% (47) were detected by Wang.

More recent summaries (Akey et al 2009; Fu and Akey 2013) have echoed this general lack of cross-study replication. A number of factors can contribute to these discrepancies besides false positives. The first is clearly power. When power is low, many sites that are under positive selection are missed, and the overlap between studies is expected to be small. Second, as we have stressed throughout this chapter, *different tests detect selection*

over different time scales. A partial sweep gives an LD signal but is not likely to give a site-frequency signal, while the converse is true for a recently completed sweep. Thus, LD-based tests (such as *rEHH* and *iHS*) are *expected* to detect different genes than site-frequency tests. Finally, selection can be *spatially localized*, being experienced in only a subset of populations. If a selected population is included in one study but not in another, the result is a lack of replication.

With this last concern in mind, several scans have searched for geographically localized selection by contrasting F_{ST} values among samples of different populations (and hence allowing for population-specific selection). Barreiro et al. (2008) examined the F_{ST} values associated with roughly 3 million SNPs over four populations (Nigerians, Europeans, Chinese, and Japanese). They used a modification of the outlier approach, binning SNPs by functional categories (e.g., synonymous, nonsynonymous, 5' UTR, etc.). They observed an excess of higher F_{ST} values (relative to the genome-wide distribution) in both nonsynonymous and 5' UTR SNPs, suggesting that there were around 600 sites under local selection. Further, the excess nonsynonymous SNPs were enriched for long haplotypes, as might be expected under a partial sweep. Pickrell et al. (2009) also found evidence of significant local adaptation (population-specific changes) in a survey of 53 populations, although Hofer et al. (2009) noted that the striking differences in allele frequencies between human populations could have easily arisen as a consequence of population expansion (and the accompanying allelic surfing). One additional concern with these studies is that (as mentioned earlier) F_{ST} values are constrained by the level of heterozygosity (which is influenced by background selection), with SNPs with higher minor-allele frequencies having higher maximal F_{ST} values.

Tempering these results was the declaration by some researchers that classic hard sweeps appear to be rare in humans (Hernandez et al. 2011; Lohmueller et al. 2011; Alves et al. 2012), or “have played a moderate, albeit significant, role” (Fagny et al. 2014). However, as discussed in Chapter 8, Enard et al. (2014) noted that a failure to account for background selection (BGS) can result in a distorted view of the importance of sweeps. After adjusting for this effect, they detected widespread signals for positive selection in humans, which were more correlated with regulatory sequences than amino acid changes. Others have stressed the importance of polygenic sweeps (Hancock et al. 2010a, 2010b; Amato et al. 2011; Fumagalli et al. 2011; Turchin et al. 2012; Daub et al. 2013; Zhang et al. 2013; Berg and Coop 2014; Mathieson et al. 2015; Robinson et al. 2015; Field et al. 2016).

The take-home message is that genomic scans in humans reveal numerous potential sites under selection but that sites are usually not replicated across studies. This could simply be a consequence of low power, but as is the case for QTL and association-mapping studies, an initial exciting finding is only the start, and not the conclusion, in the search for genes that are under selection. Unlike association studies, where support is offered by independent replication, the concept of independent replication in the search for genes under selection is more problematic. Finding similar support in two independent samples drawn from the same population is comforting, but it is not a formal validation, as demographic features could have generated the signal, and no amount of resampling will remove its effect. Similarly, a lack of replication between two different populations can easily be explained by differential selection pressures. Support for positive selection would be offered if we observe differences in fitness among alternative alleles at candidate genes, but failure to do so is also not damning. Fitness differences between alleles far below the level of detection (typically at least 1% in most studies of natural populations) can still be critically important (Chapter 5). Likewise, the nature of selection changes with the environment, and a signal could be the result of a past environmental effect that is no longer important. Finally, as discussed in Chapter 8, the geographic structure of human populations not only leads to allelic surfing, but also increases the likelihood that there will be multiple independent adaptive mutations (spread out over the geographic range) that address the same environmental challenge. Human geneticists thus face the very real possibility that only a biased set of events are being detected (along with a potentially large number of false positives),

giving a very distorted view of the genetics of human adaptation.

Balancing Selection in Humans

As discussed in Chapter 8, the expected signal from balancing selection significantly changes over time. Initially, as an allele is sweeping from some low frequency up toward its equilibrium value (under either selective overdominance or frequency-dependent selection), a partial sweep signal is expected (i.e., long haplotypes). After equilibrium is reached, the site-frequency spectrum is expected to show an excess of intermediate-frequency alleles. If the equilibrium persists beyond the neutral coalescent time, a region of increased diversity is expected around the site that is under balancing selection (Figures 8.1B and 8.2B). As more time passes, the size of the region showing excessive polymorphism and intermediate-frequency alleles will continue to be shrunk by recombination, leaving an increasingly smaller window as the age of the selective polymorphism increases. As a result, a single site under very long-term balancing selection is likely to leave very little signal (Wiuf et al. 2004; Charlesworth 2006a; Pavlidis et al. 2012). In contrast, a larger, and more persistent, window of excessive diversity occurs when multiple linked loci are under balancing selection, especially if there are epistatic fitness interactions between them, resulting in selection against recombinants (Kelly and Wade 2000; Barton and Navarro 2002).

Given this expected change in signal over time, searches for balancing selection in humans have used different statistics, depending on the time frame of interest (nicely reviewed in Fijarczyk and Babik 2015). Andrés et al. (2009) were concerned with relatively recent events. They used the intersection of two test statistics: one for excessive diversity (the *HKA* test from Chapter 10) and a nonparametric test for excessive intermediate-frequency alleles in the site-frequency spectrum (the *MWU-high* test of Nielsen et al. 2009). They scored roughly 13,000 genes in two populations (African- and European-Americans) and found 60 candidate sites that were significant for both tests. Most of these appeared to be under balancing selection in both populations, but a few were population specific. Because approximately 12 significant results were expected by chance, the false-discovery rate (Appendix 4) for these data is roughly 12/60 (20%), suggesting that roughly 50 are true positives, comprising around 0.4% of the genes surveyed. Hence, this study suggests that intermediate-term balancing selection is not common.

In searching for sites that have been under balancing selection for longer than the neutral coalescent time, Bubb et al. (2006) used a simple approach based on two results from coalescent theory. First, the expected coalescent time for two random neutral alleles is $t_2 = 2N_e$ generations (Equation 2.38), while the expected coalescent time for all alleles is $t_A \simeq 4N_e$ generations (Equation 2.41). Hence, while the average diversity between two random alleles is $2t_2\mu = 4N_e\mu = \theta$ (Chapter 2), the maximal expected diversity between the two most distinct alleles is twice this value, or $2t_A\mu = 8N_e\mu = 2\theta$. This result is only approximate, as it is based on expected values and ignores the rather large variances in these coalescent times (Chapter 2). Using these results, Bubb et al. searched the genome for regions where the diversity between the most extreme alleles greatly exceeded the value of 2θ predicted from the neutral theory. Excluding *MHC* and *ABO* (the former is known to be under balancing selection, and the latter is strongly suspected to be), the authors found 16 such regions, but they concluded from simulations that these outliers could easily have been generated by chance variation in the coalescent times under a strictly neutral process.

Searches for balancing selection over an even longer time scale involve the search for **trans-species polymorphisms** (Klein 1980)—polymorphic alleles shared by species whose divergence time significantly predates the expected coalescent time for either species. Classic examples are the vertebrate *MHC* (major histocompatibility complex) genes and self-incompatibility alleles of flowering plants (Klein et al. 1998; Richman 2000; Charlesworth 2006a). Asthana et al. (2005) compared roughly 8000 chimpanzee transcripts with their human counterparts and found evidence of eight potentially shared polymorphic sites, three of which were nonsynonymous. In contrast, 12 trans-species polymorphisms were detected at the *MHC* region, leading to the conclusion that ancient polymorphisms, and hence very

long-term balancing selection, were very rare in humans outside of the *MHC* complex. A more recent study by Leffler et al. (2013) found 125 candidate regions (based on shared haplotypes) outside of *MHC*. Surprisingly, all but two of these involved non-coding regions, suggesting that if long-term balancing selection occurs in humans, it usually involves regulatory changes.

Another approach in the search for loci under ancient balancing selection are extensions of the composite likelihood ratio (CLR) test (developed earlier for hard sweeps) by DeGiorgio et al. (2014). Recall that under the structure of CLR, one computes a likelihood for each site as a function of the putative distance (c) from a site under selection, and then (as an approximation of the full likelihood) treats each site as being independent (Equations 9.16–9.18). These authors developed two tests, T_1 based on divergence and polymorphism data, and T_2 based on the site-frequency spectrum and divergence pattern. Given that they found the T_2 test always performed at least as well as the T_1 test, this should be used. Their tests picked up strong signals for numerous *MHC* loci, but (surprisingly) did not find a signal for the *ABO* locus, which is widely speculated to be under long-term balancing selection. Rather few new candidate loci were detected by this approach. Perhaps the most interesting was the *FANK1* gene expressed during meiosis in males. They hypothesized (with some support) that any balancing selection on this locus operates by segregation distortion being balanced by negative selection, so a rather nontraditional setting for balancing selection.

As mentioned, the caveat about these studies is that the size of the region showing signals from balancing selection that is still ongoing (e.g., an excess of intermediate-frequency alleles) is progressively shrunk by recombination. Hence, most ancient events that still under selection are likely to be missed, especially if they involve only a single locus. If the region that is under balancing selection is generated by linked, epistatic loci, this can result in selection against recombination within the region separating them, allowing the signal to persist longer. A caveat with trans-species polymorphisms is that they can be generated by rare introgression events, rather than balancing selection over evolutionary time scales (Fijarczyk and Babik 2015).

Although for power reasons alone, the detection of balancing selection will almost always be more problematic than the detection of positive directional selection, a more subtle issue is the fact that balancing selection initially generated by overdominance is likely to be evolutionarily unstable, even if the selection pressures remain unchanged (Spofford 1969; Asthana et al. 2005; Bubb et al. 2006). If heterozygote advantage is generated by one of the alleles being deleterious as a homozygote, more fit alleles can arise by mutation and become fixed. A potential example is the *HbC* (hemoglobin C) allele, which provides resistance to malaria without being as deleterious as the essentially lethal sickle-cell *HbS* allele. As a result, we might expect the *C* allele to replace the *S* allele over evolutionary time (Walters and Lehmann 1956; Modiano et al. 2001). Even if both homozygotes have the same fitness, an overdominant polymorphism is evolutionarily unstable when gene duplication occurs. A gamete in which the tandem-duplicated copies are alternative alleles has a fitness advantage and can subsequently become fixed (Spofford 1969).

SEARCHES FOR SELECTION: DOMESTICATED ORGANISMS

Extensive searches of recent selection have been conducted in domesticated plants and animals. Domestication represents a major change in the environment, and hence the opportunity for significant selection to occur within a very recent time period (roughly within the past 10,000 years). Domestication thus offers model systems of adaptation (Darwin 1868; Ross-Ibarra et al. 2007), providing a “telescoped time frame in which both antecedent and descendant conditions remain extant and available for comparison” (Olsen and Wendel 2013).

The distinction between genes involved in the initial domestication events and those involved in the subsequent improvement of varieties can be rather subtle. Operationally, **domestication genes** are assumed to be present in all descendant varieties from the domes-

tication event, while **improvement** (or **diversification**) genes are viewed as being further selected in only a subset of varieties. The latter could be the result of deliberate selection, such as for sticky rice, or the result of local selection conditions that lead to the formation of **landraces** (locally adapted varieties). A knowledge of improvement genes can give the breeder insight into achieving specific objectives. For example, genes whose selection signatures are limited to varieties in high drought conditions can suggest important target genes for drought tolerance in current elite germplasms. An example of this was revealed by Kane and Rieseberg (2007), who used the $\log RH$ and $\log RV$ tests (Equation 9.14) to search for sunflower (*Helianthus annuus*) genes with signatures of selection restricted to populations in drought and/or high salt environments. A second example was provided by Vielle-Calzada et al. (2009), who detected potentially selected genes for metal tolerance in the Mexican highland popcorn landrace *Palomero Toluqueño*.

The genetics of domestication is a rapidly growing field, which we only touch on briefly here. Reviews and perspectives were offered by Diamond (2002), Doebley et al. (2006), Purugganan and Fuller (2009), Gross and Olsen (2010), Larson and Burger (2013), Meyer and Purugganan (2013), Olsen and Wendel (2013), Larson and Fuller (2014), Larson et al. (2014), and Gaut et al. (2015).

The Process of Domestication

While domestication is often perceived to be the result of weak, or even unintentional, selection over some period of time, these settings need not be the norm. Some events are very sharp and deliberate, such as the creation of novel populations by intentional species crosses. A classic example is the mule, the sterile offspring of a male donkey and a female horse. Likewise, a number of allopolyploid crops resulted from crosses between two (or more) progenitor species. At the other extreme is the genetic modification of an ancient progenitor into a modern variety, such as the dramatic changes in plant architectural from teosinte to modern maize (LW Figure 5.2). As first noted by Darwin (1868), selection for domestication traits can be due to conscious action (**conscious selection**, or **methodical selection** in Darwin's terms) or it can be entirely **unconscious**. The latter are an indirect consequence of human-induced changes in the environment, where selection can reward certain strategies or traits that favor the domestication of wild species. For example, wolves that were less timid around human refuse piles may have gathered more food, leading to higher fitness while moving them closer to domestication.

The threshold beyond which a wild species is said to be domesticated can be challenging to assess. One operational definition is that domesticated varieties survive very poorly in a natural setting, due to the establishment of traits that increase fitness in the domesticated environment but decrease it in the wild. As best stated by Zeder et al. (2006), "domestication is a unique form of mutualism," leaving both genetic and archaeological signals (see Zeder et al. for several interesting examples). It is also worth emphasizing that domestication is not a uniquely human enterprise. For example, several species of insects cultivate fungal species, and the search for domestication genes in such systems (in both the domesticating insect and their cultivated fungus) remains an intriguing possibility.

Some domesticated species appear to have a single origin. Such seems to be the case for maize (Matsuoka et al. 2002), emmer and einkorn wheats (*Triticum turgidum* and *T. monococcum*; Zohary 1999), potatoes (*Solanum tuberosum*; Spooner et al. 2005), and peanuts (*Arachis hypogaea*; Kochert 1996). The inference of a single origin is often based on the observation of a monophyletic clade when using neutral markers. A caveat with this approach is that simulations by Allaby et al. (2008) showed that such clades can be produced in crops with multiple origins, provided there is a rather protracted period of domestication. Other crops, such as barley (*Hordeum vulgare*; Zohary 1999) and *Phaseolus* beans (Gepts et al. 1986), show clear evidence of multiple domestication events.

Gene flow between lineages of independent origin, and between domesticated lines and their wild ancestors, further complicates the interpretation of any origins story. One such example is Asian rice (*Oryza sativa*), whose *indica* and *japonica* varieties have been regarded

as a single domestication event (Molina et al. 2011), as a pair of distinct domestication events (Londo et al. 2006; Sang and Ge 2007), and as three independent domestication events (with a separate origin for the variety *aus*; Civáň et al. 2015). Huang et al. (2012) suggested an even more complicated story, with *japonica* first domesticated from its wild progenitor, *O. rufipogon*, in southern China and *indica* being subsequently developed by crossing *japonica* with *rufipogon* strains from South and Southeast Asia. Even with multiple origins, gene flow between *indica* and *japonica* was likely, however, as they share a number of key domestication alleles (such as *sh4*, which reduces grain shattering) that might otherwise suggest a single origin (Sang and Ge 2007; He et al. 2011). Introgression between nascent domesticated and wild populations also appears to have been widespread in animals (Larson and Burger 2013; Larson and Fuller 2014), obscuring both their center of origin and number of founding events.

Example 9.16. A complicating factor in both resolving the origins of any particular domestication event and detecting unambiguous signatures of selection is the **introgression** of wild genes into domesticated lineages. Such gene flow can be substantial, especially in the early stages of domestication (Larsen et al. 2014). The **ABBA-BABA test**, which was first introduced to infer the flow of Neandertal genes into modern humans, provides one approach for detecting such introgression (Green et al. 2010; Durand et al. 2011). Unfortunately, this approach is also called the **D test**, creating potential confusion with Tajima's *D* (Equation 9.24a), especially when both appear together in the same paper (e.g., da Fonseca et al. 2015). Our strong recommendation is to always retain the label *ABBA-BABA* test to avoid any such confusion.

Figure 9.8 outlines the basic structure of this test, which requires an outgroup, *O*. An important assumption is that the outgroup is sufficiently distant that no shared segregating alleles from it are present in the other taxa. Rosenberg (2003) showed that 99.9% of all loci have monophyletic genealogies when compared across lineages separated by more than $5.3N_e$ generations, which sets a lower bound on the ancestral time required for a proper outgroup to develop. Let 1, 2, and 3 denote three nested taxa, with 1 and 2 sharing a common ancestor with 3 (see Figure 9.8). In the original application by Green et al. (2010), 1 and 2 were African and non-African human populations, 3 was Neandertal, and the chimpanzee was the outgroup, *O*.

Define a string of length four and with elements *A* (for the ancestral allele present in *O*) and *B* (a derived allele present in taxon 3), with the positions in this sequence corresponding to species 1, 2, 3, and the outgroup. For example, the configuration given by I in Figure 9.8 is denoted ABBA. Suppose that at a given locus, the ancestral population of 1, 2, and 3 was segregating for *A* and *B*, and that in taxon 3, the lineage was sorted such that *B* was fixed. Conditioned on taxon 3 containing the derived allele, when 1 and 2 carry different alleles (one ancestral and the other derived), the direction should be entirely random (as the sorting would be random for neutral alleles), and hence both cases (*AB* vs. *BA* in these two species, translating into *ABBA* vs. *BABA* for the four-species comparison) should be equally likely. A systematic departure in one direction (i.e., far more *ABBA* than *BABA*) implies introgression from 3 into either 2 or 1 (respectively). Green et al. found a significant skew in favor of introgression from Neandertal into non-African humans. Their *D* statistic is given by

$$D_{ABBA-BABA} = \frac{N_{ABBA} - N_{BABA}}{N_{tot}} \quad (9.43)$$

where N_x is the number of events in class *x* and $N_{tot} = N_{ABBA} + N_{BABA}$ is the total number of the two events. Significance ($D \neq 0$) is assessed using a jackknife approach. See Durand et al. (2011) for a detailed discussion and development.

Finding Domestication and Improvement Genes in Crops

One standard approach for finding domestication and improvement genes is QTL mapping in a cross between the wild ancestor (provided it still exists) and the domesticated or

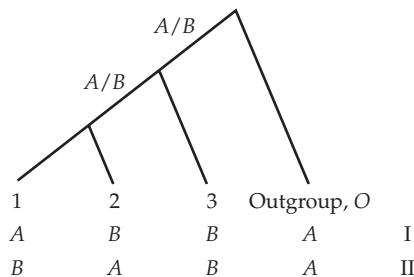

Figure 9.8 The ABBA-BABA test for detecting the introgression of genes from taxon 3 into either taxon 1 or 2; see Example 9.16 for details. Here *A* and *B* denote the ancestral and derived alleles, with the ancestral allele present in the outgroup, *O*. The test compares the distribution of *A* and *B* in taxa 1 and 2, conditioned on taxon 3 containing the derived allele, *B*. If there is simply neutral lineage sorting between the outgroup and the three resulting taxa, then configurations I (ABBA) and II (BABA) should be equally frequent. However, if there has been symmetric introgression of alleles from taxon 3 into one of these populations (but not the other), this pattern will be skewed, with one configuration being in excess of 50%.

improved variety. Such a strategy relies on knowing which *traits* are important. Classic examples of loci detected using this approach include *teosinte branched 1* (*tb1*) and *barren stalk 1* (*ba1*) for plant architecture in maize (Doebley et al. 1995; Gallavotti et al. 2004); *teosinte glume architecture 1* (*tga1*) for naked grains in maize (Wang et al. 2005); *fw2.2* for tomato fruit size (Frary et al. 2000); and *sh4*, *qSH1*, and *OsLG1* for reduced seed shattering in rice (Konishi et al. 2006; Li et al. 2006; Ishii et al. 2013). Given the obvious success of the QTL mapping approach, what role do signatures of selection play in the search for domestication and improvement genes? First, showing that QTL-detected regions were under selection provides independent support for their role in domestication. Second, one can estimate the average strength of selection on a given domestication allele, and hence obtain some indication of the required time to either fix, or substantially increase, its frequency during domestication. Finally, scans for selection are *trait-independent* searches. While some morphological features may be rather obvious candidates for domestication or improvement traits (and hence characters for QTL or association mapping), more subtle physiological changes may be less obvious. Notably, Hufford et al. (2012) found that the majority of scan-detected regions of selection in maize showed stronger signals than those for QTL regions associated with major morphological differences related to domestication.

Domestication can offer important insight into the genetics of adaptation, including the relative importance of loss-of-function versus gain-of-function mutations. For example, the *Q* gene in bread wheat (*Triticum aestivum*) is a critical domestication gene, allowing modern (nonhulled) wheat to be easily threshed (separation of the seed from chaff). A phylogenetic analysis by Simons et al. (2006) indicated that the *Q* gene had a single origin, and appears to involve a gain-of-function, rather than a loss-of-function, mutation. Likewise, Doebley et al. (2006) and Gross and Olsen (2010) noted that loss-of-function mutations are rare among known domestication genes in crops but not uncommon among improvement genes. Surveys of chickens and pigs (Rubin et al. 2010, 2012) found very little evidence that loss-of-function mutations are common in animal domestication and improvement genes.

A second general question concerns the role of regulatory changes in adaptation (Zuckerkandl 1968; King and Wilson 1975; Carroll 2008). As summarized by Doebley et al. (2006), Meyer and Purugganan (2013), and Olsen and Wendel (2013), regulatory changes underlie many domestication and improvement genes. One interesting example is the regulatory *BoCal* gene and its role in different varieties of domesticated cabbage (*Brassica oleracea*). Closely related to wild and domesticated cabbage (*B. oleracea oleracea*) are kale (*B. oleracea acephala*), cauliflower (*B. oleracea botrytis*), and broccoli (*B. oleracea italica*). The last two show significant modification of their inflorescence structures, while kale and cabbage have nor-

mal floral structures. Purugganan et al. (2000) showed that a nonfunctional allele (due to a premature termination codon) of *BoCal* is fixed in both cauliflower and broccoli, but segregating in wild cabbage and kale. Strong haplotype structure was seen, with a reduction in nucleotide diversity around this gene relative to other sites. A sample of cauliflower and broccoli alleles showed significantly negative Tajima's D and Fu and Li's D^* (Table 9.1), all consistent with recent positive selection. Neither D nor D^* was significant in a sample of kale and wild-cabbage alleles. This loss-of-function allele appears to have a single origin and is a regulatory mutation. However, the presence of this allele (at lower frequencies) in normal flowering populations of wild cabbage and kale shows that it is not sufficient by itself for the inflorescence modification that arose during the domestication.

Domestication and Improvement Genes in Rice

As perhaps the most important single staple in the world, rice has been widely searched for domestication and improvement genes. A key change during the domestication of Asian rice involved moving from a reasonably outcrossed species to a highly selfing one. Selfing reduces the effective recombination rate, causing the effects of a sweep to extend over a larger region of the genome. In particular, if η is the rate of selfing, the effective recombination rate, c^* , is well approximated by

$$c^* \simeq c \left(1 - \frac{\eta}{2 - \eta} \right) = c(1 - \tilde{F}) \quad (9.44)$$

where \tilde{F} is the equilibrium level of inbreeding under partial selection (Chapter 23; Nordborg 2000). This expression is reasonable given that $(1 - F)$ is the reduction in the frequency of heterozygotes (and hence opportunities for recombination) under inbreeding. For modern Asian rice, $\eta \simeq 0.99$, giving a roughly 50-fold decrease in the effective recombination rate. This reduction, when combined with small genome size (less than 400 Mb), implies that a significant impact on most of the rice genome is expected if even a modest number of sweeps occurred during domestication (Example 8.16). Caicedo et al. (2007) noted that domesticated rice shows a genome-wide excess of high-frequency derived alleles, which is not consistent with a simple founding bottleneck but is consistent with sweeps impacting much of the genome. Both He et al. (2011) and Huang et al. (2012) detected numerous regions of reduced diversity over a panel of domesticated lines relative to wild *O. rufipogon* populations, many of which exceeded 200 kb.

An example of a long region of depressed variation is seen around the *Waxy* gene, where a splice mutant results in low amylose levels and producing "Sticky" (glutinous) rice (reviewed by Olsen et al. 2006). This is an improvement trait, which is largely restricted to temperate *japonica* varieties. There is a massive sweep signature around this gene, with a 97% reduction in nucleotide diversity ($\pi = 0.0002$ versus normal levels of $\pi = 0.0064$ in wild accessions). The sweep signature spans 250 kb, encompassing ~ 40 genes. Further, there is a strong *EHH* signal (Table 9.3) around *Waxy*, and alleles from temperate *japonica* lines show a highly negative Tajima's D . Olson et al. assumed that $c = 3.7 \times 10^{-7}$ per bp (Inukai et al. 2000) and used Equation 8.6b to estimate the strength of selection as

$$s \simeq \frac{3.7 \times 10^{-7} \cdot 250,000}{0.02} = 4.6$$

This estimated value implies incredibly strong selection, with individuals carrying this allele leaving (on average) close to five times as many offspring as those without it. However, this estimate does not account for the reduction in recombination from selfing. Using the effective recombination rate (Equation 9.44) reduces the estimate to a more modest value of $s \sim 0.1$ (assuming a high selfing rate of $\eta = 0.99$).

Domestication and Improvement Genes in Maize

Maize is the king of crops when it comes to both genomic scans and searches for selection at specified candidate loci, and excellent overviews are given by Doebley (2004) and Tian et al.

(2009). The first demonstration in any species of selection on a putative domestication gene was for *teosinte branched 1*, (*tb1*) in maize (Wang et al. 1999; Clark et al. 2004, 2006). Given its obvious role from QTL studies as a candidate domestication gene, Wang et al. compared the levels of nucleotide diversity around this locus in maize with the corresponding region in teosinte. As shown in Figure 8.2, maize was found to have reduced levels of polymorphism (about 75%) throughout this region relative to teosinte, although this is consistent with a bottleneck during domestication influencing all loci in modern maize. More importantly, Wang et al. observed a significant *further* decrease in the amount of variation in the 5' UTR region of maize (but not teosinte) *tb1*, suggesting that a selective sweep influenced this specific region (Figure 8.2). Surprisingly, the sweep did not influence the coding region, suggesting that the selected site was in the 5' regulatory region, and not a change in the amino acid sequence of *tb1*. Clark et al. (2004) examined the 5' region of *tb1* in more detail and found evidence for a sweep influencing a region of 60–90 kb in the 5' UTR, with an average strength of selection of $s \sim 0.05$. This value implies an expected time to fixation of around 300 to 1000 years (using Equation 5.3b), indicating a fairly long period of domestication. Stuber et al. (2011) identified the likely selected site as an insertion of a *Hopscotch* retrotransposon roughly 64 kb upstream of *tb1*, which resulted in up-regulation in the amount of *tb1* transcripts. It is of note that this insertion predated domestication by at least 10,000 years, showing that standing variation was exploited during this domestication event, and yet a strong hard-sweep signal is seen (the sweep likely being hardened by the founding population passing through a bottleneck).

Other examples of selection signals on putative domestication genes in maize include the *c1* gene, which regulates anthocyanin production, and hence the transition from colorless to colored kernels in early maize (Hanson et al. 1996), genes in the starch pathway (Whitt et al. 2002), *Y1* for yellow kernels (Palaisa et al. 2004), *barren stalk 1* (Gallavotti et al. 2004), the *tga1* gene for naked seeds (Wang et al. 2005), and MADS-box regulators of plant floral development (Zhao et al. 2010).

Moving beyond tests for specific candidate genes, modest-scale genomic scans have been performed in maize by Vigouroux et al. (2002), Yamasaki et al. (2005), Wright et al. (2005), and Hufford et al. (2007). Based on the finding that 2% to 4% of 774 sampled genes showed signatures of selection, Wright et al. (2005) suggested that over 1200 maize genes have likely been influenced by artificial selection during domestication and subsequent improvement. Based on an analysis of 30 of Wright et al.'s candidates, Hufford et al. inferred that ~40 % of these are domestication genes and the remainder are improvement genes (domestication genes showing sweep signatures in all lines, but improvement genes in only a subset of lines). Regulatory genes (such as transcription factors) were not overrepresented among these candidates. However, a more recent study by Zhao et al. (2010) sequenced 32 MADS-box genes (transcription factors) and 32 randomly chosen loci and found that eight MADS-box genes were targets for domestication and an additional one was a target for improvement, while two of the random genes were domestication targets and an additional four were improvement targets. Hufford et al. (2007) also noticed that candidate genes detected from scans were significantly overrepresented in expression in ear tissue relative to vegetative tissues, again suggesting an important regulatory component to the adaptive response.

A more comprehensive scan by Hufford et al. (2012) examined 35 improved lines, 23 landraces, and 17 wild relatives with the XP-CLR test (Equation 9.20). Recall that this likelihood-based test compares the genomic spatial F_{ST} pattern in a selected line relative to an unselected control and returns an estimate of the strength of selection during the sweep. Domestication genes were detected by contrasting landraces (selected lines) with wild relatives (control), while improvement genes were located by contrasting improved lines against landraces (as the controls). The regions with the highest 10% of test scores included 484 potential domestication genes and 695 improvement genes. The average selection coefficients for these groups were $s = 0.015$ for domestication and $s = 0.003$ for improvement. Relative to random genes, domestication candidates showed greater changes in gene expression

from their teosinte ancestor, tending to have higher levels of expression and more stability in expression over maize lines. Divergence in gene expression between teosinte and maize was further studied by Swanson-Wagner et al. (2012), who found that the regions detected by Hufford et al. were significantly enriched for both differences in expression, and altered coexpression profiles, relative to random genes from the maize genome.

An especially interesting study on maize domestication was performed by Jaenicke-Després et al. (2003), who used ancient maize ears as a “time machine” to look at the fixation of domestication alleles. Five maize cobs from the Ocampo Caves in Northeast Mexico were carbon dated, with two estimated at around 4300 years old, and the other three at between 2300 and 2800 years old. Six ancient cobs from Tularosa Cave in New Mexico were also examined, two of which dated to around 1900 years old, with the remaining four dating to around 650 to 900 years ago. DNA extracted from all cobs contained the modern maize allele at *tb1*. Examination of second domestication gene, *pbf* (which is involved in seed storage protein production), had the modern allele in all cobs as well. The final domestication gene examined was *sugary 1 (su1)*, which is involved in starch expression in the kernels. Here the pattern was mixed. The alleles *M1* and *M2* at this locus are found in 30% and 62% (respectively) of modern maize lines, whereas both are around 7% in teosinte. All the cobs from Mexico were homozygous for *M2*, while the four younger cobs from New Mexico were homozygous for *M1*. However, the two older cobs from New Mexico were heterozygotes, *M1/M2* and *M1/T1*, where the *T1* allele is not seen in modern maize and found in only ~4% of current teosinte populations. Thus, it appears that while much of the initial domestication was completed by 4000 years ago, allelic selection (at least in the New Mexico populations) was still ongoing as of ~2000 years ago. See da Fonseca et al. (2015) for additional analysis of maize domestication using ancient DNA samples spanning ~6000 years.

Finally, a cautionary tale in the search for domestication genes is offered by observations on *Shrunken2 (Sh2)* (Whitt et al. 2002; Manicacci et al. 2006). This gene is involved in endosperm starch biosynthesis, and it was suggested as a target domestication gene from QTL studies that showed a seed-weight QTL in a maize-teosinte cross in the *Sh2* region. However, a more careful analysis by Whitt et al. and Manicacci et al. showed similar reduced levels of nucleotide diversity in both maize and teosinte at *Sh2*. A comparison with two sister species suggested that a sweep in the 3' region of *Sh2* occurred in teosinte prior to domestication. Because the wild ancestors of our current crops were themselves subject to selection, caution is in order when declaring selection by contrasting diversity in a domesticated variety with that in a sister species of the progenitor, rather than the progenitor itself.

Relative Strengths of Selection on Domestication vs. Improvement Genes

An unresolved question concerns the relative strength of selection on domestication versus improvement genes, a contrast first discussed by Olsen et al. (2006). Based on local estimates of recombination rates and the length of depressed variation around the candidate genes, two domestication genes in maize had estimated selection coefficients of s between 0.02 (*tga1*; Wang et al. 2005) and 0.05 (*tb1*). However, the improvement gene *Y1* has a 600 kb sweep, giving an estimated strength of selection of $s = 1.2$ (Palaisa et al. 2004), and (as previously discussed) the strength of selection on the rice improvement gene *Waxy* (correcting for the effective recombination rate) is $s = 0.1$. This small initial sample suggested that there was stronger selection on improvement genes. Conversely, in the Hufford et al. (2012) survey of the maize genome, regions involved in domestication had an average estimated value of $s = 0.015$, while regions associated with improvement had an average estimated $s = 0.003$. One potential reason for the significant decrease in s for improvement genes is that the authors lumped together both tropical and temperate landraces, which could reduce the average estimated strength of selection that would be seen if landraces were differentially selected.

If selection is too intense (especially when selfing can occur), considerable linkage drag

can allow deleterious alleles to accumulate and potentially favorable alleles to become lost. Because wild species that are subjected to very strong selection may not retain sufficient variation for subsequent improvement, it would have benefited our first breeders if selection during domestication was relatively weak.

Silkmoths and Flies

When one envisions domesticated animals, pets or farm animals usually come to mind. However, insect populations have been domesticated as well, most notably honey bees and silkmotths. Xia et al. (2009) sequenced the genomes of 29 lines of domesticated silkmotths (*Bombyx mori*) and of 11 lines from the wild progenitor species (*B. mandarina*). Their analysis clearly showed that a single domestication event gave rise to *B. mori*, with only a mild bottleneck (90% of the ancestral diversity is maintained). Using a joint statistic based on reduction in diversity (π_{mori}/π_{mand}) within a region, coupled with a low Tajima's *D* score, they identified slightly over 1000 regions of interest, spanning 3% of the genome. This suggested around 350 protein-coding regions as candidates for domestication genes (given the study's focus on structural, as opposed to regulatory, changes). Of these, 159 showed differential expression between *mori* and its wild relative, 90 of which are expressed in the silk gland, midgut, or testis. Two of the candidate genes in the silk gland were related to counterparts in *Drosophila* involved in transcriptional regulation of the glue genes (whose product is used to glue pupae to a substrate).

The selection pressures during *Bombyx* domestication were likely both deliberate (increased silk production) and unintentional (easier handling and better survival under cultivation). Such domestication selection pressures for growth and survival under laboratory conditions can potentially occur in any organism under long-term captivity, and *Drosophila* is no exception. Montgomery et al. (2010) examined the behavior of eight STRs over time in a series of replicate populations of different sizes with very tight control over the effective population sizes through complete knowledge of the population pedigree (meticulously accomplished by recording every set of parents in the population). The loss of heterozygosity at all STRs was about 12% faster than predicted from the pedigree-generated inbreeding coefficients, while the between-population divergence (F_{ST}) and temporal within-population changes in allele frequencies were significantly greater (by 25% and 33%, respectively) than predicted under drift. The authors interpreted these results as support for multiple ongoing partial sweeps throughout the genome influencing the dynamics at linked STRs, suggesting that there was ongoing selection to adapt to the domestication conditions.

Constraints on Finding Domestication and Improvement Genes Through Selective Signals

While numerous putative domestication genes have been located in a variety of species, there are reasons to suspect that many more have been missed. Given that domestication represents a sudden change in the environment, at least a fraction of any initial response likely results from standing variation. Thus, many domestication genes likely experienced soft or polygenic sweeps, potentially giving a very reduced signal (Chapter 8). For example, comparisons of dairy versus beef cattle largely rely on differences in allele frequencies, with few fixed differences (Example 9.3; Figure 9.1). Indeed, one might imagine that there is a bias in the current set of domesticated species, in that ancient farmers used the species that they could most easily exploit. This likely favored species with at least some standing variation for traits of interest, with these surpassing competing species for which farmers had to wait for new mutations to show improvement.

Other genomic features can complicate the detection and localization of domestication genes. If the ancestral species had low levels of polymorphism at the start of selection (perhaps from passing through bottlenecks and/or being under selection themselves), the additional reduction in polymorphism around the selected site will leave a much weaker signal. Thus, for some species it may be very difficult to detect signatures of selection, even for sites under strong selection. For example, Hamblin et al. (2006) found that the genome-

wide background variation in sorghum (*Sorghum bicolor*) was too low to reliably detect signatures of selection, given the markers and density they used. Wild accessions of sorghum had levels of nucleotide diversity of around $\pi = 0.0027$, far lower than teosinte, while domesticated varieties had even lower levels ($\pi = 0.0008$). The presence of low background levels of variation in the progenitor coupled with an obvious strong bottleneck during domestication makes detection of regions under selection challenging, but not impossible (Casa et al. 2006).

Finally, the average size of a domestication sweep has important evolutionary implications. Signals of a sweep arise because of a reduction in the effective population size around the selected site, resulting in decreased efficiency of selection at linked genes (Chapter 8). Within a sweep region, linked deleterious alleles are more likely, and linked favorable alleles are less likely, to become fixed, compared to sites outside of the sweep. In species with high effective recombination rates, only small genomic regions (and hence few nontarget genes) are influenced by sweeps. However, in a highly selfing species, sweeps can influence the behavior of numerous genes well beyond the target site (as we saw with the *Waxy* gene in rice). Thus, in a species where a high fraction of the genome has been influenced by domestication sweeps, numerous deleterious mutations may have become fixed as a consequence of domestication. There is at least some suggestive evidence of this occurring in rice (Example 8.16), and it is expected to be more of a concern in selfing species. This reduction in fitness caused by domestication has been called the **cost of domestication** or the **domestication load** (Gaut et al. 2015).

With the advent of high-precision **gene-editing** methods, any potential domestication load now represents an opportunity. If deleterious alleles were indeed dragged along during domestication or improvement, in many cases they can be localized through whole-genome sequencing. For example, if elite lines contain nonsynonymous substitutions that are absent (or at very low frequency) in wild lines, some fraction of these may be deleterious. By using editing to revert them to their wild-type versions, the performance of an elite line may be improved, perhaps substantially so, especially if editing is done over a number of such sites.

10

Using Molecular Data to Detect Selection: Signatures from Multiple Historical Events

Model selection is a process of seeking the least inadequate model from a predefined set, all of which may be grossly inadequate as a representation of reality. Welch (2006)

Chapter 9 reviewed tests for detecting an ongoing, or very recently completed, *single episode* of positive selection. Here we examine the complementary issue, the nature of the cumulative signature left in divergence data by *multiple* historical selective events. In contrast to the large variety of tests for detecting ongoing or recent selection, only two basic approaches use divergence data to detect the signal from multiple episodes of positive selection. The first contrasts the levels of polymorphism within a reference population with the level of divergence between populations or species, using either different classes of sites within the same gene (the **McDonald-Kreitman, or MK, test**) or different genes (the **Hudson-Kreitman-Aguadé, or HKA, test**). Because these tests require a population sample to determine the amount of polymorphism, we refer to them as **population-based divergence tests**.

The second category of tests, which uses **phylogeny-based divergence** data, contrasts the rates of evolution at different sites within a gene over a number of species in a phylogenetic context. These tests do not require a population sample, as the signal comes entirely from the pattern of divergence, and not from polymorphisms. Specifically, for protein-coding sequences in the absence of positive selection, the rate of replacement substitution is generally expected to be less than the rate of silent substitution. A replacement rate *exceeding* the silent substitution rate provides a very robust signal of positive selection. However, when applied over an entire gene, this approach has almost no power, as any signal within a gene from a few positively selected codons is swamped by a much larger signal from the majority of codons that are likely to be under purifying (negative) selection. As a result, most current phylogeny-based tests scan a gene of interest for an excess of substitutions at *single codons* when examined over a phylogeny. Given their focus on *a very special class of events*—repeated positive selection on the same codon over a number of species—phylogeny-based divergence tests likely detect only a small fraction of actual selection episodes. By contrast, the HKA and MK tests are less stringent, as they simply require multiple substitutions over the *entire gene*. Finally, hybrid population genetic-phylogenetic tests are starting to appear (e.g., Wilson et al. 2011), but these tests will not be considered further here.

The tests outlined in the previous chapter are complementary to the approaches examined here, with each detecting signals of selection that would be missed by the other. Tests from Chapter 9 cast a wide net, in that many ongoing or recent events leave some signal, albeit perhaps a very weak one. However, this signal decays very quickly, so that most sites experiencing positive selection prior to some very modest amount of evolutionary time in the past ($>N_e$ generations) will leave essentially no signal for these tests (Table 8.2). Conversely, the HKA and MK tests entirely miss genes with one or two relatively recent adaptive substitutions, as such a small number of additional substitutions will not leave a sufficient divergence signal to be detected. They can, however, detect situations in which numerous adaptive substitutions have occurred across a gene during the divergence of two populations. Phylogeny-based tests are even more restrictive, showing a signal only in very special cases: those in which the same codons are repeated targets of selection over the species in a phylogeny.

The time scale over which positive selection can be detected varies between the two

divergence-based approaches, as there must be a sufficient number of adaptive substitutions to give some signal above the expected number of neutral substitutions (Example 10.1). Given that the entire gene is the unit of analysis, HKA and MK tests require at least a relatively modest amount of evolutionary time to acquire a sufficient signal. Phylogeny-based tests, which have a much smaller unit of analysis (individual codons), typically require much longer time scales for a sufficient number of adaptive substitutions to accrue. As such, phylogeny-based methods can work over deep time scales, provided that the number of silent substitutions is not excessive (i.e., the sites have not become too saturated). They can also be applied over short time scales in rapidly evolving viruses (such as HIV), whose high mutation rates and large population sizes can introduce sufficient variation for multiple rounds of adaptive evolution to occur, even over short time spans.

Finally, it is worth noting that most applications of phylogeny-based methods use only a single sequence from each species, thus inflating the divergence, as a chance polymorphism in the sampled sequence may be recorded as a fixation. If only a few true fixations have occurred, this error can be significant. This is also a potential problem for population-based tests that use only a single reference sequence for making divergence estimates.

BRIEF OVERVIEW OF DIVERGENCE-BASED TESTS

We start with a short overview of population- versus phylogeny-based approaches before considering each approach in considerable detail. As was done in Chapter 9, the next few pages introduce the key ideas without most of the technical details.

A History of Selection Alters the Ratio of Polymorphic to Divergent Sites

Population-based tests contrast the patterns of within-species polymorphism and between-species divergence to see if they are in concordance with their neutral expectations. Under the equilibrium neutral model, two standard measures of polymorphism under the infinite-sites model are functions of $4N_e\mu$ (where μ is the per-site mutation rate): the nucleotide diversity, π , and the number of segregating sites, S . These have expected values of $E[\pi] = 4N_e\mu$ and $E[S] = 4N_e\mu a_n$, where a_n is a constant that depends only on the sample size, n (Equation 9.21a). Under the assumptions of the equilibrium neutral model, the relationship between polymorphism (measured by nucleotide diversity, π) and the between-population divergence (D) for the i th gene being considered is

$$\pi_i = 4N_e\mu_i, \quad D_i = 2t\mu_i \quad (10.1a)$$

where N_e is the effective population size, and t is the divergence time in generations. Hence,

$$\frac{\pi_i}{D_i} = \frac{4N_e\mu_i}{2t\mu_i} = \frac{2N_e}{t} \quad (10.1b)$$

Because the gene-specific mutation rates cancel, under the equilibrium neutral model, the π/D ratio at all loci should be roughly the same, namely $2N_e/t$ (subject to random sampling). When polymorphism is instead scored as the number of segregating sites, S , then

$$\frac{S_i}{D_i} = \frac{2N_e a_n}{t} \quad (10.1c)$$

Again, this ratio is expected to be roughly constant over neutral genes.

Example 10.1. McDonald and Kreitman (1991a) examined the *Adh* (alcohol dehydrogenase) locus in the sibling species *Drosophila melanogaster* and *D. simulans*. Within this gene, they contrasted **replacement (nonsynonymous)** and **silent (synonymous)** sites. At the DNA level,

a replacement-site mutation results in an amino acid change, while a silent-site mutation still codes for the ancestral amino acid. Equation 10.1c indicates that, under neutrality, the ratio of the number of segregating sites to the number of fixed differences should be the same for both categories of sites. This results in a simple association test, and significance can be assessed using either a χ^2 approximation or the (much better) Fisher's exact test, which accommodates small numbers in the observed table entries. Of the 24 fixed differences between the two species seen by McDonald and Kreitman, 7 were replacement-site mutations and 17 were silent-site mutations. The total number of polymorphic sites segregating in either species was 44, 2 of which were replacement and 42 of which were silent. The resulting association table becomes

	Fixed	Polymorphic
Silent	17	42
Replacement	7	2

Fisher's exact test gives a p value of 0.0073, indicating a highly significant lack of fit to the neutral equilibrium model. Based on the ratio of 42:2 silent/replacement polymorphisms, the expected number, x , of replacement fixations is $17/x = 42/2$, or $x = 0.81$, i.e., ~ 1 replacement polymorphism is expected under neutrality. Because 7 were seen, this suggests roughly 6 adaptive substitutions, or that 86% (6/7) of the *Adh* amino acid substitutions between these species are adaptive.

A History of Positive Selection Alters the Ratio of Silent- to Replacement-site Substitution Rates

Phylogeny-based divergence tests do not require polymorphism data, but rather simply contrast the divergence rates at silent versus replacement sites. Silent sites are treated as proxies for neutral sites, although we have seen that they may be under (at least) weak selection (Chapter 8). Mutations at replacement sites are generally viewed as being under much stronger selection, most of it purifying. The primary evidence that such *negative* selection (removal of new deleterious mutations) is widespread is the observation that silent-site substitution rates are almost always much higher than those for replacement sites, when averaged over an entire gene. This pattern is expected if a higher fraction of mutations in replacement sites is deleterious relative to that in silent sites. However, there are cases where, for a limited region within a gene, the replacement-site substitution rate exceeds that for silent sites, suggesting the presence of adaptive fixation (i.e., positive selection).

While there are several variant notations in the literature, we use K_s to denote the per-site silent substitution rate and K_a to denote the per-site replacement rate between taxa (the subscript a indicating a change in an amino acid); K_{ns} and K_n are also used in the literature to denote replacement-site (i.e., nonsynonymous) substitution rates. A value of $K_a/K_s > 1$ indicates a long-term pattern of positive selection at replacement sites. As Example 10.2 illustrates, even if this is occurring at *specific regions* within a gene, when averaged over an *entire* gene, K_a/K_s is usually < 1 . Thus, while an observation of $K_a/K_s > 1$ is almost universally accepted as a signature of a long-term pattern of multiple episodes of positive selection, such inflation is almost never seen if the entire gene is taken as the unit of analysis. Phylogeny-based methods (examined below) accommodate this concern by taking the codon as the unit of analysis, first placing genes within a phylogeny and then using codon-evolution models to test whether $K_a/K_s > 1$ for some subset of codons.

Example 10.2. One of the classic examples of using sequence data to detect signatures of positive selection is the work of Hughes and Nei (1988, 1989). They examined the major histocompatibility complex (MHC) Class I and Class II loci of mice and humans, highly polymorphic genes involved in antigen recognition. A large number of prior studies on other genes had found that an excess of silent substitutions is almost always the norm, implying that most replacement changes are selected against. Indeed, when one looks over an entire Class I (or II)

MHC gene, this pattern is also seen. The insight of Hughes and Nei was to use data on protein structure to specifically focus on the putative antigen-binding site and to compare this region with the rest of the gene as an internal control.

Hughes and Nei compared the ratio of silent- to replacement-site nucleotide substitution rates in the putative antigen recognition sites versus the rest of the gene. For both Class I and Class II loci, they found a significant excess of replacement substitutions in the recognition sites and a significant deficiency of such substitutions elsewhere. If both types of substitutions were neutral, the per-site rates should be roughly equal. If negative selection is acting, the expectation is that the silent-site substitution rate would be significantly higher (reflecting the removal of deleterious replacement mutations). However, if positive selection is sufficiently common among new mutations, one expects to find an excess of replacement substitutions. The observed patterns for both Class I and II loci were consistent with positive selection within the part of the gene coding for the antigen recognition site and purifying selection on the rest of the gene.

Divergence-based Tests are Biased Toward Conservative Sites

A major (but subtle) distinction between most methods in this chapter and those in Chapter 9 are that the latter usually have very little restrictions on the kinds of sequences being scanned for selection. In contrast, most divergence-based tests were built (at least initially) around analyses of protein-coding sequences (HKA is an exception), such as contrasts between silent and replacement sites or the substitution patterns at a codon (or set of codons) over a phylogeny. In such settings, these methods focus almost exclusively on detecting *structural* adaptations, namely, adaptive changes in the amino acid sequence. As we saw in Chapter 9, regulatory changes are thought to be at least as important as structural changes for short-term adaptation.

One reason for the focus on protein-coding regions in divergence-based tests is that one must be able to *align homologous sequences*. Because they accept relatively few insertion or deletion mutations, long open-reading frames allow one to align homologous coding sequences, even over fairly substantial periods of evolutionary time. By contrast, this is often *not* the case for regulatory sequences, especially when considering that we still have a limited (albeit improving) ability to detect the full universe of such sequences. As shown in several examples below, divergence-based approaches have been applied to *highly conserved* regulatory regions, which offer a better opportunity for comparing homologous sequences over evolutionary time. However, this also biases these tests toward regions under strong functional constraints. Thus, the very interesting question of whether structural changes may be more important than regulatory changes for long-term adaptation cannot be fully addressed by divergence-based data alone, as these have a bias toward detection in highly conserved regions, whether structural or regulatory. Extensive regulatory changes in less-conserved regions may be entirely missed by most divergence-based tests. Despite these issues, there are hints starting to emerge of at least as many adaptive substitutions in noncoding regions as there are in coding regions (as we detail below).

What Fraction of the Genome is Under Functional Constraints?

The amount of metazoan DNA that codes for proteins and structural RNAs (the so-called **coding DNA**) is usually just a fraction of their total genome. The role of the remaining (and usually majority) component of the genome, the **noncoding DNA**, has been the subject of numerous debates as to its evolutionary role and function. This raises a central question of just what fraction of the genome is under some sort of functional constraint (and therefore, selection). Chiaromonte et al. (2003) denoted this fraction by α_{sel} , which is somewhat unfortunate notation given the widespread use of α for the fraction of *adaptive* substitutions (to be covered in detail shortly). One obvious approach for estimating α_{sel} is from the amount shared conserved sequences between two divergent taxa. For example, early studies searched for regions first shared between mice, humans, and dogs, and later over

a wider range of mammals, arriving at the result that around 6% of the human genome is conserved over such time scales (Lindblad-Toh et al. 2005, 2011). This is six-fold more than the 1% of the human genome that codes for proteins (~ 33 MB out of a total of ~ 3100 MB; Church et al. 2009). Andolfatto (2005) estimated a much higher value of α_{sel} , between 40% and 70%, for *Drosophila melanogaster*, with about twice as many constrained sites in noncoding, as opposed to coding, regions. Such comparisons, especially when based on widely-divergent taxa, are simply *lower bounds*, as sequences under functional constraints can still turnover through time, escaping detection (Dermitzakis and Clark 2002). Indeed, Pheasant and Mattick (2007) suggested that the functional portion of the human genome may exceed 20%, basing their argument on the fact that rapidly evolving regions will not be detected through sequence conservation studies.

Further insight into α_{sel} can be gained by examining how the amount of conserved sequences shared between species pairs changes with their divergence times. This approach was used by Meader et al. (2010), who found that the fraction of shared conserved sequences among mammals decreased over time, and used the rate of this decrease to estimate that between 200 and 300 MB (6.5% to 10%) of the human genome is under functional constraints. A more refined estimate arrived at a value of around 8% (Rands et al. 2014). Hence, roughly 88% (7/8) of human constrained sites are found in noncoding regions. Meader et al. also used their approach on *Drosophila melanogaster*, finding an α_{sel} value of between 47% and 55%. Given around 22 MB for coding DNA and their estimate of 35–45 MB of constrained noncoding DNA, roughly two-thirds of the constrained sites are in noncoding regions.

These estimates of the amount of constrained noncoding DNA raise a number of important evolutionary questions (beyond the obvious one of their functional role). How strong is selection in noncoding regions? How often do adaptive mutations arise from these non-coding regions? What fraction of segregating deleterious mutations are attributable to these regions? While unbiased answer to these questions remain elusive, preliminary estimates based on conserved noncoding regions and on transcription factor binding sites suggest that noncoding DNA is likely a rich source of adaptive substitutions.

THE HKA AND MCDONALD-KREITMAN TESTS

Building on the basic ideas just introduced, we now develop the HKA test and present a much more in-depth discussion of the McDonald-Kreitman test, focusing on important caveats in its application.

The Hudson-Kreitman-Aguadé (HKA) Test

Hudson, Kreitman, and Aguadé (1987) proposed the first approach to jointly use polymorphism and divergence data. Unlike many of the other divergence-based tests, their's can be applied to any type of sequence data (not just a contrast between replacement and silent sites). Their **HKA test** is formulated as follows. Consider two species (or very distantly related populations) *A* and *B*, which are both at mutation-drift equilibrium with effective population sizes of $N_A = N_e$ and $N_B = \delta N_e$. Further assume that they separated $\tau = t/(2N_e)$ generations ago from a common population of size $N_e^* = (N_A + N_B)/2 = N_e(1 + \delta)/2$, the average of the two current population sizes. Suppose $i = 1, \dots, L$ unlinked loci are examined in both species. We allow the neutral mutation rate, μ_i , to vary over loci, but assume (for a given locus) that it has been the same in both species, and hence unchanged during divergence. The expected number of neutral segregating sites at locus *i* is a function of $\theta_i = 4N_e\mu_i$ in species *A*, and $4N_B\mu_i = 4(\delta N_e)\mu_i = \delta\theta_i$ in species *B*. The expected divergence between *A* and *B* is $2t\mu_i$, which we can express as

$$2t\mu_i = 2 \frac{t}{2N_e} 2N_e\mu_i = \tau\theta_i$$

Under this model, the levels of polymorphism (measured by the number of segregating sites) and divergence at the *L* loci are a function of *L* + 2 parameters: *L* gene-specific θ_i

values, and two demographic parameters (δ and τ) shared by all loci. To estimate these parameters, we have $3L$ observations: the numbers S_i^A and S_i^B of segregating sites at each of the L loci in each species or population, and the number, D_i , of substitutions between each pair of L loci. Under the HKA test, these data are first used to estimate the model parameters, and then a goodness-of-fit test is performed on the observed data. If the model provides a sufficiently poor fit, the equilibrium neutral model is rejected.

More formally, the HKA test statistic, X^2 , is given by

$$X^2 = \sum_{i=1}^L X_i^2 \quad (10.2a)$$

where

$$X_i^2 = \frac{\left(S_i^A - \hat{E}[S_i^A]\right)^2}{\text{Var}(S_i^A)} + \frac{\left(S_i^B - \hat{E}[S_i^B]\right)^2}{\text{Var}(S_i^B)} + \frac{\left(D_i - \hat{E}[D_i]\right)^2}{\text{Var}(D_i)} \quad (10.2b)$$

is the contribution to overall lack-of-fit from gene i . We use the notation $\hat{E}[\cdot]$ to denote the estimate of an expectation, which is obtained by using estimates (also denoted by carets) of the parameters (Equations 10.3a through 10.3d). For n_A samples (haploid sequences from each of the L loci) from species A and n_B samples from species B ,

$$\hat{E}[S_i^A] = \hat{\theta}_i a_{n_A}, \quad \hat{E}[S_i^B] = \hat{\delta} \hat{\theta}_i a_{n_B}, \quad \text{where } a_{n_x} = \sum_{i=1}^{n_x-1} \frac{1}{i} \quad (10.3a)$$

$$\text{Var}(S_i^A) = \hat{\theta}_i a_{n_A} + \hat{\theta}_i^2 b_{n_A}, \quad \text{Var}(S_i^B) = \hat{\delta} \hat{\theta}_i a_{n_A} + \hat{\delta}^2 \hat{\theta}_i^2 b_{n_B}, \quad b_{n_x} = \sum_{i=1}^{n_x-1} \frac{1}{i^2} \quad (10.3b)$$

$$\hat{E}[D_i] = \hat{\theta}_i \left(\hat{\tau} + \frac{1+\hat{\delta}}{2} \right) \quad (10.3c)$$

$$\text{Var}(D_i) = \hat{\theta}_i \left(\hat{\tau} + \frac{1+\hat{\delta}}{2} \right) + \left(\frac{\hat{\theta}_i(1+\hat{\delta})}{2} \right)^2 \quad (10.3d)$$

Equations 10.3a and 10.3b follow from the infinite-sites model (Equations 4.3a and 4.4a, respectively). Equation 10.3c follows if we rewrite

$$\theta_i \left(\tau + \frac{1+\delta}{2} \right) = 4N_e \mu_i \left(\frac{t}{2N_e} + \frac{1+\delta}{2} \right) = 2\mu_i t + 4\mu_i \frac{N_e(1+\delta)}{2} = 2\mu_i t + 4N_e^* \mu_i$$

The first term in the right-most expression is the between-population divergence due to new mutations, while the second term is the divergence from the partitioning of any initial polymorphism, $4N_e^* \mu_i$, present in the ancestral population. The HKA test statistic X^2 is approximately χ^2 -distributed with $3L - (L+2) = 2L - 2$ degrees of freedom, given the $3L$ observations and $L+2$ parameters to estimate. Hudson et al. suggested the following system of equations for estimating the unknown parameters $(\theta_1, \dots, \theta_L, \delta, \tau)$, given the $1 \leq i \leq L$ observed values of S_i^A , S_i^B , and D_i

$$\sum_{i=1}^L S_i^A = a_{n_A} \sum_{i=1}^L \hat{\theta}_i \quad (10.4a)$$

$$\sum_{i=1}^L S_i^B = \hat{\delta} a_{n_B} \sum_{i=1}^L \hat{\theta}_i \quad (10.4b)$$

$$\sum_{i=1}^L D_i = \left(\hat{\tau} + \frac{1+\hat{\delta}}{2} \right) \sum_{i=1}^L \hat{\theta}_i \quad (10.4c)$$

$$S_i^A + S_i^B + D_i = \hat{\theta}_i \left(\hat{\tau} + \frac{1 + \hat{\delta}}{2} + a_{n_A} + \hat{\delta} \cdot a_{n_B} \right) \quad \text{for } i = 1, \dots, L - 1 \quad (10.4d)$$

Equations 10.4a through 10.4c are each single equations, while Equation 10.4d is a set of $L - 1$ equations (Equation 10.4d is automatically satisfied for $i = L$ when Equations 10.4a–10.4c hold). This set of $L + 2$ equations can be solved numerically for the $L \hat{\theta}_i$ values unique to each locus and the common demographic values $\hat{\delta}$ and $\hat{\tau}$, thus generating the estimated values for the X^2 statistic (Equations 10.3a–10.3d). The HKA model assumes that there is no recombination within a gene but that there is free recombination between genes, thus treating distinct genes as independent. If a significant HKA value is found, the gene-specific X_i^2 values (Equation 10.2b) indicate which loci contributed the most to the lack of fit.

Modifications of the HKA test were proposed by Wright and Charlesworth (2004), who presented a maximum-likelihood version, and Innan (2006), who framed the test in terms of the polymorphism-divergence ratio, r . This formulation allowed Innan to consider a joint test involving r and a site-frequency measure (such as Tajima's D) to provide more support for selection at a site (Innan's **two-dimensional test**). An interesting application of this class of tests is the work of Ochola et al. (2010) in searching for vaccine targets in the malaria parasite *Plasmodium falciparum*. Their reasoning was that proteins in the parasite that are the target of naturally acquired host immunity (i.e., arms-race genes) are often under balancing selection. Hence, searching for loci with balancing-selection signals (a high HKA ratio coupled with high positive value of Tajima's D) can suggest potential candidates.

Example 10.3. Hudson et al. (1987) partitioned the *Adh* gene into two regions, silent sites and 4-kb of the 5' flanking region, corresponding to a test using $L = 2$ loci. (The careful reader might be concerned that these loci are linked, while the HKA test assumes independence across loci. The high recombination rates in *Drosophila* result in LD generally being over only very small distances.) A sample of 81 *Drosophila melanogaster* alleles was examined, along with a single allele from its sibling species *D. sechellia*. Based on sequencing data, the divergence was 210 differences in the 4052-bp flanking region and 18 differences in the 324 silent sites, amounting to roughly equal levels of divergence per base pair between the two "loci." Based on restriction-enzyme data, within *melanogaster*, 9 of the 414 5' flanking sites were variable, while 8 of 79 *Adh* silent sites were variable. Thus, while the per-site divergence was roughly equal, there was a four-fold greater polymorphism level at silent sites.

Hudson et al. modified their test to accommodate the use of polymorphism data from only a single population, as with no polymorphism data available from *D. sechellia*, there is no Equation 10.4b, and thus can be no S_i^B or a_{n_B} terms in Equation 10.4d. In this setting, δ cannot be estimated, so the authors assumed $\delta = 1$ (i.e., that both species have the same effective population size; an alternative approach would be to use the value of δ giving the smallest X^2 value). Given that there are different numbers of sites between the polymorphism and divergence data (which are based on restriction sites and sequence data, respectively), let θ_i be the population-scaled per-nucleotide mutation rate (for locus i), so that we have to weight the θ_i value for each term by the number of sites compared, giving Equations 10.4a, 10.4c, and 10.4d as, respectively,

$$\begin{aligned} S_1^A + S_2^A &= 9 + 8 = a_{81}(414 \cdot \hat{\theta}_1 + 79 \cdot \hat{\theta}_2) \\ D_1 + D_2 &= 210 + 18 = (\hat{\tau} + 1) (4052 \cdot \hat{\theta}_1 + 324 \cdot \hat{\theta}_2) \\ D_1 + S_1^A &= 210 + 9 = 4052 \cdot \hat{\theta}_1 (\hat{\tau} + 1 + a_{81}) \end{aligned}$$

where $a_{81} = \sum_{i=1}^{80} 1/i = 4.965$. The solutions to this system were found to be

$$\hat{\tau} = 6.73, \quad \hat{\theta}_1 = 6.6 \cdot 10^{-3}, \quad \text{and} \quad \hat{\theta}_2 = 9.0 \cdot 10^{-3}$$

yielding the resulting modified X^2 statistic (Equation 10.2a but with the terms involving S_i^B in Equation 10.2b excluded) as 6.09. There are four observations (S_1^A, S_2^A, D_1, D_2) and

three parameters to fit $(\theta_1, \theta_2, \tau)$, which results in a test with one degree of freedom. Because $\Pr(\chi^2_1 > 6.09) = 0.014$, the test indicates a significant departure from the equilibrium neutral model.

Although Equations 10.3 and 10.4 assume that all loci are autosomal, *with care*, sex-linked and organelle genes can also be incorporated. If all compared loci are *X*-linked, Equations 10.3 and 10.4 apply. However, if the loci are a mixture of autosomal and sex-linked, the θ_i terms for sex-linked loci must be multiplied by 3/4 (under equal sex ratios), as their expected levels of neutral polymorphism are $3N_e\mu_i$ (Begun and Aquadro 1991; see Lynch 2007 for more general results). Finally, while the HKA test can accommodate mitochondrial or chloroplast genes, they introduce three concerns. First, all sequences from a given organelle are generally completely linked (because such genomes typically are nonrecombining), and thus must be treated as a single locus. Second, organelle loci have a different effective population size from autosomal genes, which also requires a scaling of their θ value (typically by 1/4 to 1/2, but other values may be justified). The third issue is a bit more subtle. Given that most organelle genomes are only transmitted through females, the population structure and demographic history of nuclear genes (which are an average of the two parents) can be significantly different from that of organelle genes (females only). This raises special concerns in HKA comparisons of genes between nuclear and organelle genomes.

Example 10.4. Ingvarsson (2004) examined chloroplast (cpDNA) diversity in two plants in the genus *Silene* (family Caryophyllaceae). A standard HKA test contrasting four noncoding regions of the chloroplast (treated as a single locus) and two unlinked autosomal genes between *S. vulgaris* and *S. latifolia* gave a highly significant value, with most of the signal (using Equation 10.2b) coming from the cpDNA region. However, the estimated F_{ST} value (Chapter 2) for cpDNA was 0.546 versus 0.056 for nuclear genes, showing strong population structure at the organelle-gene level but only modest structure for nuclear genes. Ingvarsson attempted to correct for these between-gene differences in the amount of structure as follows. Under an island model of migration (Chapter 2), to a first approximation, population structure increases the amount of segregating sites and decreases the divergence, both by a factor of $1 - F_{ST}$. Ingvarsson thus corrected the observed number, S , of segregating sites by using $S_c = (1 - F_{ST})S$ and the divergence by $D_c = D/(1 - F_{ST})$. Applying these corrections to both the cpDNA and nuclear genes and using the S_c and D_c values in the HKA test yielded a nonsignificant result. Thus, the apparently strong signal of selection appears to simply be an artifact generated by nuclear and organelle genes having different population structures.

The McDonald-Kreitman (MK) Test: Basics

One of the most straightforward, and widely used, tests of selection was proposed by McDonald and Kreitman (1991a), who contrasted the amounts of polymorphism and divergence between two categories of sites within a single gene (Example 10.1). Typically, these categories are silent versus replacement sites, but the basic logic can be extended to other comparisons. Under the neutral theory, deleterious mutations are assumed to occur, but to then be quickly removed by selection, thus not contributing to either polymorphism or divergence (Figure 7.1). In the standard neutral-theory expressions for the amount of polymorphism ($4N_e\mu$) and divergence ($2t\mu$), μ is the *effectively neutral* mutation rate, which is the rate at which effectively neutral ($4N_e|s| \ll 1$) mutations arise. While most mutations at silent sites may often be effectively neutral, a much smaller fraction, f , of new mutations at replacement sites are neutral, resulting in a lower effectively neutral mutation rate, $f\mu$. Given that f is the fraction of replacement mutations that is effectively neutral, $1 - f$ is a

measure of *functional constraints*, with values of $1 - f$ near one ($f \simeq 0$) implying that most new mutations are not effectively neutral (i.e., they are deleterious). A minor bookkeeping detail is that the silent and replacement mutation rates in the MK test refer to the sum over all sites, so that $\mu_s = \mu n_s$ and $\mu_a = \mu f n_a$ are the total neutral mutation rates over the collection of n_s silent and n_a replacement sites in the gene of interest (generally $n_a > 2n_s$, as all second-base and many third-base positions within codons are replacement sites).

As before, under the equilibrium neutral model, the expected number of substitutions (D_i) in site class i is $2t\mu_i$, while the expected number of segregating sites (S_i) in a sample of n sequences is $a_n\theta_i$ (Equation 9.21a). Because S_i is a measure of the amount of polymorphism, we denote it by P_i to conform to the standard notation for MK tests. Thus, under neutrality,

$$\frac{D_a}{D_s} = \frac{2t\mu_a}{2t\mu_s} = \frac{2t\mu f n_a}{2t\mu n_s} = f \frac{n_a}{n_s}, \quad \frac{P_a}{P_s} = \frac{S_a}{S_s} = \frac{a_n\theta_a}{a_n\theta_s} = \frac{4N_e\mu f n_a}{4N_e\mu n_s} = f \frac{n_a}{n_s} \quad (10.5a)$$

where the subscript a denotes replacement (amino-acid changing) sites, and s denotes silent sites. Hence, under the equilibrium neutral model, we expect that, on average,

$$D_a/D_s = P_a/P_s \quad (10.5b)$$

If some replacement sites are under positive selection, because of their rapid sojourn times relative to drift, these will generally contribute very little to the within-species polymorphism (Kimura 1969; Smith and Eyre-Walker 2002; Figure 7.1), but they will result in an excess of replacement substitutions, so that $D_a/D_s > P_a/P_s$. Similarly, note that

$$\frac{P_a}{D_a} = \frac{a_n\theta_a}{2t\mu_a} = \frac{a_n 4N_e \mu f n_a}{2t\mu f n_a} = \frac{a_n 2N_e}{t}, \quad \frac{P_s}{D_s} = \frac{a_n\theta_s}{2t\mu_s} = \frac{a_n 2N_e}{t} \quad (10.5c)$$

and thus, under neutrality, we also have

$$P_a/D_a = P_s/D_s \quad (10.5d)$$

which is just a simple rearrangement of Equation 10.5b. It is worth noting that a very similar approach to the MK test was proposed by Templeton (1987, 1996), based on contrasting patterns in the tips versus interiors of estimated gene-tree topologies, and predates the MK test.

McDonald and Kreitman provided a more general derivation of the polymorphism ratio in Equation 10.5a, replacing $4N_e$ (the equilibrium value) by T_{tot} , the total time on all of the within-species coalescent branches (Chapter 2). By considering the ratio of the number of polymorphic sites in the two categories, the common term T_{tot} cancels, so that any effects of demography also cancel. Hence, *provided the effectively neutral mutation rates remain unchanged*, the MK test is *unaffected by population demography* (Hudson 1993; Nielsen 2001). Because the coalescent structure that determines the amount of polymorphism is explicitly removed by using the P_a/P_s ratio, there is no assumption that the allele frequencies are in mutation-drift equilibrium nor any assumption about constant population size. This is a very robust feature not shared by most other tests of selection.

Thus, while Zhai et al. (2008) found that the HKA test was more powerful than the MK test when the equilibrium assumptions hold, the robustness of the MK test (and lack of robustness of the HKA test) when demographic issues are present favors the use of the former. However, as we will see shortly, the MK test is by no means foolproof, as changes in the effective population size can influence the *effectively neutral* mutation rates (the rate at which alleles with $4N_e|s| < 1$ arise), which can bias some of the comparisons used by the test. Another complication is that mildly deleterious alleles can contribute to within-species polymorphisms, but not to between-species divergence, and thus their presence inflates the polymorphism ratio over the divergence ratio, reducing the power to detect positive selection.

The MK test is performed by contrasting polymorphism and divergence data at silent and replacement sites for the gene in question. Given that these two ratios are expected to be equal under neutrality, the test uses a simple 2×2 contingency table (Example 10.1). The presentation of the data required for the MK test is often referred to as either an **MK table** or a **DPRS table**, the latter based on the (clockwise order) of the table's four categories: Divergence (number of substitutions), Polymorphism (number of segregating sites), Replacement, and Silent (or Synonymous):

	Divergence	Polymorphism
Silent	D_s	P_s
Replacement	D_a	P_a

Example 10.1 presented the original data used by McDonald and Kreitman, while Example 10.5 shows how their test can be modified to examine different regions within the same gene.

Example 10.5. Le Corre et al. (2002) examined the *FRIGIDA* (*FRI*) gene in *Arabidopsis thaliana*, a key regulator of flowering time. European populations show significant variation in flowering time, with potentially strong selection for earlier flowering having arisen following the end of the last ice age. For the data below, fixed differences (divergence) were obtained by comparing *A. thaliana* with *A. lyrata*, while data on numbers of segregating sites are based on *A. thaliana* populations.

Entire coding region	Fixed	Polymorphic	
Silent	59	7	
Replacement	68	21	Fisher test $p = 0.056$
Exon 1	Fixed	Polymorphic	
Silent	30	2	
Replacement	38	16	Fisher test $p = 0.013$
Exons 2 and 3	Fixed	Polymorphic	
Silent	29	5	
Replacement	30	5	Fisher test $p = 1.000$

The *FRI* locus clearly shows heterogeneity in patterns of selection when contrasting exon 1 with the remaining exons, and detecting such within-gene heterogeneity may provide important clues for a putative region under functional selection.

These data could be interpreted simply as a reduction on functional constraints in exon 1, resulting in a smaller fraction of segregating replacement mutations being deleterious. In principle, this could occur because of a shift in the selection pressures or for purely demographic reasons, such as a recent reduction in the effective population size increasing the effectively neutral mutation rate. However, there is a nice internal control in that exons 2 and 3 do not display a decrease in the ratio of fixed to polymorphic replacement sites relative to silent sites, which appears to rule out a reduction in effective population size in *thaliana* accounting for the reduction in constraints. The authors noted that roughly half of the replacement polymorphisms in exon 1 are loss-of-function mutations, which result in early flowering. Hence, it appears that the excess number of replacement polymorphisms in exon 1 likely results from selection for early flowering in some populations. Further, because a nonfunctional copy of *FRI* results in early flowering, there are a large number of mutational targets to achieve this phenotype (and hence a high effective mutation rate), which likely explains the large number of replacement polymorphisms. In effect, these data appear to show an ongoing multiple-origins soft sweep (Chapter 8).

This example introduces two important statistical issues in the analysis of MK data. First, one should always use Fisher's exact test for the goodness-of-fit (which can be found in

standard statistical packages, such as R). The χ^2 and G tests (LW Appendix 4) for contingency tables are large-sample approximations, and tend to perform poorly when any table entry has an expected value of less than 5 (note the value of 2 in one of the MK data cells for exon 1). Second, many tests are often performed in a single analysis, raising the thorny issue of multiple comparisons (Appendix 4). If one desires a false-positive rate, q , over an entire collection of n independent tests, then the Bonferroni correction requires a critical value of $p = q/n$ for each test (Equation A4.4). Under this criterion, there is a probability of q that none of the tests are false positives when each is declared significant only when $p \leq q/n$.

Here there were three comparisons (entire, exon 1, and exons 2 and 3), suggesting a critical value of $p = q/3$ to give an experiment-wide value of q that none of the tests are false-positives. However, these three comparisons use overlapping data (e.g., the category “entire” contains all three exons). For the sake of discussion, assume that there are only $n = 2$ independent tests in this example. In that case, a significance threshold of $p = 0.01/2 = 0.005$ is required for each test to give a false-positive rate of 1% over the entire set of comparisons. Likewise, using $p = 0.05/2 = 0.025$ gives a false-positive rate of 5% over the entire collection. Hence, the experiment-wide significance level is closer to 5% than the 1.3% reported for exon 1. As detailed in Appendix 4, Bonferroni corrections are rather strict, and they can be improved by use of sequential Bonferroni methods, or (where appropriate) using control of the *false-discovery rate*. The latter gives the estimated fraction of false positives among a set of tests declared to be significant (“discoveries”); see Example 9.3 for an application, and Appendix 4 for much more details.

While initially presented as a contrast between silent and replacement sites within a single gene, the basic logic of the MK test is not limited to this specific type of comparison. Other types of sites can be contrasted (e.g., noncoding versus silent), and one can easily construct tests involving more than two categories with a simple extension of the contingency table logic underlying MK tests (e.g., Hudson 1993; Templeton 1996; Podlaha et al. 2005; Egea et al. 2008; Chen et al. 2009). Further, as Example 10.5 highlights, one often performs separate MK tests in different regions of the same gene. The general issue of how to detect selection heterogeneity based on a scan of a region is examined by McDonald (1996, 1998) and Goss and Lewontin (1996).

A McDonald-Kreitman test will be significant when P_a/D_a is significantly different from P_s/D_s (Equation 10.5d). Because it is assumed that the silent-site ratio is unchanged by selection, a significant MK test can occur either through an excess of replacement polymorphisms (P_a too large relative to D_a and P_s/D_s) or through an excess of replacement substitutions (D_a too large relative to P_a and P_s/D_s). The **neutrality index** of Rand and Kann (1996),

$$NI = \frac{P_a/D_a}{P_s/D_s} = \frac{P_a D_s}{P_s D_a} \quad (10.6a)$$

indicates which of these two scenarios occurs. Note that NI is simply the odds ratio for the MK contingency table (Jewell 1986). A value greater than one indicates more polymorphic replacement sites than expected, while a value less than one indicates an excess of replacement substitutions. Values less than one suggest that some of the substitutions are adaptive, while values greater than one are suggestive of weakly deleterious segregating alleles.

Note that NI is not defined if either P_s or D_a are zero, and it is biased if either is small (Stoletzki and Eyre-Walker 2011). Hence, its use is problematic when the gene being considered shows little divergence. When the observed cell numbers in any MK table are small (less than 5), a number of corrections are possible, which basically start by adding an extra count to D_a and P_s (Haldane 1956; Jewel 1986). Stoletzki and Eyre-Walker (2011) noted that these corrections are still biased, and they proposed a **direction of selection (DoS)** statistic,

$$DoS = \frac{D_a}{D_a + D_s} - \frac{P_a}{P_a + P_s} \quad (10.6b)$$

Positive values indicate an excess of replacement substitutions (suggesting adaptive evo-

lution), while negative values imply an excess of replacement polymorphisms (suggesting that slightly deleterious alleles are segregating).

While the *DoS* statistic is appropriate when comparing divergence to polymorphism features of genes as a function of some other variable (such as recombination rate or GC content), other approaches have been used when the aim is to return a single summary statistic for the entire genome. A simple average of the *NI* values over all sampled genes is biased, as genes for which *NI* is not defined (P_s or D_a are zero) are excluded, and those genes with small values for either P_s or D_a return biased estimates. Example 10.8 illustrates one commonly used approach to avoid these issues, namely, summing over all sites to create a grand MK table for the entire collection of sampled genes.

Example 10.6. Andolfatto (2005) examined 35 coding and 153 noncoding fragments from a Zimbabwe sample of 12 *D. melanogaster* X chromosomes, with a single *D. simulans* X as an outgroup. The numbers of observed polymorphic and divergent sites were then lumped into various classes as follows:

Mutational Class	Fixed	Polymorphisms		Fisher Test <i>p</i> value	
		All sites	Minus singletons	All sites	Minus singletons
Silent	604	502	323	—	—
Replacement	260	115	52	$4.7 \cdot 10^{-7}$	$4.3 \cdot 10^{-10}$
Noncoding	3168	2386	1295	$1.4 \cdot 10^{-2}$	$5.2 \cdot 10^{-3}$
5' UTRs	328	160	71	$2.7 \cdot 10^{-6}$	$1.7 \cdot 10^{-10}$
3' UTRs	143	86	36	$3.3 \cdot 10^{-2}$	$8.2 \cdot 10^{-5}$

Given the small sample size ($n = 12$ chromosomes), polymorphism data are reported both as the total number of segregating sites (all sites) and the total number of segregating sites minus the singletons. The logic for removing singletons is the concern that slightly deleterious alleles can contribute to segregating sites (although they will be rare) but are unlikely to become fixed, and if retained in the analysis, will result in the polymorphism ratio overpredicting the number of fixed sites. Using the silent class as the neutral reference, McDonald-Krietman tests were performed against each of the four remaining categories (replacement, noncoding, 5' UTR, and 3' UTR), and computed separately using either all polymorphisms or only polymorphisms that were not singletons. The exclusion of singletons ("Minus singletons" column above) decreases the *p* values (increasing significance) in all cases. Even after correcting for multiple tests, all of the comparisons based on polymorphisms minus singletons were highly significant.

Andolfatto also observed that the average nucleotide diversity, π , was higher for silent sites than for any of the other categories displayed above. This suggests that there are stronger constraints on the sampled noncoding regions than on silent sites, and hence stronger purifying selection on these noncoding sites. Conversely, these test values all show excessive substitutions relative to the amount of within-population variation, suggesting that many of the differences were likely fixed by positive selection. Both of these results (stronger purifying selection on polymorphisms and stronger positive selection for substitutions) for noncoding DNA relative to silent sites were very surprising, and they suggested that part of what is called noncoding DNA may have some functional role (the same appears to be at least partly true for humans: ENCODE Project Consortium 2012). A similar study using polymorphism data from *D. simulans* (with *D. melanogaster* as the outgroup), which has a larger effective population size than *D. melanogaster*, found an even stronger signature of purifying selection against *D. simulans* noncoding polymorphisms (Haddrill et al. 2008).

One concern when dealing with noncoding DNA is obtaining the correct alignment to ensure that homologous sites are being compared. This can be problematic for even moderately divergent species, as insertions and deletions run rampant, making correct alignment nearly impossible. Care must then be taken, as one may discard much of the noncoding sequence because of alignment issues, which could enrich the sequences remaining in the analysis with those sites under stronger functional constraints (which are more conserved and thus more easily aligned). Conversely, with coding regions, strong historical selection to keep the

sequence in frame usually results in few insertions and deletions.

Example 10.7. Consider Le Corre et al.'s data on the *FRI* gene (Example 10.5). For exon 1, the neutrality index is

$$NI = \frac{P_a/D_a}{P_s/D_s} = \frac{16/38}{2/30} = 6.42$$

showing that the significant result is due to an excess of segregating replacement sites. Conversely, for exons 2 and 3

$$NI = \frac{5/30}{5/29} = 0.97$$

suggesting a good fit to the neutral model, with neither an excess of polymorphic site nor of fixed replacement sites.

Our interpretation of the signal in exon 1 was as a sign of ongoing selection of alleles for earlier flowering (Example 10.5). However, the *NI* value is also consistent with an excess of slightly deleterious alleles in this region, thus inflating the levels of replacement polymorphisms. The lack of such a signal in exons 2 and 3 argues against this, but it remains a formal possibility that slightly weaker selection in exon 1 (relative to exons 2 and 3), coupled with a genomewide reduction in N_e , could account for the excess polymorphism in exon 1. However, evidence for a recent population expansion argues against this.

This discussion raises the more general question of how often we can safely use the MK test to detect signatures of ongoing *positive* selection. For example, what is the impact of an ongoing hard sweep? This would greatly reduce the number of all segregating sites (both silent and replacement), and hence give the MK test little, if any, power. Generally speaking, the safest interpretation of excess replacement polymorphisms is that they are slightly deleterious. Example 10.6 shows that additional information is required to make a case that these segregating sites are beneficial. Further, such an excess is expected only in rare settings, such as a multiple-origins soft sweep, in the case of *FRI* likely fueled by a large mutational target size (simple deactivation of a function) to produce the putatively favored phenotype (early flowering).

Example 10.8. Bustamante et al. (2005) sequenced roughly 11,600 genes in 39 humans and contrasted the results with human-chimp divergence at these same loci. Summing over all sites, the resulting DPRS table (where SNPs denote polymorphic sites) was

	Divergence	SNPs
Silent	34,099	15,750
Replacement	20,467	14,311

As in Example 10.6, this analysis differs from a standard MK test, as the values for a large number of loci are aggregated into a single table. The resulting *p* value, $< 10^{-16}$, was highly significant, meaning that the neutral model is rejected.

What is the source of the discrepancy? Equation 10.6a gives the neutrality index as

$$NI = \frac{P_a/D_a}{P_s/D_s} = \frac{14,311/20,467}{15,750/34,099} = 1.514$$

showing that the lack-of-fit to the neutral model is driven by an excess of replacement polymorphisms (SNPs). The authors suggest that these polymorphisms are mainly deleterious, a view echoed by Hughes et al. (2003). Consistent with this conclusion, in an analysis of ~47,500 replacement SNPs in a sample of 35 humans, Boyko et al. (2008) used the site-frequency spectrum to estimate that 27–29% of these SNPs were effectively neutral, 30–42% were moderately deleterious, and nearly all of the rest were highly deleterious (we will discuss how such values are obtained shortly). This large fraction of segregating deleterious alleles significantly lowers

the power of MK tests. Indeed, Charlesworth and Eyre-Walker (2008) noted that because of excessive replacement polymorphisms, MK tests in humans are very underpowered.

While commonly used, the approach in Examples 10.6 and 10.8 of summing the MK tables for single genes to create a single grand MK table for the entire genome is potentially problematic because of the **Yule-Simpson effect** (Yule 1903; Simpson 1951), also known as **Simpson's paradox** (Blyth 1972). This is a well-known statistical phenomena wherein the results of individual 2×2 contingency tables suggest a trend in one direction, whereas their amalgamated table suggests a trend in the opposite direction (reviewed by Good and Mittal 1987). More generally, the (unweighted) average of the odds ratios over individual tables is different from the odds ratio in the amalgamated table. This discrepancy commonly arises when there are large disparities in the sample sizes over individual tables. For MK data, this is expected when there are large between-gene differences in the number of replacement substitutions (D_a). To avoid this issue, Stoletzki and Eyre-Walker (2011) suggested using a weighted approach proposed by Tarone (1981) and Greenland (1982) for combining the odds ratio over general 2×2 contingency tables,

$$NITG = \frac{\sum_i D_{si} P_{ai} / (P_{si} + D_{si})}{\sum_i P_{si} D_{ai} / (P_{si} + D_{si})} \quad (10.6c)$$

where i denotes the i th gene. This index is defined for all genes that show any silent-site variation (either P_s or D_s is nonzero), and also weights each gene by its total silent-site sample variation ($P_s + D_s$).

The McDonald-Kreitman Test: Caveats

One of the initial criticisms of the McDonald-Kreitman test was that estimates of the number of segregating sites are rather sensitive to sampling, especially when the sample size is small (Graur and Li 1991; Whittam and Nei 1991). McDonald and Kreitman (1991b) countered that this problem is not serious, as these effects would equally influence estimates of the number of polymorphic silent and replacement sites. While largely correct, this is not always true, however, as there are generally two- to three-fold more potential replacement sites than silent sites, giving the former a slightly smaller sampling error. However, this difference in variances has more to do with power, and is unlikely to lead to false positives.

One potentially significant advantage of the MK test is that it does not assume constant population size or that mutation-drift equilibrium has been reached, and hence is rather robust against many of the demographic concerns that plague other tests. Balancing this advantage are two subtle (but serious) problems, both relating to how the distribution of fitness values for new alleles impacts the observed data (polymorphisms and substitutions).

First, the MK framework assumes that *deleterious mutations are strongly deleterious and make essentially no contribution to either the number of segregating or fixed sites*. In fact, however, weakly deleterious mutations (i.e., $-10 < 4N_e s < -1$) can contribute to segregating polymorphisms (especially because the MK test uses the number of polymorphic sites, not their frequencies), but they are highly unlikely to become fixed (Figure 7.1). Such mutations are overrepresented in polymorphic sites relative to fixed sites, which reduces the power of the MK test to detect an excess of replacement substitutions (and hence a signature of positive selection). We assume that the impact from any overrepresentation of selected polymorphisms at silent sites (our neutral proxy) is small, as these are either neutral or under very weak purifying selection. Conversely, overrepresentation is potentially a significant problem at polymorphic replacement sites. One proposed correction for this problem is to drop “rare” polymorphisms, but this is a rather subjective endeavor. Dropping singletons (Templeton 1996) as in Example 10.5 provides one simple correction, while other authors (e.g., Fay et al. 2002; Smith and Eyre-Walker 2002; Gojobori et al. 2007) have suggested including only “common” polymorphisms in the analysis, such as those with minor-allele frequencies above 0.10. We return to this issue shortly.

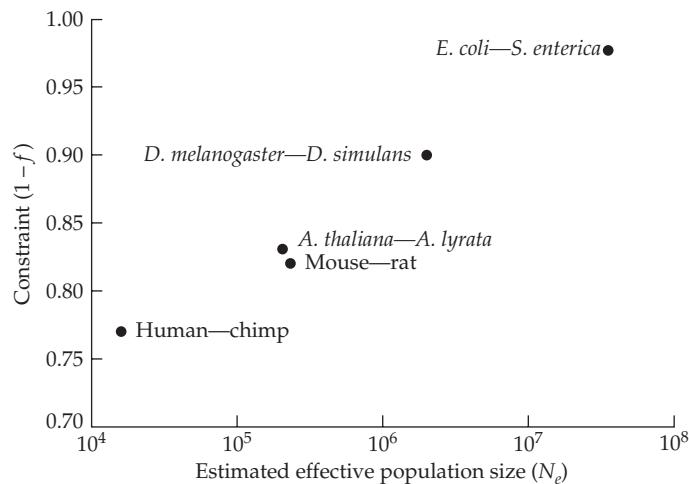

Figure 10.1 The estimated constraint, $1 - f$, on replacement sites as a function of effective population size, where f is the ratio of effectively neutral mutation rates (the fraction of new mutations that efficiently behave as neutral alleles) at replacement versus silent sites. As N_e increases, more deleterious mutations move from the effectively neutral class into the strongly deleterious class (f decreases), reducing the effectively neutral mutation rate and increasing the amount of constraint on a gene. (After Wright and Andolfatto 2008.)

The second concern is even more problematic. At the heart of the MK test is Equation 10.5a. Under the neutral hypothesis, the ratio of polymorphic sites and the ratio of substitutions both estimate the same quantity, f (scaled by the sample-size correction factor n_a/n_s), the ratio of effectively neutral mutation rates for the two categories. Recalling (Chapter 7) that any mutation for which $4N_e|s| \ll 1$ behaves as if it were effectively neutral, the caveat is that the *effectively neutral mutation rate*, $f\mu$, changes with N_e . It is important to stress that the *total* mutation rate, μ , remains unchanged, but the fraction, f , of these mutations that are effectively neutral can decline with increasing N_e , resulting in a decline in $f\mu$. Figure 10.1 shows that estimates of f do indeed decrease as the effective population size, N_e , increases, as the amount of constraint, $1 - f$, increases with N_e . For the same distribution of selection coefficients, one can raise (or lower) f (and hence the effectively neutral substitution rate) by decreasing (or increasing) the effective population size. If the effective population size is significantly different during the divergence phase (when substitutions were fixed) than in the current phase (which generates the observed number of polymorphisms), then these two phases could have different fractions of mutations that are effectively neutral. Because the ratios D_a/D_s and P_a/P_s estimate the f values for these two different phases, they can have different expected values.

McDonald and Kreitman (1991a) were aware that an increase in the effective population size could create a situation where slightly deleterious mutations that were fixed during divergence under a smaller population size do not even contribute to within-species polymorphisms. Such an increase in N_e following the bulk of divergence time would result in an inflated value of D_a and a deflated value of P_a , resulting in an inflated D_a/P_a ratio, and hence a false signal of positive selection. Eyre-Walker (2002) showed that even a modest increase in N_e can generate such false signals, and that the problem is exacerbated by culling rare polymorphisms, which (as discussed above) is common practice. In the words of Hughes (2007), this feature implies that the MK test “cannot distinguish between positive Darwinian selection and any factor that causes purifying selection to become relaxed or to become less efficient.” Phrased in terms of the neutrality index (Equation 10.6a), an NI value > 1 can be generated by either segregating deleterious alleles or by a relaxation in the functional constraints during the polymorphism phase. The latter could occur in response to a change in the environment (Example 10.9) or a change in N_e . Conversely, a value of

$NI < 1$ (which is normally taken as support for adaptive evolution) could similarly be generated by a relaxation of functional constraint during the divergence phase, so that more mutations (relative to those currently segregating in the population) were effectively neutral, and hence fixed. This effect can also occur between populations of the same species. For example, Lohmueller et al. (2008) observed a higher fraction of segregating deleterious mutations in human populations from Europe than from Africa, which they attributed to the bottleneck in the founding European population (and hence a reduction in N_e) during the migration out of Africa.

Example 10.9. An example of some of the potential difficulties in interpreting the results of a McDonald-Kreitman test was seen in a study of the human melanocortin 1 receptor (*MC1R*), a key regulatory gene in pigmentation (Harding et al. 2000). In comparing the canonical *MC1R* haplotype in humans with a sequence from chimpanzees, these authors found 10 replacement and 6 silent substitutions. An African population sample revealed no replacement and 4 silent polymorphisms, giving the MK table as

	Fixed (Human-Chimp)	Polymorphic (African)
Silent	6	4
Replacement	10	0

Fisher's exact test gives a p value of 0.087, close to significance. Taken at face value, one might assume that these data imply that the majority of the replacement substitutions between human and chimp were selectively driven. However, the authors also had data from populations in Europe and East Asia, which showed 10 replacement and 3 silent polymorphisms, resulting in a new MK table:

	Fixed (Human-Chimp)	Polymorphic (Europe/East Asia)
Silent	6	3
Replacement	10	10

with a corresponding p value of 0.453. The authors suggested that the correct interpretation of these data is as very stringent purifying selection due to increased functional constraints in African populations (due to selection for protection against high levels of UV exposure), with a release of constraints in Europe and East Asia. Asians in Papua New Guinea and India (populations living in high-UV environments) also showed very strong functional constraints (few replacement polymorphisms), consistent with a model of selection for UV protection.

The key point is that the *population chosen as the reference standard for the polymorphism ratio is critical*. The two tests above used the same divergence data, but the significance (or lack thereof) of the MK test critically depended on whether the population sample was African or European and East Asian.

Example 10.10. The effect of slightly deleterious alleles on the expected value of the neutrality index was examined by Welch et al. (2008). Assume that the scaled selection coefficient values, $\gamma = 4N_e s$, of new mutations are drawn from a reflected gamma distribution (Equation A2.25a) over the range of $-\infty < \gamma < 0$, with a shape parameter of $\beta > 0$ (the coefficient of variation for γ is given by $1/\sqrt{\beta}$, with $\beta = 1$ corresponding to the exponential distribution). Under these conditions, Welch showed that the expected value of the neutrality index is

$$NI \simeq 1 + \beta K$$

where $K > 0$ is a function of the sample size (n).

Welch further cautioned that even the usual interpretation of $NI < 1$ as positive selection is not generally true. Assume we have the same model as above, with new mutations only being deleterious, but now suppose that the population size has changed over time. In particular, suppose that the population had a constant size, N_e , for some fraction, q , of the total divergence time, after which it increased by a factor of $\delta > 1$ to $\delta N_e > N_e$. In this case, the expected

value of the neutrality index becomes

$$NI \simeq \frac{1 + \beta K}{1 + q(\delta^\beta - 1)}$$

Welch noted that if the population expansion is recent or substantial (q is near one and/or δ is large), NI can easily be less than one, giving a false signature of positive selection.

Finally, silent sites may be a rather poor proxy for neutral sites, especially in species with large effective population sizes. Chapter 8 reviewed codon usage bias, wherein some synonymous codons are preferentially used over others. Selection is thought to be weak on such sites, but it can still have an impact (Hartl et al. 1994; Akashi 1995). For example, DuMont et al. (2004) found that “preferred” synonymous codons are substituted significantly faster than unpreferred synonymous changes at the *Notch* locus in *D. simulans*, while *D. melanogaster* (with a smaller N_e) has a significantly higher substitution rate for unpreferred changes. The consensus on codon bias is that the strength of selection is very weak ($s < 10^{-5}$), making synonymous changes effectively neutral in small populations but subject to selection pressures in populations where $4N_e s$ is sufficiently large.

The nature of selection on third-base positions is further complicated by the observation that weak selection for preferred codons is not the only constraint on synonymous sites. Lawrie et al. (2013) estimated that roughly 20% of synonymous sites in *Drosophila melanogaster* are under very strong functional constraints (with an estimated $-4N_e s$ on the order of 10^3 based on the distribution of rare alleles in the site-frequency spectrum). It is striking that they found that this strong constraint was *independent* of codon bias, being driven by some feature other than selection on preferred codons.

In some settings, selection on the neutral proxy sites may actually provide some robustness to MK tests. As mentioned, false positives under an MK test can be generated by an increase in the effective population size. Eyre-Walker (2002) showed that selection on the neutral proxy sites (synonymous codons) restricts the conditions under which a false positive signal can arise via a change in N_e . Presumably this occurs because changes in N_e influence both the replacement and the neutral proxy sites, thus creating somewhat of an internal control.

Dominance in Fitness and the MK Test

One might be concerned that dominance alters the ratio of polymorphism to divergence at replacement sites, as both the frequency spectrum and the probability of fixation for a selected site are influenced by dominance (Chapter 7). While Weinreich and Rand (2000) and Williamson et al. (2004) showed that most types of dominance have little impact on this ratio, an important exception concerns weak-to-moderate overdominance. Williamson et al. showed that overdominance can increase the substitution rate at replacement sites relative to that predicted from the amount of polymorphism, giving a signal of positive directional selection in an MK test (a neutrality index less than one). The reason for this behavior follows from Robertson’s (1962) classic result examined in Chapter 7, wherein overdominance can *increase*, rather than retard, the rate of fixation when the equilibrium allele-frequency values are extreme (a minor equilibrium allele-frequency of 0.2 or less; see Figure 7.4). The idea is that selection rapidly moves allele frequencies to these equilibrium values, at which point drift can cause alleles to become fixed if selection is relatively weak.

Fluctuating Selection Coefficients and MK Tests

While we have been assuming that the selection coefficient, s , on a new mutation remains constant over its sojourn in the population, this is likely not the case. The impact of fluctuating selection on MK tests was examined by Huerta-Sanchez et al. (2008) and Gossmann et al. (2014), both of which assumed selection coefficients randomly sampled over time

from a distribution with a mean value of zero. Huerta-Sánchez et al. found that fluctuating values of s result in an increase in the probability of fixation (relative to a neutral allele) and a decrease in the amount of polymorphism. This can generate false positives for positive selection in an MK test. Gossman et al., however, noted that the results are more subtle. Because selection coefficients are randomly sampled over time, some alleles will, by chance, end up with a net positive value of s over their entire sojourn, and such mutations contribute disproportionately to levels of polymorphism and divergence. They concluded that MK signals under fluctuating selection are therefore genuine, as fixed mutations are those that, by chance, end up with a net positive s value over their entire history on their way to fixation. Further, they found that the real impact of fluctuating selection is that MK methods tend to *underestimate* the fraction of adaptive sites, as those alleles with $E[s] > 0$ during their sojourn to fixation tend to be undercounted.

Recombinational Bias in Extended MK Tests

The standard MK test, contrasting silent and replacement sites *within a single gene*, is very robust to recombination. As noted by Andolfatto (2008), this occurs because the comparison sites are fully interdigitated, with silent sites interspersed among replacement sites. If we denote these two classes of sites by a and b , standard MK tests have comparisons of the form $abababab$, with adjacent sites sharing the same coalescent structure. In this setting, recombination (or lack thereof) has little effect. Conversely, recombination *can* impact extensions of the MK test that compare classes of *non-interspersed* sites, such as contrasting the silent sites in a gene with 3' or 5' UTR sites adjacent to that gene. Again denoting classes as a or b , these comparisons are now of the form $aaaa-bbbb$. Hence, they are *not* fully interdigitated, and potentially have different coalescent structures when the distance between these comparison blocks is sufficiently large. Andolfatto (2008) found that in such noninterspersed settings, recombination can indeed bias the MK test, generating an increased number of false positives. The bias is most severe for noninterdigitated comparisons when the ratio of recombination to mutation rates is around 1.0, whereas for very small (no recombination), and very large (unlinked sites), values of this ratio, there is little bias.

ESTIMATING PARAMETERS OF ADAPTIVE EVOLUTION

As shown in Example 10.1, DPRS tables lead to a simple prediction about the expected number of replacement substitutions, given the ratio of silent to replacement polymorphisms. Under certain assumptions, this allows us to directly ask how many (if any) excess substitutions at replacement sites have occurred within a target gene. While straightforward, one issue is power: at any particular gene, the true excess has to be fairly substantial in order for the MK test to be significant. However, when we sum up such excesses over a large number of genes, we have the power to detect even a small average increase. This ability to look at the cumulative evidence over a large number of genes in order to detect a small average individual effect is one of the advantages of genomewide studies. A second approach to estimating the number of adaptive substitutions places this idea into a more formal statistical framework, called the **Poisson random field model**, which allows us to estimate the average selection coefficients of sites under positive selection. We will examine this latter approach shortly.

Estimating the Fraction, α , of Substitutions That are Adaptive

It was quickly realized that DPRS tables offer much more than simply an opportunity to test for selection (Sawyer and Hartl 1992; Charlesworth 1994b; Fay et al. 2001, 2002; Smith and Eyre-Walker 2002). A neutrality index < 1 indicates that the observed number of replacement substitutions is greater than expected from the ratio of the number of replacement to silent polymorphic sites. Assuming that the P_a/P_s ratio does indeed reflect the ratio of effectively neutral mutation rates at these two classes of sites, then, when coupled with the observed number of silent substitutions, it predicts the expected number of effectively

neutral replacement substitutions. Any statistically significant excess over this predicted value either reflects sites fixed under positive selection or is the result of changes in the effectively neutral mutation rate between the population (or populations) generating the polymorphism data and those responsible for the divergence data. As mentioned, excessive divergence can occur if the effective population size was much smaller during the divergence phase, allowing more slightly deleterious mutations to escape selection and become fixed.

As above, let μ and $f\mu$ denote the per-site rates at which effectively neutral mutations arise at silent and replacement sites, so that $\mu_a = f\mu n_a$ and $\mu_s = \mu n_s$ are the total rates for the replacement and silent sites in our sample (where n_a and n_s are, respectively, the number of replacement and silent sites). Under neutrality, the expected numbers of effectively neutral substitutions for each class are $D_s = 2\mu_s t$ and $D_{a,n} = 2\mu_a t$. Now suppose there are η_a additional replacement substitutions fixed by positive selection, giving the total number of replacement substitutions as $D_a = D_{a,n} + \eta_a = 2\mu_a t + \eta_a$. Ideally, we would like to estimate both the number, η_a , and the fraction, $\alpha = \eta_a/D_a$, of replacement substitutions that are adaptive. To estimate η_a , note that the expected number of segregating sites for category x is given by $\theta_x a_n$ (Equation 9.21a), yielding $P_s = 4\mu_s N_e a_n$ and $P_a = 4\mu_a N_e a_n$, where the latter assumes that the vast bulk of segregating sites are neutral (adaptive mutations are assumed to be both rare and also fixed quickly, and hence make little contribution to P_a). First note that

$$D_s \frac{P_a}{P_s} = 2\mu_s t \frac{\mu_a}{\mu_s} = 2\mu_a t \quad (10.7a)$$

From above, this last expression is simply the expected number of neutral replacement substitutions, $D_{a,n}$, and because $\eta_a = D_a - D_{a,n}$, our estimate of the number of adaptive replacement substitutions becomes

$$\hat{\eta}_a = D_a - D_s \frac{P_a}{P_s} \quad (10.7b)$$

as obtained by Charlesworth (1994b), Fay et al. (2001, 2002), and Smith and Eyre-Walker (2002). This immediately suggests an estimator for the fraction, α , of replacement substitutions that are adaptive,

$$\hat{\alpha} = \frac{\hat{\eta}_a}{D_a} = 1 - \frac{D_s P_a}{D_a P_s} = 1 - NI \quad (10.7c)$$

Note that a positive estimate of α requires a neutrality index < 1 . Using the data from Example 10.6 for noncoding regions on the X chromosome in *D. melanogaster*, $\hat{\alpha} = 1 - 0.906 = 0.094$ using all polymorphic sites, and $\hat{\alpha} = 1 - 0.764 = 0.236$ if singletons are ignored. Hence, between roughly 10% and 25% of all substitutions in these noncoding regions might be adaptive. Similarly, Kousathanas et al. (2010) obtained estimates of around 10% adaptive substitutions in the immediate up- and downstream regions around protein-coding genes in the house mouse (*Mus musculus castaneus*).

Finally, note that we can estimate the fraction, f , of replacement mutations that are effectively neutral by rearranging Equation 10.5a to

$$\hat{f} = \frac{P_a}{P_s} \frac{n_s}{n_a} = \frac{P_a/n_a}{P_s/n_s} \quad (10.7d)$$

This is simply the ratio of the fraction of replacement sites that are polymorphic divided by the fraction of silent sites that are polymorphic. Recall that $1 - f$ is a measure of the amount of constraint relative to a silent site, as f is the fraction of replacement-site mutations (relative to those at silent sites) that are effectively neutral. For *Drosophila*, estimated $1 - f$ values are 0.94 for replacement sites, 0.81 for UTRs, 0.61 for intergenic regions, and 0.56 for intron sequences (summarized by Sella et al. 2009). Further, Halligan and Keightley (2006) showed that silent sites are not the fastest evolving sequences in *Drosophila*: rather, this distinction belongs to FEI (fastest evolving intronic) sites. In comparison to these sites, the constraint

on silent sites is 0.09, suggesting that 9% of new silent mutations are deleterious. Lawrie et al. (2013), used site-frequency spectrum data to obtain a more extreme value, finding that close to 20% of *D. melanogaster* silent sites are under strong functional constraints.

While Equations 10.7b and 10.7c can be applied to single genes, individual-gene estimates of α are expected to have a large sampling variance and low power. If the actual fraction of adaptive substitutions is small, the modest increase in the number of substitutions will often not be large enough to be significantly different from its neutral expectation, and the resulting estimate of α will not be significantly different from zero. For example, if five substitutions are expected at our focal gene given the ratio of silent to replacement polymorphisms, an observed value of eight substitutions is unlikely to be excessive enough to be declared significantly different from five. However, if three of the eight substitutions were indeed driven to fixation by positive selection, then $\alpha = 0.375$, which is quite substantial.

Despite low power for estimating α at any *single* locus, considerable power can be obtained by estimating the expected value, $E[\alpha] = \bar{\alpha}$, over a *number of loci*. To accomplish this task, Fay et al. (2001, 2002) suggested the estimator

$$\hat{\alpha}_{Fay} = 1 - \frac{\bar{D}_s}{\bar{D}_a} \left(\frac{\bar{P}_a}{\bar{P}_s} \right) \quad (10.8a)$$

where the bar implies the average of that quantity over all sampled genes, e.g., \bar{D}_s is the average number of silent substitutions over all the sampled genes. Note that we use α when referring to a single gene, $\bar{\alpha}$ for its expected value over a set of genes, and $\hat{\alpha}$ as an estimate of $\bar{\alpha}$.

The estimator given by Equation 10.8a has two potential sources of bias, both of which can lead to an overestimation of $\bar{\alpha}$ (Smith and Eyre-Walker 2002; Welch 2006). Let μ and $f\mu$ denote the effectively neutral per-site substitution rates for silent and replacement sites within a gene, where f is allowed to vary over genes. Following Welch (2006), one can show that

$$E \left[\frac{\bar{D}_s}{\bar{D}_a} \right] = \frac{\bar{n}_s}{\bar{n}_a} \frac{1}{E[f]} \left(E \left[\frac{1}{1-\alpha} \right] \right)^{-1} \simeq \frac{\bar{n}_s}{\bar{n}_a} \frac{1}{E[f]} [1 - \bar{\alpha} - \sigma^2(\alpha)] \quad (10.8b)$$

where n_x is the average number of sites of type x over all genes, $E[\cdot]$ is the expectation over all sampled genes, and $\sigma^2(\alpha) = E[\alpha^2] - (E[\alpha])^2$ is the among-gene variance in the fraction of adaptive substitutions (α), with the last approximation following from the delta method (LW Equation A1.3). Equation 10.8b shows that when there is among-locus variation in α (so that $\sigma^2(\alpha) > 0$), $\bar{\alpha}$ is overestimated by Equation 10.8a.

A more subtle bias occurs if f and $4N_e\mu$ are *negatively correlated* over genes, as

$$E \left[\frac{\bar{P}_a}{\bar{P}_s} \right] = \frac{\bar{n}_a}{\bar{n}_s} \left(E[f] + \frac{\sigma(4N_e\mu, f)}{4E[N_e\mu]} \right) \quad (10.8c)$$

as obtained by Smith and Eyre-Walker (2002) and Welch (2006). Hence, Equation 10.7d *underestimates* f , and therefore results in an overestimation of $\bar{\alpha}$, if $4N_e\mu$ and f are negatively correlated (and underestimates $\bar{\alpha}$ if they are positively correlated). Smith and Eyre-Walker (2002) noted that a negative correlation is biologically reasonable, as the effective population size can vary over the genome (Chapters 3 and 8), and regions with smaller N_e are likely have higher f values (Figure 10.1), as more mutations become effectively neutral.

To reduce bias from correlations between f and N_e , Smith and Eyre-Walker (2002) suggested the estimator

$$\hat{\alpha}_{SEW} = 1 - \frac{\bar{D}_s}{\bar{D}_a} \overline{\left(\frac{P_a}{P_s + 1} \right)} \quad (10.9a)$$

where the second term is the average of the quantity $P_a/(P_s + 1)$ over the sampled genes. Provided that the number of polymorphic silent sites in the sample is modest (five or greater), this adjusted polymorphism ratio is unbiased by correlations between f and N_e , with

$$E \left[\hat{\alpha}_{SEW} \right] \simeq \bar{\alpha} + \sigma^2(\alpha) \quad (10.9b)$$

as shown by Smith and Eyre-Walker (2002) and Welch (2006). While this correction removes concern over correlations between f and N_e , overestimation of $\bar{\alpha}$ remains when among-locus variation in α is present.

Example 10.11. A simple model provides some insight into the amount of bias possible when using Equation 10.9b. Suppose there are just two types of genes: a fraction, q , having $\alpha = \alpha_* > 0$, and the rest having only neutral substitutions ($\alpha = 0$). Under this model, $\bar{\alpha} = q\alpha_*$, while

$$\sigma^2(\alpha) = E[\alpha^2] - \bar{\alpha}^2 = q\alpha_*^2 - q^2\alpha_*^2 = \alpha_*^2q(1-q)$$

Suppose that $\alpha_* = 0.2$ and $q = 0.5$, so that $\bar{\alpha} = 0.1$. From Equation 10.9b, the expected value of the Smith-Eyre-Walker estimate is

$$\bar{\alpha} + \sigma^2(\alpha) = 0.1 + [0.2^2 \cdot 0.5(1-0.5)] = 0.11$$

or a 10% overestimation. Conversely, consider a more extreme case where at 10% of the genes, all substitutions are adaptive, so that $\alpha_* = 1$ and $q = 0.1$. Again, $\bar{\alpha} = 0.1$, while the expected value from the Smith-Eyre-Walker estimate is $0.1 + 0.1 \cdot 1^2(1-0.1) = 0.19$, so in this extreme case, $\bar{\alpha}_{SEW}$ returns only a two-fold overestimate of $\bar{\alpha}$.

A potential concern with Equations 10.8a and 10.9a is bias due to the Yule-Simpson effect. Recalling Equations 10.7c and 10.6c suggests that the estimator

$$\hat{\alpha}_{TG} = 1 - NI_{TG} = 1 - \frac{\sum_i D_{si}P_{ai}/(P_{si} + D_{si})}{\sum_i P_{si}D_{ai}/(P_{si} + D_{si})} \quad (10.9c)$$

is perhaps the most robust approach to this problem. While Stoletzki and Eyre-Walker (2011) found very close agreement between $\hat{\alpha}_{TG}$ and $\hat{\alpha}_{Fay}$ over the data sets they examined, all of the above considerations suggest that the most prudent estimator is $\hat{\alpha}_{TG}$. We will refer to estimators of α that use departures from the expectation under neutrality in a DPRS table collectively as **MK estimators** (Equations 10.7c, 10.8a, 10.9a, and 10.9c).

Confidence intervals for $\bar{\alpha}$ using any of these estimators can be obtained using bootstrap resampling. One generates a sample of genes by drawing *with replacement* from the original list of all genes and estimates $\bar{\alpha}$ for this sample. This process is repeated a large number of times to generate a distribution of the estimate under resampling. Taking the lower 2.5% and upper 97.5% in this distribution yields the 95% bootstrap confidence interval.

While the above sources of bias (among-locus variation in α and correlations between f and $4N_e\mu$; Equations 10.8b and 10.8c) are generally modest and in a predictable direction (overestimation of $\bar{\alpha}$), the presence of mildly deleterious alleles provides a major bias, which can be either positive or negative (Eyre-Walker 2002; Bieren and Eyre-Walker 2004; Welch 2006; Charlesworth and Eyre-Walker 2008; Eyre-Walker and Keightley 2009; Halligan et al. 2010; Schneider et al. 2011; Keightley and Eyre-Walker 2012; Messer and Petrov 2013b). Estimates of α are downwardly biased by the presence of low-frequency deleterious alleles that contribute to P_a but not D_a , thus inflating the polymorphism ratio relative to the divergence ratio (Eyre-Walker 2006; Eyre-Walker and Keightley 2009). As with MK tests, one approach is to count only “common” polymorphisms for P_a and P_s . However, Charlesworth and Eyre-Walker (2008) noted that while this approach is “better than doing nothing,” estimates of α still tend to be downwardly biased even after making this correction unless the true α is fairly substantial. Further, the bias is a function of the complex distribution of fitness effects (Charlesworth and Eyre-Walker 2008; Welch et al. 2008; Eyre-Walker and Keightley 2009; Schneider et al. 2011; Keightley and Eyre-Walker 2012).

Messer and Petrov (2013b) suggested that one simple solution is to estimate $\bar{\alpha}$ using different cutoff levels for rare polymorphisms, with $\bar{\alpha}(x)$ denoting the estimate that ignores polymorphisms whose *derived* allele frequency is below x . Note that $\bar{\alpha}(x)$ could be based on any of our previous MK estimators (e.g., Equations 10.8a, 10.9a, and 10.9c) simply by ignoring polymorphisms below this threshold. Recalculating this statistic for increasing values of x , an exponential regression of the form $\alpha(x) = a + b \exp(-cx)$ is fit to the data, and the asymptotic value (the projected value at $x = 1$) is given by the **Messer-Petrov asymptotic estimate** of $\bar{\alpha}$

$$\bar{\alpha}_{MP} = a + b \exp(-c) \quad (10.9d)$$

The presence of mildly deleterious alleles also biases estimates of α if the population size differed during the divergence and polymorphism phases. If the population has recently undergone an expansion, this can upwardly bias estimates of α . In such cases, slightly deleterious alleles may have previously been fixed (contributing to divergence), but would be quickly removed in the new, larger population, thus not contributing to P_a . Conversely, if the population has recently undergone a contraction, this inflates P_a as more deleterious alleles are segregating, downwardly biasing estimates of α . Eyre-Walker and Keightley (2009) and Halligan et al. (2010) obtained a simple expression for the bias in α when the recent population size, N_P , generating the polymorphism data differs from the ancestral size, N_D , generating the divergence data. Assuming beneficial mutations are sufficiently strong that α is invariant under the two population sizes, and that deleterious new mutations have their fitness effects drawn from a gamma distribution with a shape parameter of $\beta > 0$, then the connection between the expected value, α_{est} , of an estimated α and its true value is

$$\alpha = 1 + (\alpha_{est} - 1) \left(\frac{N_P}{N_D} \right)^\beta \quad (10.10)$$

A contraction in N_e ($N_P < N_D$) leads to an underestimation of α , while an expansion ($N_P > N_D$) results in an overestimation. The same approach leading to Equation 10.10 was used in Example 10.10 to examine the behavior of the neutrality index (which is closely related to α ; see Equation 10.7c) under changes in N_e .

Maximum-likelihood (ML) estimators of α have been proposed that attempt to account for segregating deleterious mutations (Bierne and Eyre-Walker 2004; Welch 2006; Boyko et al. 2008; Eyre-Walker and Keightley 2009; Schneider et al. 2011; Keightley and Eyre-Walker 2012). This is done by assuming a standard form (such as a gamma) for the distribution of deleterious fitness effects, and then using site-frequency spectrum data to estimate the parameters of this distribution. We sketch the basic outline of this approach in the next section (in the context of Poisson random field models). While it is elegant and powerful when the model assumptions are correct, the concern is that this approach is highly dependent on the assumed functional form (e.g., gamma, normal, or other) of the unknown distribution of fitness effects for the slightly deleterious mutations. Indeed, Kousanthanas and Keightley (2013) found that these models perform poorly when the distribution of fitness effects is multimodal, and they suggested using nonparametric approaches for such cases.

Another potential source of bias, which was first noted by Akashi (1995), is codon usage. Strong codon usage bias results in the synonymous substitution rate underestimating the neutral divergence rate, which in turn inflates estimates of α . If strong bias occurs on just a few genes, this will have a minor impact on $\bar{\alpha}$. However, chromosome-wide biases can cause problems. Recall that the *D. melanogaster* X chromosome has a higher codon usage bias than the autosomes (Chapter 8). Because this appears to be due to stronger selection on X-specific genes, it can result in different biases in α between estimates based on X versus those based on autosomal loci (Campos et al. 2012).

Given these competing sources of bias (overestimation of $\bar{\alpha}$ when $\sigma^2(\alpha) > 0$ and underestimation of α when deleterious alleles are segregating), are MK estimators more likely to over- or underestimate the true $\bar{\alpha}$? Indeed, are they reliable at all? As Example 10.11 highlights, the overestimation of $\bar{\alpha}$ when α varies over genes, while not trivial, is often modest, especially if $\bar{\alpha}$ is moderate to large. Conversely, as mentioned above, the presence

of segregating weakly deleterious replacement alleles (which are unlikely to become fixed) inflates the polymorphism ratio, P_a/P_s , leading to an underestimation of the actual excess number of adaptive substitutions. This effect can be quite dramatic. In particular, if deleterious alleles are common, a neutrality index value greater than 1.0 can occur, which results in a negative estimate of α (Equation 10.7c). Upon putting these two sources of bias together, $\bar{\alpha}$ is generally likely to be underestimated unless the population has undergone a recent size expansion.

A final complication, noted by Fay (2011), is the assumption that each site evolves independently (also see Messer and Petrov 2012). Two possible sources of overestimation of α are possible when this assumption fails. First, slightly deleterious mutations may be fixed by hitchhiking to a favorable substitution, potentially inflating D_a and hence estimates of α . Second, epistasis in fitness between sites may occur such that fixation at one site changes the constraints on other sites within the gene, which again can potentially result in an inflation in D_a .

How Common Are Adaptive Substitutions?

There has been an explosion of genomewide estimates of $\bar{\alpha}$ (Eyre-Walker 2006) that will likely continue, as the required data (the amount of divergence between a set of genes in two species, and polymorphism data, or the number of segregating sites, for the same genes from one, or both, species) are becoming increasingly easy to obtain. Table 10.1 summarizes some of these studies, and Figure 10.2 shows an analysis from ten species-pairs in plants. The quest for $\bar{\alpha}$ values is very reminiscent of the mad “find them and grind them” dash in the 1970s to estimate levels of protein variation in a menagerie of species (e.g., Lewontin 1974).

The general observation for *Drosophila* is that estimates of $\bar{\alpha}$ for amino acid substitutions are high, averaging around 50%, with estimates of the fraction of adaptive changes in noncoding regions also approaching 30% in some cases. High $\bar{\alpha}$ values for replacement sites are also observed for the mouse, bacteria, and three plants (*Populus*, *Helianthus*, and *Capsella*), while very low levels are seen in other plants (Table 10.1 and Figure 10.2). Low levels in *Arabidopsis thaliana* were originally attributed to the high levels of selfing in this species (Bustamante et al. 2002), but a close outcrossing relative (*A. lyrata*) similarly shows very low levels of $\bar{\alpha}$ (Foxe et al. 2008). The case receiving the most interest is humans, where an initially rather high estimate of 0.35 by Fay et al. (2001) for a small set of genes was followed by several studies showing much lower values (Table 10.1).

One trend that has been suggested is that $\bar{\alpha}$ increases with effective population size (Eyre-Walker 2006). While intriguing, there are also apparent counterexamples. For example, Bachtrog (2008) found that *D. miranda*, which is thought to have a low effective population size, has a similar value of $\bar{\alpha}$ as *Drosophila* species thought to have a significantly larger values for N_e .

Drawing a clear conclusion from these initial data is problematic for several reasons. First, even in the same species, different genes may be used or different populations may be chosen as the polymorphism benchmark. The effect of the latter is especially prominent in Figure 10.2, with the same divergence data between two sunflower species (*Helianthus annuus* versus *H. petiolaris*) showing a significantly positive estimate of mean α when using *Helianthus petiolaris* as the polymorphism reference population, but a negative (but not significant) estimate when using *H. annuus* as the reference population (reminiscent of Example 10.9). Differences in N_e values between the two species being considered can inflate or deflate estimates of α (Equation 10.10). Second, different studies used different methods, ranging from simple MK-type estimators (Equations 10.8 and 10.9) to much more sophisticated, ML-based estimators that attempt to account for both changes in N_e and the presence of segregating deleterious alleles (Bierne and Eyre-Walker 2004; Welch 2006; Eyre-Walker and Keightley 2009). While they are certainly powerful when the modeling assumptions are correct, the robustness of these ML approaches against model misspecification is unclear.

Despite these potential misgivings, the pattern of estimates of $\bar{\alpha}$ over species, and even

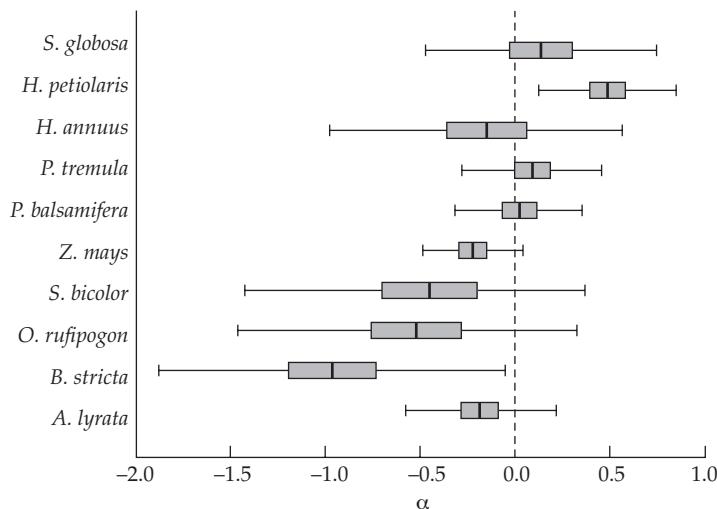

Figure 10.2 Estimated $\bar{\alpha}$ values for ten plant species, where the listed species supplied the polymorphism data. Boxes and whiskers indicate, respectively, the 50% and 95% confidence intervals for the estimates of $\bar{\alpha}$, obtained using Eyre-Walker and Keightley’s (2009) ML method, which allows for a distribution of deleterious fitness effects and potentially different effective population sizes in the divergence and polymorphism phases. Only the comparison involving sunflowers (polymorphism data from *Helianthus petiolaris*, divergence between *petiolaris* and *annuus*) had an estimated average $\bar{\alpha}$ that was significantly positive. Surprisingly, the comparison using polymorphism data from *H. annuus* and the same divergence (*petiolaris* versus *annuus*) gave a negative estimate of average $\bar{\alpha}$ (but was not significantly different from zero). Note that most estimates are negative (although only one was significantly so,). Recall that negative estimates of $\bar{\alpha}$ occur when the neutrality index (Equation 10.6a) is greater than one, namely, when there is an excessive number of segregating replacement sites. As mentioned throughout this chapter, this can occur if weakly deleterious alleles are common, which inflate the number of polymorphisms but not fixations. (After Gossmann et al. 2010.)

within genomes, is of fundamental importance to evolutionary biologists. If, indeed, some species have very low $\bar{\alpha}$ values, does this automatically imply that they have lower rates of adaptation? One surprising taxon that shows a very low estimated $\bar{\alpha}$ is the Hawaiian silversword plant genus *Schiedea* (family Caryophyllaceae), a group with rapid (and dramatic) morphological evolution over a very recent time window (Gossmann et al. 2010). One possible resolution to this apparent disconnect is that most current studies have focused on the estimation of α in coding sequences, whereas considerable adaptation (especially over short time scales) may occur at the level of gene regulation. Based upon the estimated α values in noncoding regions, Andolfatto (2005, Wright and Andolfatto 2008) suggested that the number of adaptive substitutions in noncoding regions in *Drosophila* could be far greater than the number of adaptive replacement substitutions. Given that *Drosophila* has a compact genome relative to humans and many other metazoans and land plants, the bulk of adaptive variation may not reside in the coding regions that are the focus of most current estimates of $\bar{\alpha}$. An alternative, and not necessarily exclusive, explanation for the *Schiedea* data is that only a few key genes underlie most of the morphological change, resulting in very little change in the genomewide value of $\bar{\alpha}$.

One observation consistent with the importance of regulatory changes derives from the work of Torgerson et al. (2009), who compared polymorphism and divergence levels in roughly 15,000 **conserved noncoding** (CNC) regions flanking human genes. CNCs are

Table 10.1 Partial list of estimates of the fraction, $\bar{\alpha}$, of replacement substitutions that are adaptive. The organism listed is the species that provided the polymorphism data. MK refers to a McDonald-Kreitman estimator (Equations 10.8 or 10.9), ML refers to maximum-likelihood extensions of MK estimators (Bierne and Eyre-Walker 2004; Welch 2006; Eyre-Walker and Keightley 2009; Schneider et al. 2011), PRF refers to Poisson random field estimators, and IN to the *INSIGHT* estimator (details in the text). Estimates of zero indicate a neutrality-index score exceeding one (and hence a negative estimate of $\bar{\alpha}$).

operationally defined as noncoding sequences of at least 100 nucleotides in length that show at least 70% conserved sequence identity between mice and humans. The idea is that these sequences are putative regulatory control regions, and hence under purifying selection. When comparing human-chimpanzee divergence, the authors estimated an overall $\bar{\alpha} \sim 0.05$ for all CNC, ~ 0.15 and ~ 0.23 for 5' and 3' UTRs regions of known genes, respectively, and ~ 0.12 for upstream and downstream regions from known genes. Their most interesting finding was of a lack of correlation between the estimated α values for the CNC regions flanking a gene versus that for replacement substitutions within that gene, namely, an apparent disconnect between regulatory (CNC) and structural (amino acid) substitutions.

Estimating the Rate, λ , of Adaptive Substitutions

A quantity that prominently appeared in expressions in Chapter 8 on the effects of recurrent sweeps was λ , the per-generation rate at which adaptive substitutions occur. While it might seem that estimates of λ (the number of adaptive substitutions per site divided by the total

time of divergence, $2t$) would be very difficult to obtain, fortunately this is not the case, as they follow almost directly from estimates of α (Smith and Eyre-Walker 2002; Andolfatto 2007). If $d_a = D_a/n_a$ denotes the per-site number of replacement substitutions between two species that separated t generations ago, then an upper bound for λ is simply $d_a/(2t)$. The use of D_a to compute d_a involves the assumption that all substitutions have been observed, so that no corrections for multiple substitutions at the same site are needed, which is not unreasonable when comparing two closely related species. With an estimate of α , the number of adaptive replacement substitutions is just αD_a , yielding **Andolfatto's estimator** (2007),

$$\hat{\lambda} = \frac{\alpha d_a}{2t} \quad (10.11a)$$

for the per-site, per-generation rate of adaptive substitutions.

In order to apply Equation 10.11a, one must have an estimate of the divergence time, t . This can be estimated (scaled as $\tau = t/(2N_e)$ generations) from the ratio of D_s/P_s , as follows. From Equations 10.12a and 10.12b,

$$\frac{E[D_s]}{E[P_s]} = \frac{1}{a_m + a_n} \left(\tau + \frac{1}{m} + \frac{1}{n} \right) \quad (10.11b)$$

where m and n are the sample sizes for the two populations and the sample size feature, a_x , is given by Equation 4.3b. Substituting the observed values of D_s and P_s for their expected values and rearranging provides a simple method-of-moments estimator for the scaled divergence time

$$\hat{\tau} = (a_m + a_n) \frac{D_s}{P_s} - \left(\frac{1}{m} + \frac{1}{n} \right) \quad (10.11c)$$

Using this estimate yields $\hat{t} = 2N_e \hat{\tau}$, and substituting into Equation 10.11a yields

$$\hat{\lambda} = \frac{\alpha d_a}{2N_e \hat{\tau}} \quad (10.11d)$$

Note that the estimate offered by Equations 10.11a and 10.11d for the rate, λ , is typically based on *structural changes*, namely, the adaptive rate of amino acid replacement substitutions in protein-coding genes. A more inclusive estimate would also account for regulatory adaptations, which are expected to be *at least* on par with protein structural adaptations (Chapter 9).

Example 10.12. The estimated amino acid divergence between human and chimpanzee proteins is $d_a = 0.008$ (Chimpanzee Sequencing and Analysis Consortium 2005), with a divergence time of roughly 7 million years. If we take $\alpha = 0.10$ (10% of replacement substitutions are adaptive, the rough average for human studies in Table 10.1), then from Equation 10.11a, our estimate of the rate of adaptive replacement substitutions per site, per generation is

$$\lambda = \frac{0.10 \cdot 0.008}{14 \cdot 10^6} = 5.7 \cdot 10^{-11} \text{ per site, per year}$$

Assuming a generation time of 25 years, this corresponds to a rate of $2.3 \cdot 10^{-12}$ per site, per generation.

As a point of comparison, Andolfatto (2007) contrasted X chromosome genes in *Drosophila melanogaster* (for polymorphism data) and *D. simulans* (as the outgroup for divergence). The estimated α was 0.5, while $d_a = 0.028$, and $t = 10^7$ generations, yielding

$$\lambda = \frac{0.50 \cdot 0.028}{2 \cdot 10^7} = 7.0 \cdot 10^{-10} \text{ per site, per generation}$$

Hence (for these data), *Drosophila* have a 12-fold higher per-site adaption rate than humans.

THE SAWYER-HARTL POISSON RANDOM FIELD MODEL

Another approach for extracting information from DPRS tables on the nature and amount of selection is the **Poisson random field (PRF) model** of Sawyer and Hartl (1992). Their initial version assumed that all sites within a region evolve independently and that the strength of selection on all replacement sites was the same. Strongly deleterious mutations were allowed to occur, but the assumption is that these do not contribute to either polymorphism (observed segregating sites) or divergence, and they are accounted for by simply reducing the mutation rate to exclude such mutations. Under this model, the observed counts (P_s , D_s , P_a , and D_a) in a DPRS table follow independent Poisson distributions, whose expected values are functions of four parameters (θ_a , θ_s , τ , and γ). With four observations (the DPRS entries) and four unknowns, we can estimate these parameters, but we cannot assess how well the model fits the data. Two of the parameters are the scaled total mutation rates, $\theta_a = 4N_e\mu_a$ and $\theta_s = 4N_e\mu_s$, while the third parameter is the scaled divergence time, $\tau = t/(2N_e)$. Of most interest is the fourth parameter, the scaled strength of selection, $\gamma = 2N_e s$. Sawyer and Hartl assumed there was additive fitness, so that a new mutation has a fitness of $1 + s$ as a heterozygote and $1 + 2s$ as a homozygote. In contrast to MK approaches, the PRF model does not estimate the fraction, α , of adaptive substitutions directly, but knowledge of γ can allow one to do so indirectly (Example 10.13).

Basic Structure of the Model

The PRF model assumes that each site evolves independently, and hence there are no effects from selection at linked sites—the assumption is that selection only influences a site by directly acting on it. To obtain the expected values for the entries in a DPRS table, Sawyer and Hartl used results from diffusion theory (Appendix 1) on the equilibrium distributions (under mutation-selection-drift balance) for polymorphisms at neutral and selected sites, as well as the expected divergence between sites. The PRF model is an infinite-sites model (Chapter 2), with each new mutation assumed to be unique and at a different site from previous ones. For a sample of m and n sequences from the two species, the expected values for the DPRS entries are

$$E[D_s] = \theta_s \left(\tau + \frac{1}{m} + \frac{1}{n} \right) \quad (10.12a)$$

$$E[P_s] = \theta_s \left(\sum_{j=1}^{m-1} \frac{1}{j} + \sum_{j=1}^{n-1} \frac{1}{j} \right) = \theta_s (a_m + a_n) \quad (10.12b)$$

$$E[D_a] = \theta_a \left(\frac{2\gamma}{1 - e^{-2\gamma}} \right) \left(\tau + G(m, \gamma) + G(n, \gamma) \right) \quad (10.12c)$$

$$E[P_a] = \theta_a \left(F(m, \gamma) + F(n, \gamma) \right) \quad (10.12d)$$

where

$$F(n, \gamma) = \int_0^1 \left(\frac{1 - x^n - (1 - x)^n}{x(1 - x)} \right) \left(\frac{1 - e^{-2\gamma(1-x)}}{1 - e^{-2\gamma}} \right) dx \quad (10.13a)$$

$$G(n, \gamma) = \int_0^1 x^{n-1} \left(\frac{1 - e^{-2\gamma(1-x)}}{2\gamma(1 - x)} \right) dx \quad (10.13b)$$

The full derivation is given by Sawyer and Hartl, but a brief sketch of the underlying ideas is as follows.

Recall (Equation 7.13b) Wright's (1938b) classic result for the amount of time that a new segregating mutation (with selection coefficient s) spends in the interval $(x, x + dx)$,

$$\phi(x | N_e s) = \frac{1 - e^{-2\gamma(1-x)}}{1 - e^{-2\gamma}} \frac{1}{x(1-x)} dx \quad (10.14a)$$

where x is the frequency of the derived allele. In the limit as $\gamma \rightarrow 0$, this reduces to dx/x , recovering Watterson's expression for the (unfolded) site-frequency spectrum (SFS) for neutral alleles (Equation 2.34a). Equation 10.14a is the expected equilibrium unfolded frequency spectrum for segregating sites under selection, and it is valid for both positive and negative values of s .

As a brief aside, we mentioned above that certain maximum-likelihood versions of the basic MK test use a **distribution of fitness effects** (often denoted as DFE in the literature), $\varphi(s | \Delta)$, where Δ denotes the vector of distribution parameters (such as the α and β parameters for a gamma distribution; see Equation A2.25a) (Bierne and Eyre-Walker 2004; Eyre-Walker et al. 2006; Welch 2006; Boyko et al. 2008; Eyre-Walker and Keightley 2009; Keightley and Eyre-Walker 2012). Under this model, the expected SFS becomes

$$\phi(x | N_e, \Delta) = \int \phi(x | N_e s) \varphi(s | \Delta) ds \quad (10.14b)$$

This is simply the average of the frequency spectrum, $\phi(x | N_e, s)$, for alleles with a set value of s over the assumed distribution, $\varphi(s | \Delta)$, of s . Equation 10.14b is then used to obtain a maximum-likelihood estimate of the vector of distribution parameters, Δ , given the SFS data, with the resulting DFE used to adjust for the effects of segregating deleterious alleles.

Returning to the PRF model, we do not use the site-frequency spectrum, but rather translate the SFS into the four cell counts in the DPRS table. If x is the population frequency of a segregating allele, the probability that we score it as a polymorphic site in a sample of size n is $1 - x^n - (1 - x)^n$, where the last two terms account for all n draws either being only the derived allele or only the ancestral allele (Equation 2.36b). Hence, the probability that we will score a truly segregating site as polymorphic in a sample of size n becomes

$$\int_0^1 [1 - x^n - (1 - x)^n] \phi(x | N_e, s) \quad (10.14c)$$

This follows by averaging the probability of scoring a site as polymorphic given a derived allele frequency of x over the distribution $\phi(x | N_e, s)$ of x given the selection model. The function $F(n, \gamma)$ given by Equation 10.13a follows upon substitution of Equation 10.14a in Equation 10.14c (a similar approach was used in Chapter 9 for ML-based detection of hard sweeps; see Equation 9.16a).

The Sawyer-Hartl model also correctly accounts for the possibility that segregating mutations are scored as substitutions because the sample size is insufficient to contain both alleles. If the derived-allele frequency is x , the probability that we score a polymorphic site as a substitution event (for the derived allele) is x^n , giving the additional increment to the probability of an observed substitution as

$$\int_0^1 x^n \phi(x | N_e, s) \quad (10.14d)$$

This term is added to the probability of a true substitution to give a full accounting of the number of sites in the sample that are scored as substitutions (Equation 10.12c), with $G(n, \gamma)$ following from Equations 10.14a and 10.14d.

The basic similarities, and fundamental differences, between MK estimators (e.g., Equations 10.7–10.9) and the PRF approach can be easily obscured by the imposing nature of the PRF equations. The similarity is that both approaches use the same data, the four values in a DPRS table. However, the two approaches estimate different quantities and have

different underlying model assumptions. MK estimators make no assumption about the nature or strength of selection on replacement sites, but instead estimate f , the reduction in the effectively neutral substitution rate at replacement sites, and α , the fraction of replacement substitutions at a gene that are adaptive. The effect of purifying selection enters only through f , while the effects of positive selection enter only through α .

In contrast, the PRF equations estimate θ_a and θ_s , the scaled total mutation rates over all sites of the two categories within the gene. The ratio of θ_a/θ_s (suitably corrected for the number of sites within each category; see Equation 10.7d) is *not* an estimate of f , as the PRF model *does* allow for slightly deleterious alleles to be segregating (i.e., the estimate of $\gamma = 2N_e s$ might be negative). The original Sawyer-Hartl model was very restrictive, with only a single fitness class for replacement sites (which is approximately treated as an average selection coefficient over mutations). Extensions (discussed shortly) remove this restriction, allowing for neutral, deleterious, and advantageous classes, with either constant values of γ within each class, or (more generally) class-specific distributions of γ values. Thus, the PRF model does *not* estimate α directly, but given estimates of γ , we can compute the expected fraction of substitutions that are fixed by positive selection (Example 10.13 and Equation 10.16c).

The original Sawyer-Hartl analysis equated the observed entries in a DPRS table with their corresponding expected values (Equations 10.12a–10.12d), and then solved for the unknowns of interest (the ratio $\theta_a/\theta_s = \mu_a/\mu_s$, the scaled average strength of selection $\gamma = 2N_e s$, and the scaled time of divergence $\tau = t/[2N_e]$). A value of γ significantly different from zero implies selection on replacement sites, with $\gamma > 0$ implying positive selection and $\gamma < 0$ implying negative selection (the latter applies only to mildly deleterious alleles, as the PRF model treats very deleterious alleles by lowering the mutation rate: these are assumed to be not seen as either polymorphisms or divergences). This original model, which only assumes a single selective class with silent sites being neutral, can be placed in a likelihood framework by recalling that each observed entry in a DPRS table is an independent Poisson random variable. The probability that the count X in a specific category is x , given its expected value ζ , follows from the Poisson distribution,

$$\text{Prob}(X = x | \zeta) = \zeta^x \exp(-\zeta)/x!, \quad \text{where } \zeta = E[X]$$

The likelihood of the data in the DPRS table for gene i is thus given by

$$L_i = \prod_{j=1}^4 \left(\frac{\zeta_{i,j}^{x_{i,j}} \exp(-\zeta_{i,j})}{(x_{i,j})!} \right) \quad (10.15)$$

where $x_{i,j}$ denotes the observed DPRS table values for category j in gene i , with

$$x_{i,1} = P_{s,i}, \quad x_{i,2} = P_{a,i}, \quad x_{i,3} = D_{s,i}, \quad x_{i,4} = D_{a,i}$$

and $\zeta_{i,j}$ are the corresponding gene-specific expected values,

$$\zeta_{i,1} = E[P_{s,i}], \quad \zeta_{i,2} = E[P_{a,i}], \quad \zeta_{i,3} = E[D_{s,i}], \quad \zeta_{i,4} = E[D_{a,i}]$$

Note from Equations 10.12a–10.12d that $\zeta_{i,1}$ through $\zeta_{i,4}$ are functions of the unknown parameters ($\theta_{a,i}, \theta_{s,i}, \gamma_i, \tau$) that we wish to estimate by ML. A numerical search over all possible values of these parameters for the combination that maximizes Equation 10.15 given the data (treating the $x_{i,j}$ as fixed constants) yields the ML solutions (LW Appendix 4). Under the assumption of independence across genes, the combined likelihood over k genes becomes

$$L = \prod_{i=1}^k L_i$$

where θ_a, θ_s , and γ can potentially vary over the genes, while the divergence time, τ , is shared by all. Hence, for M genes, there are $3M + 1$ unknown parameters.

As noted, this basic model can be expanded by considering more realistic fitness models. For example, Nielsen et al. (2005a) allowed three fitness classes for replacement sites: neutral, deleterious, and beneficial (advantageous). While fitness is assumed to be the same within each class, this is a significant improvement over the original Sawyer-Hartl model. The resulting likelihood now has four parameters for selection (as opposed to one, γ). These are p_b , p_0 , and p_d , the frequencies of beneficial, neutral, and deleterious mutations (where $p_b = 1 - p_0 - p_d$), and γ_b and γ_d , the scaled selection coefficients for the beneficial and deleterious alleles (which are assumed to be the same over all genes). Nielsen et al. applied their method to a set of 50 human genes with prior evidence for possible positive selection. The resulting ML estimates were $p_d = 0.748$, $p_0 = 0.172$, and $p_b = 0.080$ as the fraction of deleterious, neutral, and advantageous mutations, and $\gamma_d = -34.96$ and $\gamma_b = 267.11$ as the scaled strengths of selection of deleterious and advantageous mutations. Note that even in this case where genes were ascertained as likely to be under positive selection, most mutations were still deleterious. A similar analysis of two *Drosophila melanogaster* data sets by Schneider et al. (2011) found that ~1.5% of all replacement mutations were adaptive (i.e., $p_b \sim 0.015$), but with a much smaller scaled strength of selection, $\gamma_b \sim 10$.

While the PRF model does not directly estimate the fraction of adaptive replacements (α), this can be obtained from the estimates of γ and the fraction, p_b , of advantageous mutations as follows. The expected rate of effectively neutral substitutions at replacement sites is μp_0 (the neutral mutation rate), whereas the expected number of favorable mutations arising in each generation is $2N\mu p_b$, where μp_b is the favorable mutation rate. For large γ , each favorable mutation has a fixation probability of $2sN_e/N$ (Chapter 7), for an expected per-generation substitution rate of favorable alleles of

$$\lambda \simeq (2N\mu p_b)(2sN_e/N) = \mu p_b(2\gamma) \quad (10.16a)$$

The fraction of adaptive substitutions is the rate of adaptive substitutions divided by the total rate of substitutions (adaptive plus neutral),

$$\alpha = \frac{\lambda}{\lambda + \mu p_0} \quad (10.16b)$$

Substituting Equation 10.16a yields

$$\alpha = \frac{2\gamma\mu p_b}{2\gamma\mu p_b + \mu p_0} = \frac{2\gamma}{2\gamma + (p_0/p_b)} \quad (10.16c)$$

Equation 10.16c relates the selection estimates p_b and γ from a PRF model with the selection estimate α from an MK approach. Inspection shows that small p_b (or more precisely a small value of p_b/p_0) does not mean that α is small, as $\alpha > 0.5$ when $2\gamma > p_0/p_b$. One final result emerges from Equation 10.16a. Because μp_b is the rate of beneficial mutation, which (in keeping with our notation from Chapter 8) we denote by μ_b , Equation 10.16a becomes

$$\lambda = 2\gamma\mu_b \quad (10.16d)$$

which immediately suggests the **Bachtrog estimator** (2008),

$$\mu_b = \frac{\lambda}{2\gamma} \quad (10.16e)$$

Example 10.13. What is the estimate of α for the subset of human genes considered by Nielsen et al. (2005a) that was previously discussed (immediately preceding Equation 10.16a)? Here $p_b = 0.08$, $p_0 = 0.172$, and $\gamma_b = 267.11$. While only 8% of all new replacement mutations were deemed to be advantageous, α is considerably larger than 0.08, as Equation 10.16c yields

$$\alpha = \frac{2 \cdot 267.11 \cdot 0.08}{(2 \cdot 267.11 \cdot 0.08) + 0.172} = 0.996$$

The reason for this high value is that the estimated advantageous mutation rate (0.08μ) is just slightly below half of the estimated neutral rate (0.172μ), while the fixation probabilities for advantageous mutations are over 500 times greater. If we lumped the neutral and deleterious mutations rates together and assumed these were all effectively neutral (i.e., replacing 0.172 by $1 - p_b = 0.920$), our estimate of α would still be very high (0.980). It is also important to recall that Nielsen et al. focused on a highly biased set of genes, which were chosen to be enriched for positive selection. It is thus likely that the p_b , γ , and α estimates based on this set of loci are larger than those for typical human genes.

Now consider the Schneider et al. (2011) values for *Drosophila melanogaster* ($p_b \sim 0.015$, $\gamma_b \sim 10$). If we assume that all of the remaining mutations are neutral ($p_0 = 1 - p_b = 0.985$), Equation 10.16c yields

$$\alpha = \frac{2\gamma}{2\gamma + (p_0/p_b)} = \frac{20}{20 + 0.985/0.015} = 0.23$$

If we assume that 50% of all new mutation are deleterious ($p_0 = 1 - p_b - 0.5 = 0.485$), then $\alpha = 0.38$. A key point of this example is that α can be quite substantial even when p_b is very small.

The robustness of PRF estimates to violations of model assumptions has been examined by several authors. While the model assumes additive selection, estimates of γ are relatively insensitive to dominance (Williamson et al. 2004). Wakeley (2003) examined the effects of population structure (assuming an island model; Chapter 2). While estimates of the divergence time, τ , are significantly affected, estimates of γ are only weakly affected and tend to be conservative (closer to neutrality). Desai and Plotkin (2008) noted that the infinite-sites assumption (that mutations never reoccur at the same site) breaks down under high scaled mutation rates ($\theta > 0.05$). In such cases, recurring mutations at the same site can result in genes under weak negative selection giving a signal of strong positive selection. This may be especially problematic for viral populations with high mutation rates and large population sizes.

One critical difference between PRF and MK analyses is the contribution of information from silent sites (e.g., P_s, D_s), a point stressed by Li et al. (2008). Estimates of selection under an MK analysis are in the form of estimates of α , which are critically dependent upon P_s and D_s (e.g., Equations 10.8a and 10.9a), in addition to D_a and P_a . Conversely, under the PRF model, positive selection is estimated only through γ . An examination of Equations 10.12c and 10.12d shows that estimates of γ depend *only* on D_a and P_a , and that information from silent sites (P_s and D_s) does not enter into them. As a consequence, the control for demographic effects on P_a provided by P_s does not enter, and over- or under-inflated estimates of P_a from population structure can significantly bias estimates of γ . Further, Equation 10.14a (from which the PRF equations follow) is an *equilibrium* model, which assumes that the population size has been stable for sufficient time to reach the mutation-selection-drift equilibrium. Chapter 9 was littered with the bodies of tests that critically depend on this same assumption.

In contrast, because MK estimates involve the ratio of P_a/P_s , recent demographic effects influencing polymorphism levels are accounted for, and there is no assumption about the population being at an equilibrium value for the current amount of genetic variation (see the discussion following Equation 10.5d). Thus, while both MK and PRF approaches face bias from differences in population size between the divergence and polymorphism phases, PRF approaches have additional bias introduced by any nonequilibrium patterns in the polymorphism data. As noted by Li et al. (2008), tests of selection using PRF theory (i.e., γ significantly greater than zero) are closer to an HKA than an MK test, as the former compares the P/D ratio over different genes and lacks the internal control of comparing polymorphism levels from two different classes *within* the same gene.

Finally, while we have framed the PRF approach in terms of simple DPRS count data, it can be modified to directly estimate γ using the site-frequency spectrum from a single

population (Hartl et al. 1994; Bustamante et al. 2001; Williamson et al. 2004; Huerta-Sánchez et al. 2008). DPRS data are very granular, collapsing all of the polymorphism and divergence information into just four data points. In contrast, the site-frequency spectrum is a very rich source of additional information on the structure of the polymorphism data (Chapters 2 and 9). Using the PRF model to estimate γ directly from the frequency spectrum is done in a fashion analogous to estimating sweep parameters using the frequency spectrum discussed in Chapter 9. In particular, Equation 10.14a is substituted into Equation 9.16a to form the (composite) likelihood, from which an MLE for γ can be obtained by standard approaches (LW Appendix 4). While elegant, this approach is not generally recommended due to the very delicate dependence of the frequency spectrum on demographic structure, which is not accounted for by the current models. Likewise, Equation 10.14a assumes additive fitnesses, whereas even small amounts of dominance can alter the site-frequency spectrum (Williamson et al. 2004).

Bayesian Extensions

More fine-grained variation in the fitness of replacement mutations was allowed by Bustamante et al. (2002) and Sawyer et al. (2003) in the form of Bayesian models (an approach discussed more fully in Chapter 19 and in great detail in Appendices 2 and 3). Instead of returning a point estimate, $\hat{\theta}$, for an unknown parameter, θ (or vector of parameters, Θ), a Bayesian analysis returns the full distribution (the **posterior**), $\varphi(\theta | \mathbf{x})$, for that parameter, given any previous information (the **prior** for Θ) and the likelihood given the data, \mathbf{x} .

Bayesian analysis of PRF data typically uses a **hierarchical model**, the motivation for which comes from random-effects models (Chapter 19). Suppose we have p parameters of interest. Treating the parameters as fixed effects requires p degrees of freedom, but often there are more parameters than observations ($p \gg n$). In some settings, we can treat these p quantities as random effects: draws from some unknown distribution, such as a normal, with unknown mean and variance. Because all draws (realizations) are assumed to come from this common distribution, we can borrow information across observations to estimate the distribution parameters, using (for the case of a normal) only two degrees of freedom (estimation of the unknown mean and variance).

Bayesian hierarchical models take this idea a step further. Consider data structured into a number of categories (say, genes), with multiple observations (draws) from each category (say, new mutations in a particular gene). Assuming that the draws from a given category are all from the same distribution (say, a normal with a category-specific mean and variance), then when the number of categories is large, so too is the parameter set (all of the category-specific means and variances). A hierarchical model reduces the number of parameters to estimate by assuming that the mean (and/or variance) for each category-specific distribution is *itself* a draw from a second distribution. Once each draw is made, these parameter values are fixed for that category. This reduces the estimation problem to one of simply estimating the parameters in the second distribution.

An example of this approach was presented by Bustamante et al. (2002), who assumed that all new replacement mutations at gene i have the same selection value, γ_i , but allowed these gene-specific values to vary among loci. This was done by assuming each γ_i to be a random variable drawn from a normal distribution with a mean of μ_γ and a variance of σ_γ^2 , both estimated from the data. In other words, this model allows selection to vary over loci (but not between replacement mutations in the same gene) as a function of just two parameters ($\mu_\gamma, \sigma_\gamma^2$). Formally, the selection coefficient associated with the j th new replacement mutation at locus i is

$$\gamma_{i,j} = \gamma_i, \quad \text{where } \gamma_i \text{ is a single draw from a } N(\mu_\gamma, \sigma_\gamma^2) \quad (10.17a)$$

Because the divergence time, τ , is a common factor over all genes, this allows information to be borrowed across loci (i.e., all loci contribute to the estimation of τ), improving power, while only loci with sufficient polymorphism and divergence information (a rough rule of thumb is $P_a + D_a \geq 4$) are likely to be informative about γ . Figure 10.3 shows an example of

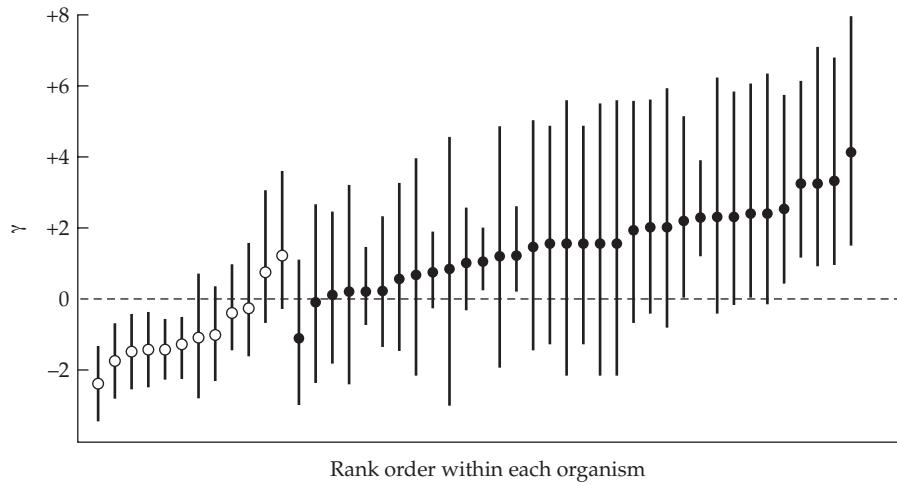

Figure 10.3 Bustamante et al. (2002) examined 12 genes from *Arabidopsis thaliana* (using a single allele from *A. lyrata* to compute divergence) and 34 genes from *D. melanogaster* (with a single allele for *D. simulans*). This figure plots the resulting posterior distribution for γ for each gene (i.e., the locus-specific value, γ_i from Equation 10.17a). The circle represents the mean, and the vertical lines denote the 95% credible intervals (the shortest span of the posterior distribution containing 95% of the probability; Appendix 2). These are plotted by rank order within the two species, with *Arabidopsis* plotted first (open circles) and *D. melanogaster* second (filled circles). If the vertical line is entirely below zero, selection on mutations at this locus is significantly negative (i.e., purifying selection). For lines entirely above zero, selection on new variants is significantly positive. Half (6 of 12) of the *Arabidopsis* genes are significantly negative, while none are significantly positive. Conversely, no *Drosophila* genes are significantly negative, while 9/34 are significantly positive.

the output from such an analysis. The analysis uses estimates of the distribution parameters (μ_γ and σ_γ^2 ; obtained from using all of the loci) to return estimates (formally, these are random-model predictors) of the selective value, γ_i , associated with each gene, as plotted in the figure.

Sawyer et al. (2003) extended the Bustamante et al. (2002) approach by allowing each new mutation (j) at locus i to potentially have a different fitness value, $\gamma_{i,j}$, with $\gamma_{i,j} \sim N(\mu_{\gamma,i}, \sigma_w^2)$. Hence, each new mutation has a fitness value drawn from a distribution with a locus-specific mean, $\mu_{\gamma,i}$, and a variance, σ_w^2 , that is common over all loci (allowing us to share information over genes). This is a two-stage hierarchical model, where (as in Equation 10.17a) the mean fitness effect, $\mu_{\gamma,i}$, for locus i is drawn from a normal distribution with a mean of μ_γ and a variance of σ_γ^2 . Once the locus-specific mean fitness effects are assigned, the fitness of a new replacement mutation at gene i is drawn from a *second* normal, with this locus-specific mean, $\mu_{\gamma,i}$, and a variance, σ_w^2 , assumed to be common over all loci (again allowing us to share information over genes). This model can be more compactly written as

$$\gamma_{i,j} \sim N(\mu_{\gamma,i}, \sigma_w^2), \quad \text{where } \mu_{\gamma,i} \sim N(\mu_\gamma, \sigma_\gamma^2) \quad (10.17b)$$

which has three distribution parameters to estimate: μ_γ , σ_γ^2 , and σ_w^2 . Comparison with Equation 10.17a shows that *each* replacement mutation at a given locus is now a random draw (as opposed to all having the same value), and that (as before) the locus-specific mean also varies. This increased flexibility comes at the cost of only a single additional parameter, σ_w^2 , the variance in gene-specific γ values about their mean (under the assumption of homoscedasticity).

Example 10.14. Sawyer et al. (2007) applied their 2003 model (Equation 10.17b) to a sample of 91 genes from an African population of *D. melanogaster*, using a *D. simulans* sequence to assess divergence. After ignoring very strong deleterious mutations that are unlikely to contribute to polymorphisms, they found that approximately 95% of all new replacement mutations are deleterious (estimates of $\gamma_{i,j} < 0$), with an estimated 70% of all replacement polymorphisms observed in the sample being deleterious. Conversely, they estimated that over 95% of the fixed differences at replacement sites are due to positive selection ($\gamma_{i,j} > 0$), albeit it was fairly weak. Within this class of replacement substitutions with estimated positive values, 46% were estimated to have $\gamma_{i,j} < 4$, 85% have $\gamma_{i,j} < 8$, and 99% have $\gamma_{i,j} < 14$.

While Bayesian models allowing fitness to vary over new mutations are powerful and potentially offer a solution to the vexing problem of segregating deleterious mutations that plagued MK tests and estimates of α , their robustness remains unclear. Current versions (as applied to PRF data) all assume normal distributions of fitness effects, but this is clearly not a realistic model (Eyre-Walker et al. 2006; Eyre-Walker and Keightley 2007; Boyko et al. 2008; Welch et al. 2008). The normal distribution has symmetry about the mean, while asymmetric (e.g., the gamma) and/or more heavy-tailed (e.g., *t*) distributions appear to be a better reflection of biology based on these references.

A second concern is somewhat technical. In a Bayesian analysis, one has to specify a prior (some statement about our uncertainty as to the true parameter values), and a key measure of this uncertainty is the prior's variance (Appendix 2). For example, our initial uncertainty in σ_γ^2 would be set by the variance chosen in the prior for this parameter. As developed in Appendix 2, the usual prior for an unknown variance in a normal distribution is a scaled inverse chi-square distribution (Equations A2.30a and A2.32a), which is a function of two parameters (the prior **hyperparameters**). Ideally, we would like the choice of these hyperparameters to have little impact on the posterior, with the signal from the data overwhelming any impact of the prior. Instead, however, Li et al. (2008) found that the prior can have a very strong effect in PRF models. Specifically, the number of genes with γ values declared to be significantly different from zero increased with the assumed uncertainty in the variance of σ_γ^2 (i.e., the variance hyperparameter in the scaled-inverse chi-square prior). This makes sense, in that restricting σ_γ^2 to be small constrains most realized values of γ to be close to the mean value, while increasing it allows estimates to deviate substantially from the mean (and hence have their credible intervals avoid overlapping zero). Strong dependency of the posterior on the prior is always problematic in a Bayesian analysis, and it is good practice to run the model over several, rather different, sets of prior hyperparameters (such as using a range for the variance of the prior) to assess the stability of the posterior under different priors. Li et al. (2008) noted that a plot of a number of positively selected sites (genes with γ values whose credible intervals are all greater than zero) increases with the assumed variance in γ , but appeared to show signs of approaching an asymptote in humans and *Drosophila simulans* over the values for σ_γ^2 used in the analysis. However, the same curve for yeast (*Saccharomyces cerevisiae*) showed no signs of approaching an asymptote over this range.

INSIGHT Analysis of Human Transcription Factors

As mentioned above, the use of conserved noncoding sequences as a proxy for all regulatory sequences likely represents a rather biased set, and global inferences on regulatory selection from this collection may be distorted. A different (albeit also potentially biased) group of noncoding DNAs are transcription factor binding sites. Through the use of **ChIP-seq** (**c**hromatin **i**mmonoprecipitation **a**nd **s**equencing) technology, nucleotide-level resolution can be achieved in delimiting binding sites, which while short, are abundant throughout the genome. Hence, issues of alignment are somewhat avoided by having a direct functional

assay.

To analyze such data, Gronau et al. (2013; Arbiza et al. 2013) proposed a method that falls between the MK and PRF approaches, in that it contrasts polymorphism and divergence data between a target and control sequence, but also uses (in a coarse granular fashion) information on allele frequencies. Their approach (**INSIGHT: Inference of Natural Selection from Interspersed Genomically coHerent elemenTs**) is essentially a likelihood model, where the target sites are the very short sequences used by transcription factors, which were contrasted over humans and chimp. As a control sequence, they examined a 20K flanking block around each target sequence, which was then trimmed to consider only sites regarded as neutral. This left a contrast of around 10 bases for a typical binding site and around 7000 bases for the neutral control region for each comparison. The logic of *INSIGHT* was that only three types of events are presented in the divergence and polymorphism data. Strongly deleterious mutations never appear as either polymorphisms or as substitutions. Neutral mutations can contribute to both polymorphisms and divergence, while strongly selected mutations only contribute as substitutions (of derived alleles). Finally, weakly deleterious mutations appear as polymorphisms with low-frequency derived alleles, but such derived alleles are never fixed. Sites were binned as substitutions or either low or high-frequency derived-allele polymorphisms. A probability model was then fit using maximum likelihood to estimate the fraction α of adaptive substitutions (among other parameters).

Using this approach, Arbiza et al. (2013) estimated a value of $\alpha = 0.05$ for transcription-factor binding sites. As an internal control, they also ran the same analysis on second-base positions in codons, which returned an α value of essentially zero. When applied to a filtered set of roughly 15,000 proteins, their method estimated $\alpha \approx 0.2$ over all coding-region substitutions. Given that their analysis examined roughly 5% of all transcription factors, Arbiza et al. extrapolated that adaptive substitutions were equally likely to occur in binding sites as in protein-coding genes. When coupled with the fact that binding sites represent a fraction of all regulatory DNA (assuming that most conserved sequences are regulatory in some sense), this suggests that adaptive substitutions are far more likely to arise in regulatory, as opposed to structural, sites. Obviously, these are only preliminary analyses, but they make an intriguing case for the importance of regulatory substitutions.

PHYLOGENY-BASED DIVERGENCE TESTS

Finally, we briefly consider divergence tests that examine the pattern of substitutions over a known phylogeny. These tests are designed to detect a rather different pattern of selection than was assumed in Chapter 9 (single events) or earlier in this chapter (multiple substitutions over an *entire gene* between two populations or species). While multiple substitutions are also required for a signal in phylogeny-based divergence tests, these must be at the same *site* (typically a codon) within a gene. Single substitutions over a number of different codons across a gene may leave very little signal for these tests (unless very few silent substitutions have occurred). As such, phylogenetic tests are biased toward detecting sites that undergo repeated evolution, and are likely to miss many, indeed perhaps *most*, adaptive substitutions (Hughes 2007). Given this restriction, these methods may work well in so-called “**arms race**” scenarios, in which trait values between two interacting species escalate to increasingly extreme values (Bergelson et al. 2001), such as the interactions between hosts and parasites.

The required input for phylogeny-based tests is a set of aligned DNA sequences and a predetermined phylogenetic tree for the sampled species. The assumption is that all sequence differences are the result of fixation events. Thus, if a site is segregating in one (or more) of the taxa from which a single sequence is drawn, one may incorrectly infer that it is a substitution event. The taxa must also have the correct amount of divergence, as either too little or too much, will result in very low power. With too little divergence, there are not enough substitutions, and hence there is little power to detect small percentage differences in silent versus replacement changes at particular sites. Further, if little true divergence has

occurred, even a few segregating sites incorrectly called as substitutions can significantly inflate the divergence. Conversely, with too much divergence, multiple substitutions at single sites may occur between lineages, and adjustments for such multiple hits can introduce substantial bias if an incorrect statistical model is used to account for these.

A few comments are in order on the phylogeny for the sampled taxa, as this determines the covariance structure of the data. For proper analysis, we require, not only the topology (the pattern of common ancestry), but also the *branch lengths*, or the distances (divergence times) between taxa. Errors in either type of information obviously compromise these tests. For example, one expected pattern of repeated selection is independent mutations of the same key amino acid at a particular critical site (e.g., Example 10.15). The topology of a phylogeny can inform us as to whether a cluster of taxa sharing this key amino acid are all descendants from a single fixation event or comprise a collection of independent events. An erroneous topology for the species tree can thus introduce serious errors. Likewise, errors in some of the branch lengths relative to the rest of the phylogeny can bias rate estimates, which in turn can generate false positives.

There is a very rich literature on molecular evolution, and our purpose here is only to provide a brief overview of divergence-based tests at the phylogenetic level. As such, our treatment of phylogeny-based methods is more superficial than the more detailed treatment of tests for recent or ongoing selection (Chapter 9) and polymorphism-based tests (covered above). Readers seeking a fuller treatment of many of the important side issues (such as tree construction) not addressed here should consult any number of excellent texts on the subject (Kimura 1983; Page and Holmes 1998; Hughes 1999; Graur and Li 2000; Nei and Kumar 2000; Felsenstein 2004; Yang 2006, 2014; Li 2006).

The K_a to K_s ratio, ω

The basis for divergence-based tests is $\omega = K_a/K_s$, the (per-site) ratio of replacement (nonsynonymous) to silent (synonymous) substitution rates, which Miyata and Yasunaga (1980) referred to as the **acceptance rate** and which also appears in the literature as the **width of the selective sieve**. For sites under the standard neutral model (deleterious mutations can arise, but are quickly removed), the expected value of ω at a site (or gene) is $\omega = \mu f / \mu = f \leq 1$, where f is the ratio of the effectively neutral mutation rates. Thus, in the absence of positive selection, we expect $\omega < 1$. Moreover, if adaptive mutations are absent (or very rare), then $1 - \omega$ is a direct measure of the amount of constraint ($1 - f$) on a site. Conversely, $\omega > 1$ is usually taken as an unmistakable signature of selection (Kimura 1983). Even if a demographic change results in a lowering of the effective population size (increasing the effectively neutral mutation rate at replacement sites), such a change (in the absence of positive selection) only brings K_a/K_s closer to, but still likely leaves it smaller than, 1.0.

There are cases where $\omega > 1$ is *not* a signal for positive selection. Ratnakumar et al. (2010) noted that a resolution of heteroduplex DNA during gene-conversion events often results in a bias toward G and C bases (also see Galtier et al. 2001; Webster and Smith 2004; Lassalle et al. 2015). Given that replacement-codon positions often have lower GC content than synonymous sites, there can be more opportunities for A/T at these sites to be changed to G/C, resulting in replacement substitutions and potentially inflating the K_a/K_s ratio (Berglund et al. 2009; Galtier et al. 2009). Ratnakumar et al. analyzed a dataset of roughly 18,000 human genes compared against their orthologs in at least two other mammalian genomes. They found that genes giving divergence-based signals of selection had a significant tendency to also display genomic signals of GC conversion bias. They estimated that >20% of elevated ω values in this dataset could be the result of biased gene conversion. A second factor is mutational bias. McVean and Charlesworth (1998) and Lawrie et al. (2011) found the counterintuitive result that weak selective constraints that oppose a mutational bias can actually *accelerate* the rate of evolution over that of a neutral site. In the words of Lawrie et al., this occurs because

Common mutations drive substitutions away from the fitter states despite purifying selection, whereas selection favors fixation of uncommon mutations resulting in faster back substitutions

to the fitter states. This allows for greater overall flux between states and thus a higher rate of substitution at the constrained sites compared with the neutrally evolving sites.

A final factor that can upwardly bias estimates of ω is the presence of strong selective constraints on *silent* sites, was found in *Drosophila* by Lawrie et al. (2013). Chamary et al. (2006) reviewed some of the evidence that silent sites may still be subjected to constraints (beyond any weak ones from codon usage bias; Chapter 8) because they affect mRNA stability, splicing, or microRNA binding. A cautionary tale is offered by the work of Hurst and Pál (2001), who examined constraints on the breast cancer *BRCA1* gene. A sliding window of roughly 300 nucleotides, allowing for average regional estimates of K_a and K_s , was used to scan across this gene in two pairs of comparisons, human-dog and mouse-rat. The window around position 200–300 showed a relatively normal level of K_a (relative to the rest of the gene), while K_s plummeted dramatically, especially in the human-dog comparison. The result was an ω value significantly greater than one, not due to an elevation in the replacement-substitution rate, but rather to a decrease in the silent-substitution rate. Wolf et al. (2009) found that an upward bias in ω from reduced K_s values can be especially problematic when using closely related taxa, as a small value of D_s causes excessive stochastic variation in the denominator of a K_a/K_s ratio. Pond and Muse (2005) noted that if variation in K_s occurs over the gene, failure to include this heterogeneity in the model can easily result in false positives (estimated $\omega > 1$ for particular codons). Thus, while $\omega > 1$ is usually taken as a gold standard for positive selection, a little more humility in its use may be in order.

While conceptually straightforward, the operational problem in using ω is that while one or a few sites may be under *repeatedly* strong directional selection ($\omega > 1$ at these residues), most sites in a protein are expected to be under some selective constraints ($\omega < 1$), so that the average over all sites yields $\omega < 1$. Indeed, a meta-analysis by Endo et al. (1996) found that only 17 out of 3595 proteins (from a wide range of species comparisons) showed $\omega > 1$. There were, however, a few early success stories. Example 10.2 discussed the work of Hughes and Nei (1988), who used the three-dimensional (3-D) protein structure of the major histocompatibility complex to suggest potential sites to examine (those amino acids on the surface in critical positions). Within this set of residues, $\omega > 1$, while $\omega < 1$ when averaged over the entire gene. Unfortunately, most proteins lack this amount of detailed biological knowledge for an investigator to draw upon. Because amino acid residues in close proximity on the 3-D structure of a protein can be scattered all over the primary (i.e., linear) sequence, grouping sites for analysis by their position in the primary sequence can be very ineffective, and even misleading. The key is to base tests of ω values on a *codon-by-codon* basis, so that codons, rather than genes, become the unit of analysis. The limitation for this approach is the need for sequences from a sufficiently dense and well-supported phylogeny.

Two general approaches have been suggested to estimate ω . Both require a phylogeny, and issues such as the correct multiple-sequence alignment as well as errors in the assumed tree potentially loom in the background. **Parsimony-based** approaches reconstruct the ancestral sequence at each node in the tree, and then use these to count up the number of silent and replacement substitutions for each codon. **Likelihood approaches** (LW Appendix 4) are on a much firmer statistical footing, but they are computationally intense and can be rather model-specific. Both approaches allow for tests of whether a protein is under positive selection and, more specifically, tests of positive selection at specific *sites* in that protein. As with extensions to PRF models, more recent tests are being built around **Bayesian approaches** that extend the ML models (Appendix 2), which allow for the management of uncertainty in very complex statistical models.

Parsimony-based Ancestral Reconstruction Tests

Fitch et al. (1997) and Suzuki and Gojobori (1999) proposed similar parsimony-based approaches for detecting selection at single sites. Both start with a phylogeny and then use **parsimony** (i.e., choosing the solution requiring the fewest number of changes) to recon-

struct the ancestral sequences at all of the nodes in the tree. With these estimated sequences in hand, one can then simply count the number of silent and replacement substitutions on the tree. The method of Fitch et al. computes an average, ω , rate for the entire gene and then looks for excessive variation at particular codons, while the method of Suzuki and Gojobori performs the analysis by considering each codon separately. The false-positive rate of both methods is generally small (Suzuki and Gojobori 1999; Suzuki and Nei 2002), but they suffer from low power (Wong et al. 2004). Further, both are subject to several rather delicate issues of sequence evolution that, if not correctly accounted for, can introduce rather significant artifacts.

First, it is well known that **transitions** ($A \leftrightarrow G, C \leftrightarrow T$) can occur at different rates than **transversions** (e.g., $A \leftrightarrow T$, etc.), and (at third-base positions) transitions are more likely to give synonymous changes. Failure to incorporate these rate differences can result in an overestimation of the number of replacement substitutions (Yang and Nielsen 2002). Second, any codon usage bias (Chapter 8) must be accommodated. Third, when divergence times are modest to large, to avoid undercounting the number of the actual substitution events one must correct for the possibility of multiple substitutions between lineages at a site. All of these issues can have a highly significant effect on estimates of ω (Yang and Bielawski 2000). Finally, given that the ancestral states are likely estimated with error, parsimony analysis has no formal procedure to take this uncertainty into account. Bayesian posterior distributions can account for these errors, but this requires moving from a parsimony to a likelihood framework. For these reasons, most analyses use likelihood-based approaches (and their Bayesian extensions), wherein one explicitly allows the model to account for transitions vs. transversions, codon usage bias, and multiple substitutions.

Maximum-likelihood-based Codon Tests

Maximum-likelihood (ML) methods following the evolution of a codon over a phylogenetic tree were introduced by Goldman and Yang (1994) and Muse and Gaut (1994). While conceptually straightforward, they involve a fair bit of bookkeeping. They assume that each site is evolving independently, which can be compromised by two rather different factors. First, a substitution at one site can change the nature of selection at other sites (epistasis). Second, high levels of recombination can lead to false signals of selection, as recombination results different parts of the gene having different coalescent structures (Anisimova et al. 2003). While generally not an issue, this can be problematic with viral populations that have high sequence diversity and frequent recombination.

ML methods require a specific probability model for the movement among the 64 different codons. They start with a vector representing the 61 different nonstop codon states (stop codons are assumed lethal). At any point in time, a codon can mutate to one of nine other codons following a single base change (Figure 10.4). The model given by Goldman and Yang (1994) defines the following relative rates for movement between codons i and j ,

$$Q_{ij} = \begin{cases} 0 & \text{if } i \text{ and } j \text{ differ at more than one position} \\ \pi_j & \text{for a silent transversion} \\ \kappa\pi_j & \text{for a silent transition} \\ \omega\pi_j & \text{for a replacement transversion} \\ \omega\kappa\pi_j & \text{for a replacement transition} \end{cases} \quad \text{for } 1 \leq i, j \leq 61 \quad (10.18)$$

The 61×61 Q matrix is specified by Equation 10.18. The π_j are the equilibrium frequencies of codon j (often calculated from the nucleotide frequencies at the three codon positions), while κ and ω are estimated parameters intended to account for biases in codon changes. Potential differences in transition versus transversion rates are accounted for by κ . One takes the currently observed codons over the phylogeny, and then runs the model backward in time by considering all possible ancestral codons at each of the internal nodes (ancestors) in the tree. The model thus corrects for multiple hits. The key parameter of interest is ω , the strength of selection on replacement substitutions. In the early models using

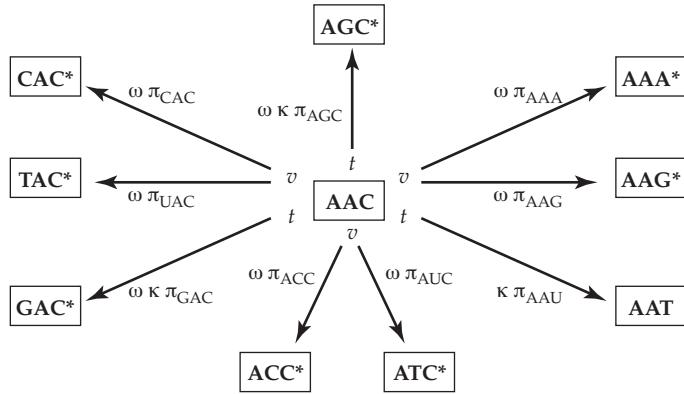

Figure 10.4 The various possible state changes and their rates under the codon evolution model (Equation 10.18) for the nine new codons that are within a single nucleotide change from the target codon (here AAC). Asterisks denote a replacement change, where the rate is a function of selection, and hence ω . Because transitions (denoted in the figure by t) and transversions (v) may occur at different rates, setting the transversion rate as the baseline, κ denotes any transition rate correction (with $\kappa = 1$ if the two rates are equal). All changes are a function of π_j , the equilibrium frequency of the mutant codon, j . Performing these same calculations over all 60 other nonstop codons generates the full transition matrix, \mathbf{Q} .

this approach, ω was a fixed constant over all genes, but later models allowed ω to vary over sites (nicely paralleling the development of extensions of the Poisson random field model to allow γ to vary over genes/alleles), a point upon which we will expand shortly. Figure 10.4 shows the basic structure of these various state changes for a particular codon. The mutational structure in Equation 10.18 (where mutation rates are functions of κ and π_j) is known in the molecular evolution literature as the **Hasegawa-Kishino-Yano, or HKY, model** (Hasegawa et al. 1985).

Tests for directional selection on a gene are accomplished by using this codon model superimposed on the phylogenetic tree to run the likelihood calculation (over all codons) to find the ML solutions for the \mathbf{Q} matrix parameters. This allows for a direct test that $\omega > 1$ using the likelihood-ratio approach (LW Appendix 4). The key to these likelihood calculations is that $\mathbf{P}(t)$, the codon state matrix at time t , is related to the instantaneous rate matrix, \mathbf{Q} , by

$$\mathbf{P}(t) = \exp(\mathbf{Qt}) \quad (10.19)$$

The corresponding elements of the 61×61 matrix \mathbf{P} are

$$P_{ij}(t) = \Pr(\text{codon } i \text{ at time } t \mid \text{codon is } j \text{ at time } t = 0) \quad (10.20)$$

The matrix exponential, $\exp(\mathbf{Qt})$, is computed by diagonalizing the \mathbf{Q} matrix by writing $\mathbf{Q} = \mathbf{U}\Lambda\mathbf{U}^T$, where Λ is a diagonal matrix, whose i th diagonal element is the eigenvalue λ_i of \mathbf{Q} (Equation A5.10a), and \mathbf{U} is a matrix of the eigenvectors of \mathbf{Q} (Equation A5.10c). With this transformation, Equation 10.19 now becomes

$$\exp(\mathbf{Qt}) = \mathbf{U} \exp(t\Lambda) \mathbf{U}^T$$

where

$$\exp(t\Lambda) = \begin{pmatrix} e^{t\lambda_1} & 0 & \cdots & 0 \\ 0 & e^{t\lambda_2} & \cdots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ 0 & \cdots & \cdots & e^{t\lambda_n} \end{pmatrix} \quad (10.21)$$

A variety of likelihood models based on Equation 10.19 are typically tested (much in the same way that one tests subsets of complex segregation analysis models; see LW Chapter

13), adding additional factors (i.e., $\kappa \neq 1$, etc.) if they improve the model fit (i.e., give a significantly better likelihood ratio). Evidence for positive selection on a gene is indicated if the likelihood-ratio test for $\omega > 1$ is significant.

The base model (Equation 10.18) assumes that all codons within a given gene have the same ω value, which is not only unreasonable but also destroys most of the power of this approach, as it returns an estimate of ω based on a gene-wide average. Given that $\omega < 1$ for most codons, the signal from the majority of codons then masks the signal from any small fraction of codons where indeed $\omega > 1$ (e.g., Example 10.2). Nielsen and Yang (1998) and Yang et al. (2000) extended the base model by assuming a mixture-model (LW Chapter 13), with the codons in a sequence being drawn from one of several selection categories, each with different ω values. For codons from selection category k , Equation 10.18 becomes

$$Q_{ij}^{(k)} = \begin{cases} 0 & \text{if } i \text{ and } j \text{ differ at more than one position} \\ \pi_j & \text{for a silent transversion} \\ \kappa\pi_j & \text{for a silent transition} \\ \omega^{(k)}\pi_j & \text{for a replacement transversion} \\ \omega^{(k)}\kappa\pi_j & \text{for a replacement transition} \end{cases} \quad (10.22a)$$

The simplest version of biological interest has three selection classes, with codons either being neutral (with probability p_0), deleterious (with probability p_d), or advantageous (with probability $p_b = 1 - p_n - p_d$). Within each class there is a fixed selective value, with

$$\omega^{(k)} = \begin{cases} 0 & \text{deleterious class} \\ 1 & \text{neutral class} \\ \omega > 1 & \text{positively selected class} \end{cases} \quad (10.22b)$$

The parameters p_0 , p_d , and ω are estimated from the data by maximum likelihood (LW Chapter 13 examines ML on mixture models). The idea is that one fits a base model (allowing only neutral and deleterious classes), and then fits the full model (Equation 10.22b or other extensions), using a likelihood-ratio test to see if the fit is significantly improved. If so, this is taken as support for a history of repeated positive selection on a subset of codons in the gene of interest.

While Equation 10.22b is clearly an improvement over models assuming a single value of ω for *all* replacement mutations, assigning all codons in the deleterious class an ω value of 0 (i.e., no substitutions) is clearly too restrictive, as is assigning all codons in the advantageous class the same ω value. Nielsen and Yang (1998) and Yang et al. (2000) further expanded Equation 10.22b by taking

$$\omega^{(k)} = \begin{cases} w^{(d)} \sim (0, 1) & \text{deleterious class} \\ 1 & \text{neutral class} \\ w^{(a)} \sim (1, \infty) & \text{positively selected class} \end{cases} \quad (10.23)$$

where now the fitness values, $\omega^{(k)}$, for any particular codon in class k are *random draws* from some specified distribution (as opposed to Equation 10.22b, which assumed they are unknown constants) whose parameters are again estimated by maximum likelihood. This is exactly the approach used previously to allow γ to vary over genes in the PRF model (e.g., Equations 10.17a and 10.17b). A number of candidate distributions for ω are possible, depending on whether we wish to restrict values to between $(0, 1)$ or to $(1, \infty)$, for codons in the deleterious and positively selected classes (respectively). For example, Nielsen and Yang (1998) and Yang et al. (2000) used either a beta or truncated gamma distribution (restricted to returning values of $0 < \omega < 1$) for the deleterious class and a truncated gamma (restricted to returning values of $\omega > 1$) for the positively selected class (Appendix 2 reviews the beta and gamma distributions). Again, a model-fitting approach is used where one first fits a

lower-order model, and then progressively adds in additional parameters to see if the fit is significantly improved.

The power of the basic ML approach was examined by Anisimova et al. (2001, 2002, 2003) and Wong et al. (2004), and is a function of two different sample sizes: the number of codons in the sequence, and the number of actual sequences (number of taxa in the phylogeny). The more codons in a gene the better, although 100 seems to give reasonable power. Power is more efficiently increased by adding more sequences (species), as opposed to looking at longer genes. For moderately long sequences (~ 100 codons) with a modest phylogeny (10–20 species), power can be quite reasonable, at least under the parameters simulated (typically 5–10% adaptive codons, each with ω around 5). They also found that the χ^2 test used to compute the significance of likelihood ratios is conservative, and hence can be safely used, albeit suffering some reduction in power.

As might be expected, this basic framework can be modified in a number of ways, for example by letting some branches of the phylogeny be under selection and others not (Yang and Nielsen 2002; Zhang et al. 2005). **Branch models** assume the same value of ω over all sites, but allow ω to vary over branches; **site models** (our main focus here) allow ω to vary over sites, but not branches; while **branch-site** models allow ω to vary over both (e.g., Kosakovsky Pond and Frost 2005; Anisimova and Yang 2007; Kosiol et al. 2008; Kosakovsky Pond et al. 2011). These ML approaches can also be used to estimate the strength of selection on particular substitutions (Halpern and Bruno 1998; Yang and Nielsen 2008; Rodrigue et al. 2010; Tamuri et al. 2011).

ML methods are not foolproof, and their robustness to the underlying distributional assumptions (for ω) remains unclear (Suzuki and Nei 2004; Nozawa et al. 2009). For example, Zhang (2004) found 20–70% false positives in a branch model by Yang and Nielsen (2002) that allowed selection to operate on some branches but not others. By simply replacing the assumption of $\omega = 0$ for the deleterious class with ω being an unknown to be estimated that lies within the interval (0,1), Zhang et al. (2005) obtained much better branch-model behavior (also see Yang and dos Reis 2011). These results point out how fragile some of these models can be, with essentially no internal controls to check for model consistency.

Finally, while our discussion of phylogeny-based divergence tests has focused exclusively on coding sequences, such a restriction is not essential. Wong and Nielsen (2004) extended the logic of codon-based models to noncoding regions. Here the test is the substitution rate in noncoding regions versus the rate at nearby silent sites. Using this approach, Wong and Nielsen found little signal of selection on noncoding regions of the sequences from 13 viral data sets, but strong signals of positive selection in protein-coding regions in five of these data sets. As noted above, the major complication with using noncoding sequences is alignment, as homologous positions need to be compared over a phylogeny. Given that insertions and deletions are common in such regions, the time window for unambiguous alignment tends to be rather short.

Bayesian Estimators of Sites Under Positive Selection

Provided that one has the correct model, likelihood methods can be used to infer which actual *sites* have likely been under repeated positive selection. This powerful idea, which due to Nielsen and Yang (1998), first tests to see if a model allowing for a subset of codons to be positively selected significantly improves the fit. If so, this provides evidence of positive selection *somewhere* in the gene of interest, but it does not specify *which* particular codons are the actual targets. To find these, Nielsen and Yang used Bayes' theorem (Equation A2.2). Equations 10.18, 10.22, and 10.23 can be used to generate the conditional probability $\Pr(D | \omega_i)$ of the observed states at a particular codon over the sampled tree (the data D), given that the codon came from fitness class i (typically there are three classes: neutral, deleterious, and advantageous; each with a different ω value). However, it is more desirable to flip this conditional and obtain $\Pr(\omega_i | \text{data})$, i.e., $\Pr(\text{in class } i | \text{data})$. Our particular interest is the posterior probability of a codon being in the advantageous class given the observed data. Bayes' theorem allows us to do this.

Suppose there are k classes, with each class having a different associated ω . The posterior probability that a specific codon is in fitness class i is

$$\Pr(\text{class } i | D) = \frac{\Pr(D | \text{class } i) \Pr(\text{class } i)}{\Pr(D)} = \frac{\Pr(D | \omega_i) \Pr(\omega_i)}{\sum_{i=1}^k \Pr(D | \omega_i) \Pr(\omega_i)} \quad (10.24a)$$

where D is the pattern of codons for that site in the tree, and the prior $\Pr(\text{class } i)$ —the values for p_0 , p_b , and p_d —is estimated by maximum likelihood. The case of interest is whether the codon belongs to the class of advantageous sites, $\Pr(\omega > 1 | D)$,

$$\Pr(\text{advantageous} | D) = \frac{\Pr(D | \omega > 1) p_b}{\Pr(D | \omega < 1) p_d + \Pr(D | \omega = 1) p_0 + \Pr(D | \omega > 1) p_b} \quad (10.24b)$$

This approach allows us to directly assign probabilities of selective classes to any particular site. Anisimova et al. (2002) found that large ω values and a modest to large number of sequences are required for this approach to have reasonable power. A number of technical issues that arise when applying Equation 10.24a were examined by Huelsenbeck and Dyer (2004), Newton et al. (2004), Scheffler and Seoighe (2005), Yang et al. (2005), Aris-Brosou (2006), Guindon et al. (2006), and Anisimova and Liberles (2007).

Example 10.15. Bishop et al. (2000) examined the class I chitinase genes from 13 species of mainly North American *Arabis* (tower mustards), crucifers closely related to *Arabidopsis*. Chitinase genes are thought to be involved in pathogen defense, as they destroy the chitin in cell walls of fungi. Many fungi have evolved resistance to certain chitinases, so these genes are excellent candidates for repeated cycles of selection (i.e., an “arms race” scenario). Codon-evolution models estimated that between 64 and 77% of replacement substitutions are deleterious, with 5–14% being advantageous (analyses using phylogenies estimated by different methods all yielded similar results). These favored sites had an estimated value of $\omega = 6.8$. Using the criterion of a posterior probability of membership in the advantageous class in excess of 0.95 (i.e., $\Pr(\text{advantageous class} | D) > 0.95$), 15 putative sites were located (using Equation 10.24b). Seven of these sites involved only one substitution type, which evolved multiple times over the phylogeny. The authors had access to the 3-D structure of chitinase, which shows a distinctive cleft thought to be the active site. Mapping putative sites of positive selection showed a significant excess of these sites clustered at the cleft.

Balancing this apparently successful application of these methods to detect selected sites is the work of Yokoyama et al. (2008). These authors examined the evolution of dim-light vision in vertebrates, which is determined by the wavelength of maximal absorption of rhodopsin. This can be directly measured in the lab, allowing the authors to experimentally determine the role of particular substitutions in dim-light adaptation using 11 engineered ancestral rhodopsin sequences. They found that most of the change in maximal absorption can be accounted for by 12 sites. In contrast, Bayesian methods predicted a total of 8 positively selected sites, none of which corresponded to sites shown by mutagenesis to have adaptive roles.

CONNECTING THE PARAMETERS OF ADAPTIVE EVOLUTION

As summarized in Table 10.2, a number of different parameters of adaptive evolution have been introduced in this chapter (as well as in Chapter 8), along with various machinery for estimating them. We have examined the connections between some of these parameters (e.g., Equations 10.16a–10.16e). However, we have yet to develop a connection between the two key parameters: the scaled strength of selection, $\gamma = 2N_e s$, at a site (Poisson random field models) and the ratio of substitution rates, $\omega = K_a/K_s$ (codon models).

We can connect these parameters as follows. Assume that silent sites are taken as the neutral benchmark, so that (as a first approximation) their per-site mutation rate, μ_s is also

Table 10.2 Summary of the key parameters of adaptive evolution and their connections. Chapter 8 first introduced several of these (α , γ , and μ_b), while ω and f were introduced in this chapter.

α	The fraction of substitutions that are adaptive
γ	The scaled strength of selection, $2N_e s$
μ	The total per-site mutation rate
μ_s	The effectively neutral per-site mutation rate at silent sites (usually assume $\mu_s \simeq \mu$)
μ_b	The adaptive (beneficial) mutation rate
p_b	The fraction of new mutations at a site that are advantageous, $\mu_b = p_b \mu$
λ	The rate of adaptive fixations, $\lambda = 2\gamma\mu_b$
$f = p_0$	The fraction of neutral mutations
$1 - f$	The amount of constraint on a site (relative to some standard, typically silent sites)
ω	The ratio of the replacement- to silent-site substitution rates

$$\omega = f + 2\gamma p_b = \frac{2\gamma p_b}{\alpha} \quad (\text{Equations 10.25a and 10.25c})$$

$$\gamma = \frac{\omega - f}{2p_b} = \frac{\omega - p_0}{2p_b} \quad (\text{Equation 10.25b})$$

$$\alpha = \frac{\lambda}{\lambda + \mu p_0} = \frac{2\gamma}{2\gamma + p_0/p_b} = \frac{2\gamma p_b}{\omega} \quad (\text{Equations 10.16b, 10.16c, and 10.25c})$$

the actual mutation rate, μ . Two types of mutations contribute to the rate of replacement substitutions: a fraction f (notationally interchangeable with p_0 , as $f = p_0$) that is effectively neutral and a much smaller (perhaps zero) fraction p_b that are favored. Effectively neutral substitutions accrue at a rate of $f\mu_s$, while (Equation 8.24a) beneficial substitutions accrue at rate $\lambda = (2N\mu_b)(2sN_e/N) = 2(2N_e s)\mu_b = 2\gamma\mu_b = 2\gamma p_b\mu_s$. Hence

$$\omega = \frac{K_a}{K_s} = \frac{f\mu_s + 2\gamma p_b\mu_s}{\mu_s} = f + 2\gamma p_b = p_0 + 2\gamma p_b \quad (10.25a)$$

so that very strong, or frequent, selection ($\gamma p_b > 1$) is required for $\omega > 1$. Similarly, we can rearrange this equation to solve for γ ,

$$\gamma = \frac{\omega - f}{2p_b} = \frac{\omega - p_0}{2p_b} \quad (10.25b)$$

If $f = 0.5$ and $p_b = 0.01$, so that half of the mutations are effectively neutral and 1% are favored, $\gamma = 25$ is required for $\omega = 1$, while $\omega = 3$ requires $\gamma = 125$. If p_b is 0.001, a value of $\gamma = 400$ only gives $\omega = 1.3$, which is a sufficiently small deviation to avoid detection in many cases. Finally, to connect α and ω , from Equations 10.16b and 10.25a, we have

$$\alpha = \frac{2\gamma p_b}{2\gamma p_b + p_0} = \frac{2\gamma p_b}{\omega} \quad (10.25c)$$

which can alternately be expressed as

$$\alpha \omega = 2\gamma p_b, \quad \text{and} \quad \omega = \frac{2\gamma p_b}{\alpha} \quad (10.25d)$$

THE SEARCH FOR SELECTION: CLOSING COMMENTS

Detecting selection using molecular data is a major growth industry and will continue to accelerate as whole-genome sequencing becomes increasingly faster and cheaper. As the

last two chapters indicate, there is an enormous amount of statistical machinery proposed to carry out this task, but every method has major limitations. As detailed in Chapters 29 and 30, ecologists and evolutionary biologists search for selection using complementary trait-based approaches, which require specifying potential traits under selection, and measuring the association between these and individual fitness. While such trait-based approaches allow us to consider particular traits of interest, molecular data have several advantages.

Two advantages are fairly obvious, in that traits need not be specified and measurement of individual fitness is not needed. The greatest advantage of the molecular approach, however, is that molecular data are a time machine. We cannot go back in the past to measure traits and fitness, but past selection *may* leave a number of different signals in the genome. Very recent events *may* leave sweep-like signatures (Chapter 8); and Chapter 9 reviews the myriad of tests for detecting these. If polygenic adaptation is the rule, major changes in trait values can occur through only cumulative changes at multiple loci, each of small effect. In this case, very little molecular signal is expected, whereas ongoing selection can be detected using trait-based methods, *provided* one knows the correct traits! Over a longer time scale, repeated selection events *may* leave molecular patterns. Population-based divergence tests (HKA, MK) can detect patterns of repeated positive selection over an entire gene during the divergence of two populations or species, while phylogeny-based divergence tests (codon models) can detect repeated positive selection at the same *codon* over a phylogeny.

Finally, there is an intermediate between this marker-based vs. trait-based dichotomy, namely **trait-augmented marker methods**, which are examined in Chapter 12. Here, one focuses on the QTL and GWAS hits associated with a particular trait and queries whether something about them is nonrandom (such as a set of correlated allele-frequency changes).

Caution is in Order When Declaring Positive Selection

Because nearly every test can give a false positive for reasons other than positive selection, any detected region should *always* be viewed as no more than a candidate to be followed up by direct work assessing any functional impact and, if so, the nature of selection. In particular, investigators should be extremely wary of “just-so” stories, wherein once a region is detected, some clever story is proposed as to the cause of selection. One must resist the notion that functional differences can automatically be equated to adaptive changes (Gould and Lewontin 1979; Storz and Wheat 2010; Barrett and Hoekstra 2011). In the words of Nielsen (2009), “evidence of selection, and knowledge of the function of a gene, does not constitute evidence for adaptation,” as the following cautionary tale illustrates.

Example 10.16. Humans show a dramatic expansion of brain size with respect to most mammals, with this increase in (relative) size usually being assumed to be correlated with increased cognitive abilities. Primary microcephaly is a pathological condition in humans resulting in small heads, but other normal features. Nonfunctional alleles at the genes *microcephalin* and *ASPM* (abnormal spindle-like microcephaly associated) both display microcephaly phenotypes, with a typical individual having a brain size of around 400 cm^3 , comparable to that in early hominids (versus the normal 1400 cm^3 in modern humans). Not surprisingly, several studies have searched for selection on these genes within the primate lineage.

Zhang (2003) inferred a K_a/K_s ratio of 1.03 for *ASPM* on the branch from the human-chimpanzee common ancestor to humans, but a ratio of 0.66 on the branch from this ancestor to chimpanzees. Values of 0.43 to 0.29 were found along other branches in mammals, suggesting positive selection along the human lineage. Evans et al. (2004a) also examined *ASPM* over a larger phylogeny ranging from New World monkeys through humans. Accelerated rates of evolution ($K_a/K_s > 1$) were seen between gibbons and the ancestor of the great apes, and a large acceleration ($K_a/K_s = 1.44$) was seen on the lineage from the human and chimpanzee ancestor to humans. Evans et al. also performed a McDonald-Kreitman test, comparing the polymorphisms within humans to the divergence between the human-chimpanzee common ancestor and finding

	Fixed	Polymorphic
Synonymous	7	10
Replacement	19	6

Fisher's exact test gives a p value of 0.01, with these data showing an excess of around 15 replacement substitutions over what is expected from the replacement-to-silent ratio seen in the polymorphism data ($\alpha = 15/19 \sim 80\%$).

Similar results were seen for *microcephalin*. Upon examining different parts of the phylogeny of this gene, Evans et al. (2004b) found $K_a/K_s = 1.05$ in the simian lineages leading to humans, and ratios of 0.4 to 0.6 along other mammalian lineages. A further breakdown showed that most of the excess in K_a/K_s occurred from prosimians to the branching of the great apes, with values < 1 within the great apes. They also found a significant McDonald-Kreitman result, with an estimated 45 adaptive replacement substitutions occurring between prosimians and humans. Thus, the data suggest that *microcephalin* is associated with expansion of brain size leading to the great apes, while *ASPM* is inferred to be further associated with the increase in brain size specifically along the lineage leading to humans.

Building on these strong observations of selection leading to the human lineage, Mekel-Bobrov et al. (2005) and Evans et al. (2005) searched for ongoing selection in these two genes, and found strong signals in each. Evans et al. (2005) found that the *microcephalin* gene had one haplotype in humans (associated with a replacement substitution) at much higher frequencies than the others, with extended linkage disequilibrium and small intra-allelic variation. Using intra-allelic variation, the age of this haplotype was estimated at 37,000 years (with a range of 14,000 to 60,000). Young alleles at high frequencies are hallmark indicators of positive selection (Chapter 9). Extensive coalescent simulations using a variety of population structures all gave high levels of significance to these results. This same pattern was seen by Mekel-Bobrov et al. (2005) with *ASPM*: a common haplotype with long LD and a very recent estimated origin (5800 years). Again, coalescent simulations of neutral drift under a variety of proposed models of human population growth and expansion showed these results to be highly significant.

Given two functional genes that both influence brain size, a presumed correlate of intelligence, coupled with a history of past and ongoing selection, these data do indeed seem to suggest a case for selection on intelligence. As such, they gathered a significant amount of attention, in part from the finding that the putative adaptive haplotypes were in higher frequencies in Europe and Asia relative to Africa.

This view, however, was quickly dispelled. Timpson et al. (2007) and Mekel-Bobrov et al. (2007) showed in large sample sizes (900 and 2400, respectively) that there was no correlation between the putative adaptive haplotypes and increased intelligence. Thus, any ongoing selection on these genes does not appear to correlate with selection for increased cognition. Currant et al. (2006) further noted that spatial models of population growth were not considered, and the above patterns for neutral mutations can passively arise along the leading edge of a recent population expansion (through allelic surfing; see Chapter 9). If not for the concern among many geneticists at drawing social implications from the initial selection findings, this saga might have become a textbook standard in the search for selection. This case provides as especially strong lesson, as in most studies, few loci with signatures of selection would have received this level of scrutiny.

Curbing Our Enthusiasm

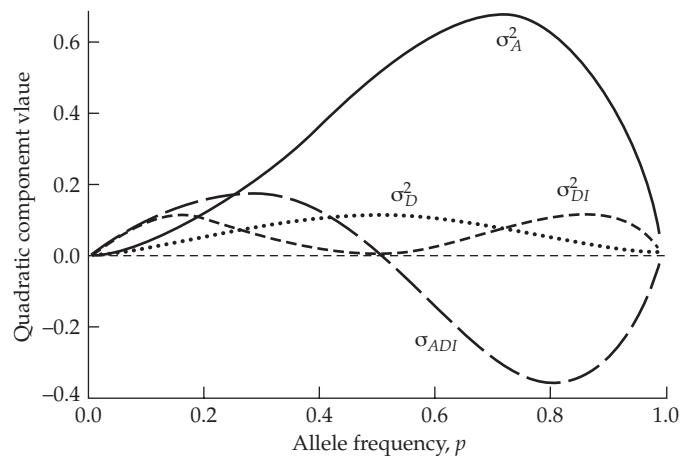

We started this set of chapters with a plea for caution and will do so again to draw our discussion to a conclusion. As in the great electrophoresis hunt in the 1970s (grinding up every species or population in sight to measure segregating protein variation) and the great QTL hunt in the 1990s (trying to find QTLs for traits in favorite organisms), we are now experiencing the great selection hunt phase of evolutionary genomics. The obvious excitement of detecting either ongoing selection or targets with a history of repeated past selection must also be tempered with caution. There are a huge variety of different tests, but no one best test even for a particular situation (much less over all settings). Simple methods may lack power, but very sophisticated, highly parametric tests may not be very robust to modeling assumptions. As mentioned on numerous occasions, complications involving

demography (changes in population size) and population structure can cripple most tests. More sophisticated methods developed to circumvent some of these issues are not yet fully vetted, and must be used with caution. Finally, there is the **Beavis effect** (LW Chapter 15), also known as the **winner's curse** (Kraft 2008), in which a parameter (such as a strength of selection) that is declared significant often has its value overestimated. This problem is especially acute when the power for detection is low, as often occurs with using more stringent individual p values to control false positives under multiple comparisons. When a selection signal is detected (likely out of a sea of candidates, with each test having moderate to low power), the actual effect is likely overestimated, and potentially by a very large amount. These comments are not meant to discourage the use of these molecular-marker methods, but rather to ensure that the enthusiasm with which they are applied is tempered by the cold reality of their limitations.

Finally, as stressed throughout the last few chapters, even when successful, these tests give us an insight into *just a tiny fraction* of all selective substitutions. How representative this subsample is of adaptive evolution in general is unclear, but it is certainly biased toward large-effect mutations. Thus, significant caution is in order in extrapolating results to general statements about adaptation. In closing, what is clear is that multiple selection events (be they recurrent sweeps or background selection) leave an impact on linked neutral sites, and most genomes show ample signals that this a very common phenomena (Chapter 8).

III

Drift and Quantitative Traits

11

Changes in Genetic Variation Induced by Drift

You want to shave with Occam's razor, not cut your throat. J. B. Walsh

We noted in Chapter 2 that, when operating as the sole evolutionary force, random genetic drift leads inevitably to the loss of alleles within populations as well as to the fixation of alternative alleles in different populations. These conclusions extend logically to quantitative characters. Following a reduction in population size, for example, we expect the genetic variance within populations to decline and the mean phenotypes of isolated populations to diverge. There are some interesting surprises, however, particularly when the mode of gene action has a nonadditive component. In this case, the genetic variance for a trait is not a simple function of the underlying heterozygosity (LW Chapter 4), so we cannot expect the temporal dynamics of the genetic variance to strictly reflect changes in heterozygosity. Indeed, as we will show, under certain conditions, the genetic variance for a quantitative trait is expected to transiently *increase* during the early phase of a population bottleneck.

The goal of the following two chapters is to develop a null (neutral) hypothesis for quantitative-trait evolution under the assumption that selection is a negligible evolutionary force. For the most part, we will continue to adhere to an ideal Wright-Fisher population structure, with random mating and discrete generations. In this vein, our conceptual approach will be to consider a series of replicate populations, all isolated at the same time from a large base population, which is generally assumed to be in Hardy-Weinberg and gametic-phase equilibrium, and all subsequently kept indefinitely at an identical population size. The current chapter focuses on the expected dynamics of the genetic variance within populations, whereas Chapter 12 focuses on interpopulation divergence.

In both chapters, we initially assume that the dynamics of evolutionary change are due entirely to genetic properties of the base population, which is essentially the case with short-term population bottlenecks. Then, the role of mutation will be taken up. In this chapter, for example, we will end by considering the levels of genetic variance expected in the absence of selection, when a stochastic equilibrium has been reached between the input of variation by mutation and the loss by genetic drift. We also consider the statistical underpinnings of the covariance between relatives in inbred populations, as this has special relevance in attempts to derive inferences about the mode of gene action from phenotypic observations.

The subject material of this chapter is rather technical in places, as it involves the expected temporal dynamics of higher-order gene-frequency moments, including, at the minimum, fourth-order moments, as well as a number of quadratic components of gene action not previously encountered with outbred populations. With quantitative traits, we must also worry about the joint distribution of allele frequencies at different loci, so issues of linkage disequilibrium come in as well. These complexities quickly get out of control in considering the sampling variances of genetic variances and covariances, and we will keep our treatment of these issues to a minimum (which is not to deny their substantial practical significance). Finally, we note that most of our coverage will be concerned with genetic *variance*, although all moments of the phenotype distribution are subject to change in the presence of drift and mutation.

RESPONSE OF WITHIN-POPULATION GENETIC VARIANCE TO DRIFT

Complete Additivity

Consider a diallelic locus (indexed by i) with a strictly additive genetic basis, such that

the three genotypic values contributing to a quantitative trait are scaled to be 0, a_i , and $2a_i$. Assuming Hardy-Weinberg equilibrium, at any particular generation, t , the total (and additive) genetic variance associated with this locus is $2a_i^2 p_i(t)[1 - p_i(t)]$, where $p_i(t)$ is the allele frequency at time t (LW Chapter 4). Assuming gametic-phase equilibrium, this expression is readily extended to a multilocus trait with a purely additive genetic basis. If we sum over all n loci contributing to the trait, the expected within-population genetic variance is

$$\sigma_A^2(t) = 2 \sum_{i=1}^n E \{ a_i^2 p_i(t)[1 - p_i(t)] \} \quad (11.1)$$

From Chapter 2, we know that the expected heterozygosity after t generations at an effective population size of N_e is simply $[1 - 1/(2N_e)]^t$ times the initial value. Moreover, under the assumption of neutrality, there should be no correlation between allele frequency and effect, so, substituting from Equation 2.5,

$$\begin{aligned} \sigma_A^2(t) &= 2 \sum_{i=1}^n a_i^2 p_i(0)[1 - p_i(0)] \left(1 - \frac{1}{2N_e}\right)^t \\ &= \sigma_A^2(0) \left(1 - \frac{1}{2N_e}\right)^t \simeq \sigma_A^2(0) \exp\left(-\frac{t}{2N_e}\right) \end{aligned} \quad (11.2)$$

as obtained by Wright (1951).

Equation 11.2 illustrates the simplest possible behavior that can be expected for the genetic variance within a finite population, starting with a baseline level of $\sigma_A^2(0)$. For a character with a purely additive genetic basis, in the absence of any significant replenishing forces for variation (mutation or migration), the additive genetic variance within populations is expected to decline exponentially at the rate of $1/(2N_e)$ per generation. When linkage disequilibrium is present, the additive *genic* (as opposed to the additive *genetic*) variance declines at this rate (Chapters 16 and 24). A key point worth stressing is that Equation 11.2 describes the *expected* behavior of the genetic variance, as averaged over a very large number of replicate populations. As discussed below, as a consequence of the stochastic sampling of gene frequencies, any single replicate population can deviate substantially from its expected trajectory.

The Effects of Dominance

Robertson (1952) extended the preceding theory to loci with dominance and obtained the surprising result that rare recessive alleles can sometimes cause an initial *increase* in both the additive and dominance components of variance in an inbreeding population. A rare neutral allele will usually be lost from a small population, in which case the variance will decline, but if the frequency of a rare recessive allele stochastically increases, the frequency of the extreme genotype will also increase. For completely recessive alleles, a temporary inflation of the expected within-population variance will occur, provided the initial frequency of the recessive genotype is less than 0.17 (Robertson 1952). Although an inflation of the expected variance can also occur with partial dominance, the critical initial frequency for the recessive allele becomes progressively smaller as additivity is approached. Regardless of the degree of dominance, however, the within-population variance eventually declines to zero as loci move toward fixation, as in the case of pure additivity.

Robertson (1952), and thereafter Willis and Orr (1993), considered only a single diallelic locus, whereas the analysis is much more complex with multiple loci or with more than two alleles per locus. Fairly general results have been obtained for the case in which all of the genetic variance can be partitioned into additive, dominance, and additive \times additive epistatic components (Cockerham 1984a, 1984b; Cockerham and Tachida 1988; Tachida and Cockerham 1989). Even for this case, however, and assuming initial conditions of Hardy-Weinberg and gametic-phase equilibrium, the temporal dynamics of genetic

Table 11.1 Factors contributing to the additive, dominance, and additive \times additive components of genetic variance in finite populations. Here n is the number of loci, n_k is the number of alleles at the k th locus, p_{ki} is the frequency of the i th allele at locus k , α_{ki} is the additive effect of the i th allele at locus k , δ_{kij} is the dominance effect at locus k associated with genotype ij , and $(\alpha\alpha)_{ki,mj}$ is the additive \times additive effect of alleles i and j from different loci (k and m) (LW Chapters 4 and 5). The inbreeding depression is defined for individual loci (ι_k for locus k) as well as for the sum over all loci (ι). The α_{ki} , δ_{kij} , and $(\alpha\alpha)_{ki,mj}$ are defined from the standpoint of a randomly mating base population (LW Chapter 4).

Additive variance	$\sigma_A^2 = 2 \sum_{k=1}^n \sum_{i=1}^{n_k} p_{ki} \alpha_{ki}^2 = 2 \sum_{k=1}^n E[\alpha_{k\cdot}^2]$
Dominance variance	$\sigma_D^2 = \sum_{k=1}^n \sum_{i=1}^{n_k} \sum_{j=1}^{n_k} p_{ki} p_{kj} \delta_{kij}^2 = \sum_{k=1}^n E[\delta_{k..}^2]$
Epistatic variance	$\sigma_{AA}^2 = 4 \sum_{k,m=1}^n \sum_{i=1}^{n_k} \sum_{j=1}^{n_m} p_{ki} p_{mj} (\alpha\alpha)_{ki,mj}^2 = 4 \sum_{k,m=1}^n E[(\alpha\alpha)_{k\cdot,m\cdot}^2]$
Inbreeding depression	$\iota_k = \sum_{i=1}^{n_k} p_{ki} \delta_{kii} = E[\delta_{kii}] \quad \iota = \sum_{k=1}^n \iota_k$
Sum of squared locus-specific inbreeding depressions	$\iota^* = \sum_{k=1}^n \iota_k^2$
Variance of dominance effects in inbred individuals	$\sigma_{DI}^2 = \sum_{k=1}^n \sum_{i=1}^{n_k} (p_{ki} \delta_{kii}^2 - \iota_k^2) = \sum_{k=1}^n (E[\delta_{kii}^2] - \iota_k^2)$
Covariance of additive and dominance effects in inbred individuals	$\sigma_{ADI} = 2 \sum_{k=1}^n \sum_{i=1}^{n_k} p_{ki} \alpha_{ki} \delta_{kii} = 2 \sum_{k=1}^n E[\alpha_{ki} \delta_{kii}]$

variance depend on seven quadratic properties of the base population (Table 11.1), as well as on several expectations for the higher-order moments of allele and gamete frequencies. We first present the general model, and then consider some illuminating results that arise under special conditions.

Quadratic Components for Inbred Populations

When dominance is present, the covariance between relatives (and hence the trait variance) under inbreeding is no longer fully described by just σ_A^2 and σ_D^2 . Rather, additional **quadratic components of covariance** are required, as outlined in Table 11.1. For the case of dominance and additive \times additive variance, these include the familiar parameters σ_A^2 , σ_D^2 , and σ_{AA}^2 (i.e., the additive, dominance, and additive \times additive components of genetic variance; LW Chapter 5); the inbreeding depression, ι , here defined to be the difference between the mean phenotypes of outbred and completely inbred individuals (by construction, $E[G] = 0$ for an outbred population, where G denotes the genotypic value, measured as a deviation from the overall mean); the sum, ι^* , of squared locus-specific inbreeding depressions; the variance of dominance effects among inbred individuals, σ_{DI}^2 ; and the covariance of additive and dominance effects in inbred individuals, σ_{ADI} . Simplification is possible under certain circumstances. Most notably, with only two alleles per locus, $\iota^* = \sigma_D^2$, and if all alleles have a frequency of 0.5, as in a cross between two pure (i.e., fully inbred) lines, then $\sigma_{DI}^2 = \sigma_{ADI} = 0$.

Table 11.2 Some of the alternative notations used for the genetic components required under inbreeding: Harris = Harris (1964); Gallais = Goldringer et al. (1996); Jacquard = Jacquard (1974); Cornelius = Cornelius (1975); Cockerham = Cockerham (1984a, 1984b); de Boer = de Boer and Hoeschele (1993); Smith = Smith and Mäiki-Tanila (1990); Abney = Abney et al. (2000).

Ours	Harris	Gallais	Jacquard	Cornelius	Cockerham	de Boer	Smith	Abney
σ_A^2	σ_{Ar}^2	σ_A^2	V_A	σ_A^2	σ_A^2	σ_{Ar}^2	σ_a^2	V_a
σ_D^2	σ_{Dr}^2	σ_D^2	V_D	σ_D^2	σ_D^2	σ_{Dr}^2	σ_d^2	V_d
ι	–	–	–	–	H	Δ_I	μ_δ	–
ι^*	D_I^2	$\sum D o^2$	D_H^2	μ_∞	H^*	Δ_I^2	–	SS_{μ_h}
σ_{DI}^2	σ_{DI}^2	σ_{Do}^2	$V_h - D_H^2$	$\sigma_\infty^2 - 2C + 2\sigma_A^2$	D_2^*	σ_{DI}^2	σ_δ^2	V_h
σ_{ADI}	σ_{ADI}	σ_{ADO}	$2\text{Cov}_H(A, D)$	$C - 2\sigma_A^2$	$2D_1$	σ_{ADI}	$\sigma_{a\delta}$	$\text{Cov}_h(a, d)$

As shown in Table 11.2, numerous alternative notations for these quadratic components appear in the literature, with almost every new paper seeming to invent its own terminology, which is often a hybrid of several previous papers. Additionally, there are also reparameterizations of these components, such as the **Q model** of Cornelius and Van Sanford (1988). As Example 11.1 shows, the dominance-related quadratic components are easily computed if one knows the genotypic frequencies in the (randomly mating) base population. Because these components depend on α and δ , which themselves depend on allele frequencies, their behavior under a change in allele frequency can be complex.

Example 11.1. Consider a population with a single locus with genotypic values of $A_1A_1 = 0$, $A_1A_2 = 1.67$, and $A_2A_2 = 2$. What are the quadratic components when $p = \text{freq}(A_1) = 0.8$? Using standard expressions (LW Chapter 4), the random-mating parameters are

$$\begin{array}{ccccccc} \alpha_1 & \alpha_2 & \delta_{11} & \delta_{12} & \delta_{22} & \sigma_A^2 & \sigma_D^2 \\ -0.2804 & 1.1216 & -0.0536 & 0.02144 & -0.8576 & 0.628993 & 0.045967 \end{array}$$

Note that the mean value of $G = 2E[\alpha] + E[\delta] = 0$ under random mating, as

$$(2\alpha_1 + \delta_{11})p^2 + (\alpha_1 + \alpha_2 + \delta_{12})2p(1-p) + (2\alpha_2 + \delta_{22})(1-p)^2 = 0$$

The mean value (ι) of G under complete inbreeding (which is the inbreeding depression change in the mean as $E[G] = 0$ under random mating), follows upon recalling that a fraction, p_1 , are A_1A_1 and a fraction, p_2 , are A_2A_2 and that $p_1\alpha_1 + p_2\alpha_2 = 0$, yielding

$$\begin{aligned} \iota &= p_1(2\alpha_1 + \delta_{11}) + p_2(2\alpha_2 + \delta_{22}) \\ &= p_1\delta_{11} + p_2\delta_{22} = 0.8 \cdot (-0.0536) + 0.2 \cdot (-0.8576) = -0.2144 \end{aligned}$$

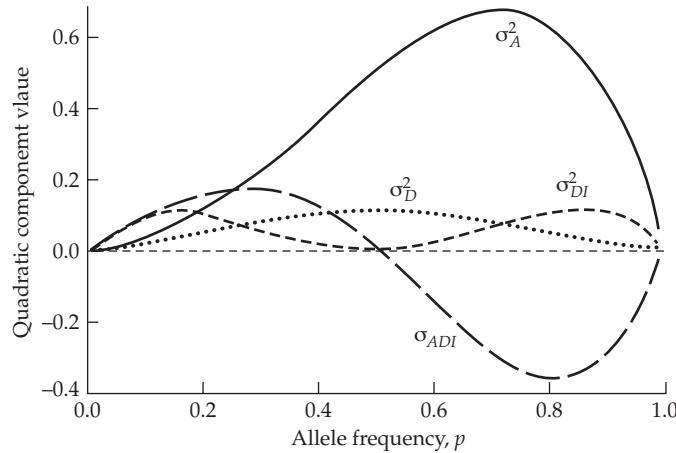

Because there are only two alleles, $\iota^* = \sigma_D^2$ (Cockerham and Matzinger 1985), and this is confirmed as

$$\iota^* = (p_1\delta_{11} + p_2\delta_{22})^2 = (-0.2144)^2 = 0.045967 = \sigma_D^2$$

As for the other two quadratic components,

$$\begin{aligned} \sigma_{DI}^2 &= p_1\delta_{11}^2 + p_2\delta_{22}^2 - \iota^* \\ &= 0.8(-0.0536)^2 + 0.2(-0.8576)^2 - 0.045967 = 0.103427 \\ \sigma_{ADI} &= 2(p_1\alpha_1\delta_{11} + p_2\alpha_2\delta_{22}) \\ &= 2[0.8(-0.2804)(-0.0536) + 0.2(1.1216)(-0.8576)] = -0.360707 \end{aligned}$$

These quadratic components for other allele frequencies are graphed below.

One- and Two-locus Identity Coefficients

The contributions of the factors in Table 11.1 to the traditional components of genetic variance (σ_A^2 , σ_D^2 , and σ_{AA}^2) in a finite population depend upon several one- and two-locus identity coefficients. As shown in Figure 11.1, these give the probabilities that randomly drawn combinations (from the population) of two, three, or four alleles at a given locus are identical by descent (both IBD and ibd are used in the literature; LW Chapter 7), with extensions to the two-locus case for randomly drawn combinations of two, three, or four two-locus gametes. Of the one-locus coefficients, f is the familiar inbreeding coefficient, i.e., the probability that two alleles are identical by descent at a particular locus (Chapter 2). The probabilities that the members of random groups of three and four alleles are all identical by descent are denoted by γ and δ (the latter is not to be confused with the dominance effects, which are subscripted in Table 11.1).

The coefficient Δ also involves four gametes (Figure 11.1), and is the probability of IBD within two pairs of gametes (including the possibility that all four genes are IBD). Under the random union of gametes, this corresponds to the probability that two (diploid) individuals have genotypes that are IBD. With a probability of δ , both individuals are inbred, and thus all four alleles are IBD, with the resulting genotypes being homozygotes. The more interesting scenario, which occurs with a probability of $\Delta - \delta$, is that where the two genotypes are IBD but the alleles within each individual are not (i.e., neither individual is inbred). Hence, the shared genotypes could be either heterozygotes or homozygotes. For example, suppose both of diploid genotypes are AA and that the maternal copy of A in both individuals is IBD, as is the paternal copy of A , but the maternal and paternal copies are not IBD. This generates two homozygotes that are not inbred (the two copies of A within each individual are not IBD), yet both genotypes are IBD to each other. Similarly, if both genotypes are Aa , neither individual is inbred, but if the A is IBD in both individuals, and so too are the a alleles, then the genotypes are IBD, but not inbred.

For randomly mating monoecious populations under the classical Wright-Fisher model, the transition equations for these coefficients are functions of N_e and t , with

$$f_t = 1 - \lambda_1^t \quad (11.3a)$$

$$\gamma_t = 1 - \frac{3\lambda_1^t}{2} + \frac{\lambda_2^t}{2} \quad (11.3b)$$

$$\Delta_t = 1 - \frac{24\lambda_1^t - 10\lambda_2^t + \lambda_3^t}{15} + \frac{\lambda_1^t - \lambda_3^t}{5(5N_e - 3)} \quad (11.3c)$$

$$\delta_t = 1 - \frac{9\lambda_1^t - 5\lambda_2^t + \lambda_3^t}{5} - \frac{3\lambda_1^t}{20(5N_e - 3)} + \frac{\lambda_2^t}{12(N_e - 1)} - \frac{(8N_e - 3)\lambda_3^t}{30(5N_e - 3)(N_e - 1)} \quad (11.3d)$$

where $\lambda_j = 1 - (j/2N_e)$ for $j = 1, 2, 3$ (Cockerham and Weir 1983).

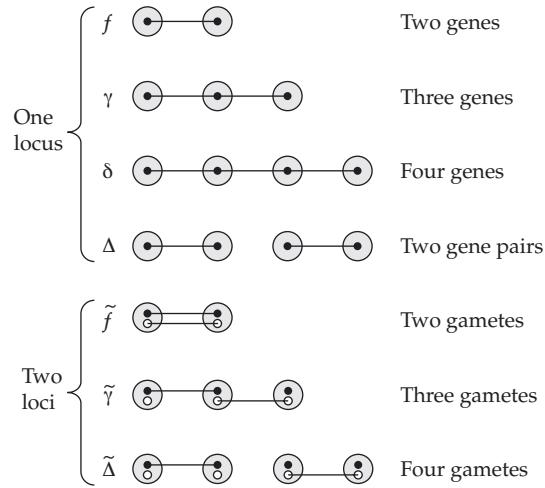

Figure 11.1 Measures of identity by descent (IBD) for single loci (f , γ , δ , Δ) and pairs of loci (\tilde{f} , $\tilde{\gamma}$, $\tilde{\Delta}$). The large circles denote gametes (alleles when restricted to a single locus), and the open and closed dots within them represent alleles from one (top four relationships) or two (bottom three) loci. Identity by descent is indicated by a horizontal line. For example, δ is the probability that four randomly chosen alleles are all IBD, while Δ is the probability that, in any two pairs of gametes, each pair has an IBD allele (i.e., two diploid genotypes are IBD). As discussed in the text, Δ includes δ as a special case.

The three two-locus coefficients (denoted by tildes in Figure 11.1) refer to joint identities by descent at two loci. First, \tilde{f} refers to pairs of alleles on two gametes and is the joint probability of IBD at locus 1 and IBD at locus 2. Under neutrality, random mating, and linkage equilibrium, \tilde{f} cannot be less than the product of the separate identity probabilities for each locus, f^2 . Second, $\tilde{\gamma}$ refers to the situation in which each member of a pair of genes in one gamete is identical by descent with a gene in a separate gamete (IBD at locus 1 for gametes one and two, IBD at locus 2 for gametes two and three). Finally, $\tilde{\Delta}$ is the joint identity by descent of genes (two at each locus) in two pairs of different gametes (IBD at locus 1 for gametes one and two, IBD at locus 2 for gametes three and four). The transition equations for these double identity-by-descent measures, which were derived by Weir and Cockerham (1969) for ideal monoecious populations, depend upon N_e , t , and the linkage parameter $\rho = 1 - 2c$ (where $c \leq 0.5$ is the recombination frequency between loci). Letting $\tilde{f}_t = \tilde{f}_t^* + 2f_t - 1$, $\tilde{\gamma}_t = \tilde{\gamma}_t^* + 2f_t - 1$, and $\tilde{\Delta}_t = \tilde{\Delta}_t^* + 2f_t - 1$, the coefficients are obtained by use of Equation 11.3a and the following matrix expression,

$$\begin{pmatrix} \tilde{f}_{t+1}^* \\ \tilde{\gamma}_{t+1}^* \\ \tilde{\Delta}_{t+1}^* \end{pmatrix} = \mathbf{M} \begin{pmatrix} \tilde{f}_t^* \\ \tilde{\gamma}_t^* \\ \tilde{\Delta}_t^* \end{pmatrix} \quad (11.4a)$$

starting with $\tilde{f}_0^* = \tilde{\gamma}_0^* = \tilde{\Delta}_0^* = 1$, where

$$\mathbf{M} = \begin{pmatrix} \frac{(1+\rho)^2}{4} - \frac{\rho}{2N_e} & \frac{(N_e-1)(1-\rho^2)}{2N_e} & \frac{(N_e-1)(1-\rho)^2}{4N_e} \\ \frac{1+\rho}{4N_e} - \frac{\rho}{4N_e^2} & \frac{(N_e-1)[N_e+1+\rho(N_e-2)]}{2N_e^2} & \frac{(N_e-1)(2N_e-3)(1-\rho)}{4N_e^2} \\ \frac{2N_e-1}{4N_e^3} & \frac{(N_e-1)(2N_e-1)}{N_e^3} & \frac{(N_e-1)(2N_e-1)(2N_e-3)}{4N_e^3} \end{pmatrix} \quad (11.4b)$$

Table 11.3 Coefficients for the quadratic properties defined in Table 11.1 (necessary for the definition of the variance components noted in the Source column) for lines derived from a base population. For example, the total within-population genetic variance (first row) is equal to the weighted sum over all the quadratic components. The among-population variance follows similarly, with the total genetic variance being the sum of the within- and among-population components. Likewise, we can decompose the within-population variance into the contributions from the additive, dominance, and additive-by-additive components under inbreeding (the sum of these equal the within-population variance). The numerical values of the coefficients must be computed with Equations 11.3 and 11.4, and in practice, the two-locus identity coefficients need to be averaged over all pairs of loci, with each two-locus estimate depending on the recombination fraction.

Impact of Drift Under Nonadditive Variance

With definitions in hand for the quadratic expressions in the base population (Table 11.1) and the temporal dynamics of the identity coefficients (Equations 11.3 and 11.4), we are now in a position to explore the impact of finite population size on the components of variance for a quantitative trait with a nonadditive genetic basis. The expected dynamics are determined by summing the products of the seven quadratic terms listed across the top of Table 11.3 with their associated tabulated identity coefficients in the table. For example, the expected within-population dominance variance is

$$[1 - 3f + 2(\Delta + \gamma - \delta)]\sigma_D^2 + (f + \delta - 2\gamma)\sigma_{DI}^2 + (f + \Delta - 2\gamma)\iota^* + (\tilde{f} - 2\tilde{\gamma} + \tilde{\Delta})(\iota^2 - \iota^*)$$

Here, σ_D^2 , σ_{DI}^2 , etc. are the base-population values of these components under random mating.

To gain a more intuitive feel for the source of the expressions in Table 11.3, we first consider the total genetic variance in a collection of lines, each inbred to level f , while ignoring epistasis until the following section. Subscripting loci with k and the two alleles at a locus as i and j , the genotypic value, G (expressed as a deviation from the mean), of an individual can be written as

$$G = \sum_{k=1}^n [(1 - \phi_{kij})(\alpha_{ki} + \alpha_{kj} + \delta_{kij}) + \phi_{kij}(2\alpha_{ki} + \delta_{kii})] \quad (11.5)$$

where ϕ_{kij} is equal to one if the two alleles at a locus are identical by descent and equal to zero otherwise.

To compute the mean genotypic value, $\mu_G = E[G]$, note that the expected value of ϕ_{kij} is f and that we can write the expected value of G as two components: if not inbred ($\phi_{kij} = 0$), then $E[\alpha_{ki} + \alpha_{kj} + \delta_{kij}] = 0$, as these are deviations from the mean, leaving

$$E[G] = E \left[\sum_{k=1}^n \phi_{kij} (2\alpha_{ki} + \delta_{kii}) \right] = f \left[\sum_{k=1}^n \sum_{i=1}^{n_k} p_{ki} (2\alpha_{ki} + \delta_{kii}) \right]$$

If inbred, the two alleles at locus k are identical, giving the frequency of genotype $A_{ki}A_{ki}$ as $f p_{k,i}$, yielding the last equality. Because $\sum_i \alpha_{ki} p_{ki} = 0$ (by construction), we are left with

$$E[G] = \mu_G = f \sum_{k=1}^n \sum_{i=1}^{n_k} \delta_{kii} p_{ki} = f \cdot \iota$$

the last step following from the definition of ι (Table 11.1). Under complete inbreeding, $\mu_G = \iota$, the change in the mean from inbreeding depression (as $\mu_G = 0$ under random mating). In addition,

$$E[G^2] = \sum_{k=1}^n \left\{ (1-f)E[(\alpha_{ki} + \alpha_{kj} + \delta_{kij})^2] + fE[(2\alpha_{ki} + \delta_{kii})^2] \right\} + \tilde{f}(\iota^2 - \iota^*) \quad (11.6a)$$

The final term in Equation 11.6a summarizes the consequences of joint inbreeding at pairs of loci, with \tilde{f} being the probability that two loci in the same individual are inbred (Figure 11.1) and $\iota^2 - \iota^* = 2 \sum_{k < m} \iota_k \iota_m$ being the sum of cross-products of the locus-specific inbreeding depressions. In obtaining Equation 11.6a, note that all other products across loci have expectations equal to zero because $E[\alpha_{ki}]$ is always equal to zero and $E[\delta_{kij}] = 0$ at non-inbred loci (LW Chapter 4).

Recalling that the genetic variance is defined to be $\sigma_G^2 = E[G^2] - \mu_G^2$, we obtain

$$\begin{aligned} \sigma_G^2 &= \sum_{k=1}^n \left\{ (1-f)(2E[\alpha_{ki}^2] + E[\delta_{kij}^2]) + f(4E[\alpha_{ki}^2] + 4E[\alpha_{ki}\delta_{kii}] + E[\delta_{kii}^2]) \right\} \\ &\quad + \tilde{f}(\iota^2 - \iota^*) - f^2 \iota^2 \end{aligned} \quad (11.6b)$$

Further simplification is achieved by adding and subtracting $f(1-f)\iota^*$ on the right side of this expression, which, after using the expressions in Table 11.1, leads to

$$\sigma_G^2 = (1+f)\sigma_A^2 + (1-f)\sigma_D^2 + 2f\sigma_{ADI} + f\sigma_{DI}^2 + f(1-f)\iota^* + (\tilde{f} - f^2)(\iota^2 - \iota^*) \quad (11.6c)$$

in agreement with the final row in Table 11.3.

Although the preceding results apply to the genetic variance summed within and among a set of hypothetical isolated subpopulations, an expression for the average within-population variance can be obtained by removing the among-population component. The simplest route to this result is to recall the general rule that the variance among groups is equivalent to the covariance between individuals within groups (e.g., LW Chapter 18). Using this principle, the contribution of each quadratic component in Table 11.1 to the among-population variance can be obtained in the following way.

First, in the context of the entire collection of populations, f is equivalent to the probability that single alleles in the same population are identical by descent (the average coefficient of coancestry), so the additive genetic covariance for members of the same population is equal to $2f\sigma_A^2$ (LW Chapter 7). Second, two individuals within a population may also share both genes at a locus, in which case they will exhibit dominance genetic covariance, the magnitude of which will depend on whether the locus is inbred or not. From Figure 11.1, we see that the probability that both individuals are inbred and share the same genotype by descent is equal to the identity measure δ , so the genetic covariance by this route is $\delta\sigma_{DI}^2$.

The probability that the two individuals are not inbred but share identical genotypes by descent is $2(\Delta - \delta)$ (the 2 accounts for paternal-paternal and maternal-maternal versus cross paternal-maternal sources of identity by descent), so the covariance by this route becomes $2(\Delta - \delta)\sigma_D^2$. Third, the probability that three alleles in two members of a population are identical by descent is equal to γ , and there are two ways in which this can arise, so the covariance between additive and dominance effects is $2\gamma\sigma_{ADI}$. Finally, the covariance resulting from shared inbreeding depression is $(\Delta - f^2)\iota^*$ because Δ is the probability that two members of the same population are jointly inbred at the same locus, while the average fraction of individuals that are inbred over all populations is f per locus, and ι^* is the sum of squared per-locus inbreeding depressions. Similarly, the covariance due to joint inbreeding depression at different loci is equal to $(\tilde{\Delta} - f^2)(\iota^2 - \iota^*)$, with the latter term being the sum of cross-products of per-locus inbreeding depressions.

Upon summing all six of these contributions, we obtain the genetic variance among populations given in the second row from the bottom of Table 11.3. The within-population genetic variance is then obtained by subtracting the among-population component from the total genetic variance. Results such as these provide a mechanistic explanation for the changes in components of genetic variance that can be induced by small population size. For example, it can be seen from the second line of Table 11.3 that inbreeding always converts some initial dominance genetic variance into additive genetic variance. This does not necessarily imply that there will be a net increase in additive genetic variance in a bottlenecked population, as the total dynamics depend critically on the relative magnitudes and temporal dynamics of all five of the quadratic components involving dominance in the base population (Figure 11.2). However, it does imply that Equation 11.2 cannot be strictly correct in the presence of dominance. While the contribution to the additive genetic variance from the base population, σ_A^2 , declines in each generation, Figure 11.2 shows that all other contributions first increase before eventually decreasing to zero. Thus, whether a population bottleneck will induce an increase in additive genetic variance depends critically on the magnitude of σ_A^2 relative to the other quadratic components in the base population.

Note that the two-locus identity coefficients (\tilde{f} , $\tilde{\gamma}$, and $\tilde{\Delta}$) appear only in association with quadratic terms involving pairs of loci, in this case ($\iota^2 - \iota^*$). Two-locus identity by descent is of relevance in finite populations because the gametic-phase disequilibrium that inevitably develops by chance causes **identity disequilibrium** between loci (Weir and Cockerham 1968)—individuals that are inbred at one locus are likely to be so at other loci, causing a transient inflation of the genetic variance through the production of extreme phenotypes.

Although it may not be immediately apparent, the coefficients in the final two (bottom) columns in Table 11.3 are equivalent to measures of identity disequilibrium (Cockerham 1984a). For example, $\tilde{f} - f^2$ is the deviation of the double identity-by-descent within gametes in the same population from that based on the assumption of independence between loci. This difference is simply the logical extension of the notion of disequilibrium, where we defined $D_{AB} = p_{AB} - p_A p_B$, with \tilde{f} being the analog of p_{AB} (the frequency of the AB gamete) and f being the analog of p_A and p_B . Although \tilde{f} depends upon the average linkage relationships between all relevant pairs of loci (Weir and Cockerham 1968, 1969), in most cases, if most pairs of loci are on different chromosomes, or if the population is randomly mated and expanded following the bottleneck, \tilde{f} will be approximately equal to f^2 . Under such conditions, $(\tilde{f} - f^2)$, as well as the other coefficients of $(\iota^2 - \iota^*)$ in Table 11.3, will be very close to zero, removing at least this one term from the variance expressions (Figure 11.2).

The Effects of Epistasis

The fundamental point in the preceding section is that because dominance is a function of a two-allele interaction, the variance in dominance effects can be altered in unexpected ways when inbreeding alters the average background on which an allele appears. This same issue applies to epistatic effects, although on a potentially larger scale because the

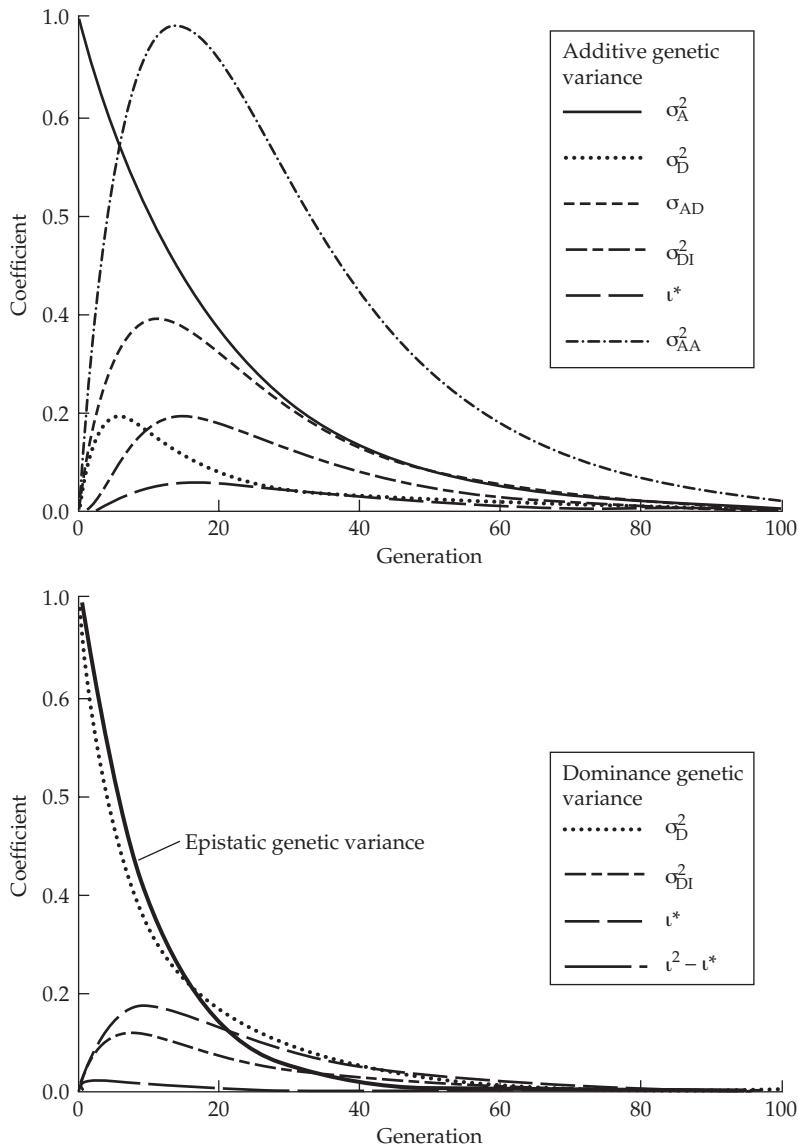

Figure 11.2 Dynamics of the coefficients for the terms contributing to the additive, dominance, and additive \times additive genetic variance within populations for an effective population size of 10 and freely recombining loci ($c = 0.5$), obtained by use of Equations 11.3 and 11.4, along with Table 11.1. The top panel gives the contributions of each term to the within-population additive variance, while the bottom panel gives the same for the within-population dominance (and $A \times A$) variance. The coefficient for the contribution of $(\iota^2 - \iota^*)$ to the additive genetic variance is barely visible on the scale in the bottom graph. These results apply approximately to any other population size, N_e , if the time scale is transformed by multiplying by $N_e/10$. To obtain the actual dynamics of the variance components, the coefficients need to be multiplied by the base-population properties. For example, the additive genetic variance in generation 50 is approximately $0.08(\sigma_A^2 + \sigma_{ADI}) + 0.04\sigma_{DI}^2 + 0.01(\sigma_D^2 + \iota^*) + 0.28\sigma_{AA}^2$, while the additive \times additive genetic variance is ≈ 0 , and the dominance genetic variance is $\approx 0.04(\iota^* + \sigma_D^2)$.

additive \times additive epistatic variance (σ_{AA}^2) is a function of n^2 terms, while all of the other quadratic components in Table 11.1 (except $\iota^2 - \iota^*$, which seems to be of little significance) are functions of only n terms. If we assume unlinked loci, the coefficient of the σ_{AA}^2

Table 11.4 A simple two-locus system with epistasis. Elements in the table are the expected genotypic values for the two-locus genotypes.

	A_1A_1	A_1A_2	A_2A_2
B_1B_1	$4a + i$	$3a$	$2a - i$
B_1B_2	$3a$	$2a$	a
B_2B_2	$2a - i$	a	i

contribution to the additive genetic variance rises to nearly 1.0 in a little over N_e generations, i.e., the equivalent of all of the base-population σ_{AA}^2 is added to the (otherwise declining) additive genetic variance at this point (Figure 11.2).

Thus, the potential exists for substantial additive \times additive epistatic variance in the base population to spawn a prolonged increase in the additive genetic variance following a reduction in population size, or at least to slow the erosion relative to the expectation given by Equation 11.2. The matter is of considerable interest because whereas inflations in the additive genetic variance induced by dominance effects are accompanied by the maladaptive effects of inbreeding depression (i.e., a deleterious change in the mean phenotype), those caused by a conversion of epistatic additive effects have no side effects on the mean (unless there is linkage disequilibrium, in which case the Griffing effect, discussed in Chapter 15, can be important), and simply increase the range of variation upon which natural selection can act.

To see how this might happen, consider the following. From the standpoint of any locus, variation in epistatic interactions with genes at other loci amounts to a reduction in the efficiency with which allelic effects are transmitted from generation to generation—segregation and recombination ensure that interlocus interactions in parents are not transmitted faithfully through gametes. However, as genetic drift moves alleles toward fixation at one or both loci or as identity disequilibria increase, this variation in the genetic environment is reduced. In Table 11.4, for example, the A_1 allele is present in genetic backgrounds that lead to five distinct genotypic values in a randomly mating population. If, however, the B_2 allele becomes fixed, then an A_1 allele can only be in two backgrounds ($A_1A_1B_2B_2$ and $A_1A_2B_2B_2$). In this case, the epistatic interactions are still present, but they are transmitted reliably as additive effects (the difference between adjacent pairs of A -locus genotypes being a constant, $a - i$).

Some simple insight into the role of additive \times additive epistatic variance in the dynamics of genetic variance of finite populations can be achieved if one is willing to assume that the loci involved are unlinked ($c = 0.5$), meaning that identity disequilibria are of negligible significance. Returning to Table 11.3, it can be seen that the coefficient for the contribution of base-population additive \times additive variance to future additive genetic variance is $(4f - \tilde{f} - 2\tilde{\gamma} - \tilde{\Delta})$, which reduces to $4f(1 - f)$ under the assumption that all of the two-locus identities $\simeq f^2$. If we ignore any contributions from dominance, the expression for the dynamics of the additive genetic variance then simplifies to

$$\sigma_A^2(t) \simeq (1 - f_t)\sigma_A^2(0) + 4f_t(1 - f_t)\sigma_{AA}^2(0) \quad (11.7a)$$

and the expression for the additive \times additive variance simplifies to

$$\sigma_{AA}^2(t) \simeq (1 - f_t)^2\sigma_{AA}^2(0) \quad (11.7b)$$

assuming the absence of any higher-order epistatic variance (Cockerham and Tachida 1988; Goodnight 1988; López-Fanjul et al. 1999). Equation 11.7a shows that the conversion of additive \times additive to additive genetic variance, which scales as $(1 - f_t) \cdot f_t$, is maximized at $f_t = 0.5$. Because $f_t \simeq 1 - \exp(-t/2N_e)$, this translates to $t \simeq 1.4N_e$ generations in accordance with Figure 11.2.

Based on results from Barton and Turelli (2004), van Buskirk and Willi (2006) proposed to approximate the additive variance (with epistasis and dominance) under inbreeding by

$$\sigma_A^2(t) \simeq (1 - f_t) [\sigma_A^2(0) + 2f_t\sigma_D^2 + 4f_t\sigma_{AA}^2(0)] \quad (11.7c)$$

This is simply Equation 11.7a with a dominance term (σ_D^2) added. While this expression appears in the literature (e.g., Taft and Roff 2012), comparison with the exact result (given from the A row in Table 11.3) shows that Equation 11.7c ignores other quadratic components involving dominance (σ_{ADI} and σ_{DI}^2) and the contributions from other identity coefficients besides f , and thus may be a poor approximation in some settings.

Limited attention has been given to the role of two-locus epistasis involving dominance effects in finite populations (Weir and Cockerham 1977; Cheverud and Routman 1996; López-Fanjul et al. 1999; Barton and Turelli 2004), and no general formulation exists for the dynamics of genetic variance resulting from higher-order epistatic interactions. We can anticipate that the necessary algebra for such a solution would be extremely tedious, as it would involve descent measures involving three and more loci, and as will be discussed below, the existing data do not support the need for such a theory. For heuristic purposes, however, we will consider the approximate case for higher-order epistasis involving only additive effects, again assuming freely recombining loci and ignoring identity disequilibrium.

As a simple entrée into this matter, recall that in the absence of dominance, the expected covariance between the relatives x and y is $\sigma_G(x, y) = 2\theta_{xy}\sigma_A^2 + (2\theta_{xy})^2\sigma_{AA}^2 + \dots + (2\theta_{xy})^n\sigma_{A^n}^2$, where θ_{xy} is the coefficient of coancestry (LW Chapter 7), and $\sigma_{A^n}^2$ refers to epistatic variance involving the additive effects of n loci. The total genetic variance (summed over the within- and among-population components) is equivalent to the covariance of individuals with themselves, which is obtained by letting $\theta_{xy} = (1 + f)/2$ (LW Chapter 7), whereas the variance among isolated subpopulations is equivalent to the covariance of random members from the same subpopulation, which is obtained by letting $\theta_{xy} = f$. Thus, for any n -locus epistatic interaction, the contribution to the total genetic variance is $(1 + f)^n\sigma_{A^n}^2$, to the among-population component of variance is $(2f)^n\sigma_{A^n}^2$, and to the within-population component is the difference, $[(1 + f)^n - (2f)^n]\sigma_{A^n}^2$. This implies that the base-population additive and additive \times additive genetic variances contribute $(1 - f)\sigma_A^2$ and $(1 + 2f - 3f^2)\sigma_{AA}^2$, respectively, to the within-population genetic variance, a result that can also be obtained directly from Equations 11.7a and 11.7b. The contribution from additive \times additive \times additive epistatic variance is $(1 + 3f + 3f^2 - 7f^3)\sigma_{AAA}^2$, etc.

Each of these terms (except those involving σ_A^2) reaches a maximum at an intermediate level of inbreeding and then declines to zero as $f \rightarrow 1$. For additive epistatic effects involving $n = 2, 3$, and 4 loci, the peak contributions to the within-population genetic variance occur when f is approximately 0.33, 0.55, and 0.66, respectively. For randomly mating populations, these maxima occur at $0.8N_e$, $1.6N_e$, and $2.2N_e$ generations, with the peak contributions to the total within-population genetic variance being equal to $1.33\sigma_A^2$, $2.39\sigma_{AA}^2$, and $4.56\sigma_{AAA}^2$, respectively. Thus, even if levels of higher-order epistatic genetic variance are relatively low in a base population, they may have a significant influence on the within-population variance under inbreeding, with the full impact not being revealed for many generations. One potential consequence of this, as noted by Naciri-Graven and Goudet (2003), is that as the number of loci increases, epistasis becomes more important than dominance. However, López-Fanjul et al. (2002) reached the opposite conclusion for two loci, namely, that dominance is more important than epistasis, thus showing that intricacies of the genetic architecture impact our predictions.

Under the model of only additive epistasis, the components of within-population genetic variance are described by the following general expression,

$$\sigma_{A^n}^2 = (1 - f)^n \sum_{i=0}^{x-n} \binom{n+i}{n} (2f)^i \sigma_{A^{n+i}}^2 \quad (11.8)$$

where x denotes the highest level of epistasis involving additive effects influencing the trait (Barton and Turelli 2004; Hill et al. 2006). When $x = 2$, this expression recovers Equations 11.7a and 11.7b, and with x as high as 3, we obtain

$$\sigma_A^2(t) = (1 - f_t)[\sigma_A^2(0) + 2(2f_t)\sigma_{AA}^2(0) + 3(2f_t)^2\sigma_{AAA}^2(0) + \dots] \quad (11.9a)$$

$$\sigma_{AA}^2(t) = (1 - f_t)^2[\sigma_{AA}^2(0) + 3(2f_t)\sigma_{AAA}^2(0) + \dots] \quad (11.9b)$$

$$\sigma_{AAA}^2(t) = (1 - f_t)^3[\sigma_{AAA}^2(0) + \dots] \quad (11.9c)$$

with the dots denoting potential contributions from higher-order effects.

These expressions show that, under progressive inbreeding, the expected values for each variance component depend on all higher-order epistatic variances, and that the erosion of the higher-order components proceeds most rapidly. Most notably, Equation 11.9a shows that the presence of any epistatic variance will inflate the additive genetic variance above the simple expectation $(1 - f)\sigma_A^2(0)$, but whether $\sigma_A^2(t)$ rises beyond the base-population level, $\sigma_A^2(0)$, depends on the magnitude of the base-population epistatic variance components. From Equation 11.8, it can be seen that for any $n > 1$, the peak contribution of $\sim(2^{n-1}/2.72)\sigma_{A^n}^2$ to the additive genetic variance occurs at $f = 1 - (1/n)$ (Turelli and Barton 2006).

A practical way of evaluating the conditions necessary for a net increase in the additive genetic variance is to consider the nature of empirical estimates of additive genetic variance. As noted in Lynch and Walsh (1998), clean estimates of the causal components of genetic variance are generally unachievable. For example, although twice the parent-offspring covariance is often used as an estimate of the additive genetic variance, the true expectation is actually $\sigma_A^2 + (\sigma_{AA}^2/2) + (\sigma_{AAA}^2/4) + \dots$. Ignoring all but the additive \times additive genetic variance, Equations 11.7a and 11.7b can be used to show that the parent-offspring covariance after inbreeding to level f will exceed that in the base population if $\sigma_{AA}^2 > 2\sigma_A^2/(6 - 7f)$, which reduces to $\sigma_{AA}^2 > \sigma_A^2/3$ as $f \rightarrow 0$.

Although it is exceedingly difficult to obtain perfectly isolated estimates of σ_A^2 and σ_{AA}^2 , a survey of the existing data combined with a number of indirect arguments suggests that the condition of $\sigma_{AA}^2 > \sigma_A^2/3$ is hardly ever met in natural populations (Hill et al. 2008; Mäki-Tanila and Hill 2014). As reviewed in Lynch and Walsh (1998) and reemphasized by Hill et al. (2008), this situation is not likely to be a consequence of limited epistatic interactions among genes. Rather the very nature of variance-component partitioning, with higher-order effects being defined as residual deviations from expectations based on lower-order effects, largely ensures that epistatic components of variance will be small relative to σ_A^2 , especially when most alleles have frequencies far from 0.5.

Finally, we emphasize that although all of the previous results strictly apply to ideal monoecious populations that become inbred via random genetic drift, the general approach applies to any mating system, provided appropriate modifications are made to the recursion formulae for the identity coefficients. For monoecy with the avoidance of selfing and for separate sexes, the appropriate expressions were given by Weir et al. (1980) and Weir and Hill (1980), and explicit formulae for obligate self-fertilization, full-sib mating, and other special systems of mating are developed in Cockerham and Weir (1968, 1973) and Weir and Cockerham (1968), with a useful review provided in Cockerham and Weir (1977).

Sampling Error

It cannot be emphasized too strongly that the preceding expressions give only the *expected* change of the within-population variance for a neutral quantitative character. Due to the stochastic nature of random genetic drift, departures from this expectation will arise in any individual population, so a central concern is the degree to which the average behavior of a small number of populations (e.g., a typical replicated experiment) will represent the expected pattern.

In the following discourse, we denote the realized additive genetic variance for any particular population by $\hat{\sigma}_A^2(t)$. Estimation error on the part of the investigator aside, three

sources of error contribute to the variation in $\hat{\sigma}_A^2(t)$ among replicate populations: (1) variation in the genetic variance among founder populations caused by sampling; (2) subsequent departures of the within-population heterozygosity from its expectation caused by drift; and (3) deviations from Hardy-Weinberg and gametic-phase equilibrium.

Quantification of these sources of variation is difficult, but some general results have been obtained for characters with a purely additive genetic basis. The additive genetic variance within a particular population can be written as

$$\hat{\sigma}_A^2(t) = \sigma_a^2(t) + \hat{\sigma}_{HW}(t) + \hat{\sigma}_L(t) \quad (11.10)$$

where $\sigma_a^2(t)$ is the variance due to the true gene effects expected if the line were expanded into an infinitely large, randomly mating population with global Hardy-Weinberg and gametic-phase disequilibrium (the **genic variance**; Chapters 16 and 24), while $\hat{\sigma}_{HW}(t)$ and $\hat{\sigma}_L(t)$ are transient covariances of genic effects within and among loci caused by disequilibria within and between loci. The expected value of $\sigma_a^2(t)$, given by Equation 11.2, is $\sigma_A^2(t)$, as the disequilibria are equally likely to occur in positive and negative directions in the absence of selection. Thus, the expected value of $\hat{\sigma}_A^2(t)$ is also equal to $\sigma_A^2(t)$.

Each of the terms on the right side of Equation 11.10 has a variance associated with it, meaning that the expected variance of the within-population additive genetic variance among hypothetical replicate populations can be expressed as

$$\sigma^2[\hat{\sigma}_A^2(t)] = \sigma^2[\sigma_a^2(t)] + \sigma^2[\hat{\sigma}_{HW}(t)] + \sigma^2[\hat{\sigma}_L(t)] \quad (11.11)$$

The variance of the “true” additive genetic variance is

$$\sigma^2[\sigma_a^2(t)] = \sum_{i=1}^n a_i^4 \sigma_{H_i}^2(t) \quad (11.12)$$

where $\sigma_{H_i}^2(t)$ is the expected variance of heterozygosity, $H_i(t) = 2p_i(t)[1 - p_i(t)]$, at a locus i among replicate populations t generations after divergence. Bulmer (1980) obtained an expression for $\sigma_{H_i}^2(t)$ for a locus with two alleles, and a very close approximation to this is given in Example 2.5. While the exact dynamics of $\sigma^2[\sigma_a^2(t)]$ will depend on the initial allele frequencies at all loci, which are generally unknown, a useful qualitative statement can be made. For fixed initial genetic variance in the base population, the average value of a_i^2 must scale inversely with the number of loci. Thus, because $\sigma^2[\sigma_a^2(t)]$ is the sum of n terms, each of which is a function of $a_i^4 \propto n^{-2}$, then $\sigma^2[\sigma_a^2(t)]$ must be inversely proportional to n . Therefore, for characters with large effective numbers of loci, deviations from the true additive genetic variance caused by variance in heterozygosity are likely to be of negligible importance.

The expected variance of the within-population variance from Hardy-Weinberg deviations is $\sigma^2[\hat{\sigma}_{HW}(t)] \simeq \sigma_A^4(t)/N_e$ (Bulmer 1976, 1980), but the variation due to gametic-phase disequilibrium is more substantial, and the details of the rather tedious derivations appear in Avery and Hill (1977) and Bulmer (1980). Regardless of the degree of linkage, $\sigma^2[\hat{\sigma}_L(1)] \simeq \sigma_A^4(0)/N_e$ in the first generation of inbreeding, and thereafter for the special case of unlinked loci, $\sigma^2[\hat{\sigma}_L(t)] \simeq 5\sigma_A^4(t)/(3N_e)$. With linkage $\sigma^2[\hat{\sigma}_L(t)]$ is necessarily larger, but for most cases it will not be substantially so (Avery and Hill 1977), and regardless of the state of disequilibrium in the base population, the expected value of $\sigma^2[\hat{\sigma}_L(t)]$ is almost always attained within five generations.

An advantage of the preceding expressions for the variance of the components of the within-population genetic variance is that they are defined in terms of measurable quantities. However, to achieve this useful property, several assumptions (ideal population structure, no association between map distances and effects of genes, additivity of gene effects) had to be made, violations of which will tend to inflate the variance of $\hat{\sigma}_A^2(t)$. Thus, summing over the two disequilibrium sources, we find that $\sigma^2[\hat{\sigma}_A^2(t)]$ must be at

least $8\sigma_A^4(t)/3N_e$. A similar conclusion was reached by Zeng and Cockerham (1991), who presented a more thorough and highly technical analysis.

These theoretical results have significant implications for the interpretation of observed changes of genetic variance in small populations, in particular in the use of such observations to infer any significant conversion of nonadditive to additive genetic variance. Clearly, estimates of $\hat{\sigma}_A^2(t)$ derived from a small number of replicate populations, even over several generations, provide unreliable assessments of the expected dynamics of $\sigma_A^2(t)$. If we average over L independent lines, the sampling variance of the average of the within-line additive variances is at least $8\sigma_A^4(t)/(3LN_e)$. Therefore, if it is desirable to keep the standard error of an estimate of the additive genetic variance at a level of 10% of the expectation, $\sigma_A^2(t)$, the design must be such that $N_e L \simeq 270$, i.e., approximately 70 lines of $N_e = 4$, or 17 of $N_e = 16$. For self-fertilizing lines, the sampling variance is closer to $7\sigma_A^4(t)/L$ over the first five generations of inbreeding (Lynch 1988a), so on the order of 700 lines would have to be monitored to achieve a similar level of precision. In practice, one would need to set the target number of lines even higher than these estimates, because the additional variation due to parameter estimation, i.e., the deviation of the observation $\text{Var}(A, t)$ from the realized parameter $\hat{\sigma}_A^2(t)$, which may be considerable, has been ignored in the preceding arguments.

One final problem that bears mentioning is that the values of $\hat{\sigma}_A^2(t)$ observed in successive generations are not independent, as the minimum correlation between adjacent generations equals one-half for unlinked loci. Thus, if the genetic variation within a particular population exceeds the expectation due to chance in one generation, it is likely to remain in excess for several consecutive generations. When this problem is confounded with the sampling variance described above, there is a substantial possibility that $\hat{\sigma}_A^2(t)$ for a particular replicate population may on occasion increase for several generations, contrary to the expected trend, and even for characters with a purely additive genetic basis (Avery and Hill 1977; Bulmer 1980).

In summary, even in the case of purely additive gene action, obtaining a reliable empirical view of the expected dynamics of the additive genetic variance requires a very large number of replicate populations. There are three levels at which sampling error plays a role. First, in each replicate, the variance observed by the investigator, $\text{Var}(A)$, is likely to deviate substantially from the parametric value $\hat{\sigma}_A^2$ for the replicate, due simply to the finite number of individuals monitored. Second, the true realized variance, $\hat{\sigma}_A^2$, in each line may deviate considerably from the actual equilibrium value, σ_a^2 , expected in the absence of Hardy-Weinberg and gametic-phase disequilibria. Finally, random genetic drift will cause σ_a^2 to deviate from the global expectation, σ_A^2 . One can expect the situation to get even more complex in the presence of nonadditive gene action, but mastering the details of the sampling theory remains a formidable challenge.

Empirical Data

The influence of small population size on components of genetic variance is of substantial relevance to several areas of inquiry. For example, an underlying assumption of much of conservation genetics is that the loss of heterozygosity from small populations translates immediately into a loss of variation for adaptive traits. As noted above, however, this need not be the case in the presence of nonadditive gene action. A key additional question is whether increases in the additive genetic variance following a population bottleneck, if they do indeed occur, are accompanied by changes in the mean phenotype that are contrary to the maintenance of high fitness. Nothing is gained from a population bottleneck if the extreme phenotypes that are produced are simply low-fitness individuals resulting from inbreeding depression.

The preceding theory is also of potential relevance to the field of speciation. Substantial uncertainty exists over the importance of population bottlenecks for the speciation process (Mayr 1954; Templeton 1980; Barton and Charlesworth 1984; Carson and Templeton 1984), and much of the debate revolves around verbal arguments regarding additive and epistatic

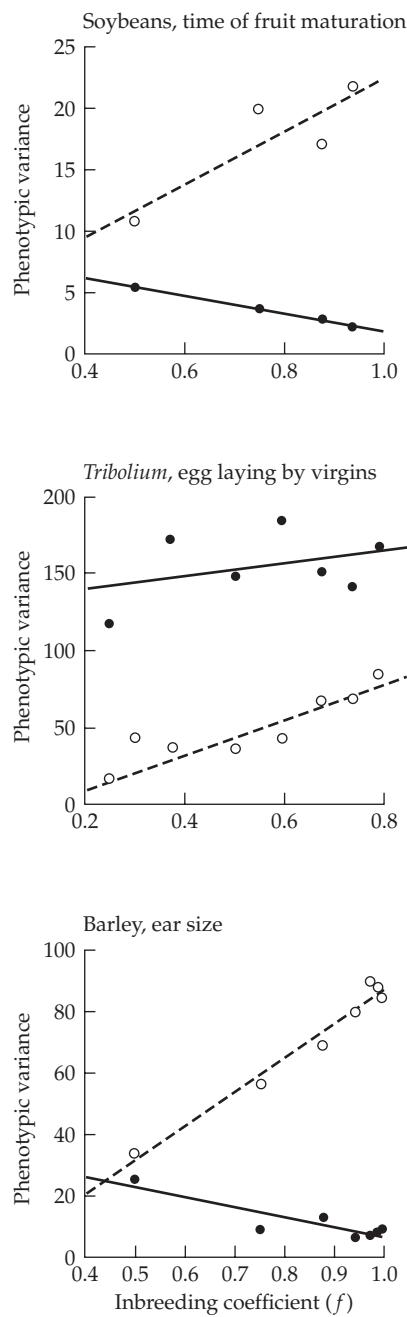

Figure 11.3 Response of the average within-line and among-line phenotypic variance to inbreeding in experimental lines. References and system of mating: **top:** Horner and Weber (1956), selfing; **middle:** López-Fanjul and Jódar (1977), full-sib mating, control-corrected; **bottom:** Bateman and Mather (1951), selfing. Solid and open points denote the within- and among-population components of phenotypic variance.

gene action. In Carson's (1968, 1975) **founder-flush** theory, for example, it is assumed that a period of population expansion following a bottleneck will often result in a conversion of various types of epistatic interactions into additive genetic variance. Similar issues were raised by Templeton (1980) in his hypothesis of speciation via **genetic transilience**. Although such arguments sometimes appear intuitive on the surface, the preceding theoretical exam-

ples amply illustrate that intuition can be quite misleading with respect to the dynamics of genetic variance in small populations. The consequences of a population bottleneck are highly sensitive to the nature of gene action and the frequency distribution of alleles, and establishing whether increases in bottleneck-induced variance are common is ultimately an empirical question.

Unfortunately, only a few well-designed empirical studies have addressed the influence of inbreeding on the genetic variance within populations. Studies that strictly focus on *phenotypic* variance often reveal essentially linear declines in the phenotypic variance with f , as expected for a character with a purely additive genetic basis, but in other cases the response has been so noisy that no general conclusion could be drawn, and sometimes the within-population variance steadily increases over time (Figure 11.3). A substantial limitation of studies of this sort is that the environmental component of variance often increases with inbreeding as a consequence of reduced developmental stability (Chapter 17; LW Chapter 6; Whitlock and Fowler 1999; Kelly and Arathi 2003), thereby obscuring the relationship between phenotypic and genetic variance.

A study by Cheverud et al. (1999) provided a clear example of the creation of additive genetic variance by a population bottleneck. By crossing two long-established mouse lines, one selected for large body size and the other for small body size, an F_2 base population with high genetic variance for adult weight was constructed. Thirty-nine replicate inbred lines were then initiated from the F_3 generation, each maintained as two pairs of males and females through four generations of inbreeding to yield an average $f = 0.39$. Two contemporary control strains were maintained by randomly mating 60 pairs of individuals derived from the base (hybrid) population. Using a full-sib analysis, the authors found that the average additive genetic variance for adult weight after inbreeding was about 1.75-fold greater (and significantly so) than expected under the additive model (a fraction, $1 - f = 0.61$, of the additive variation in the base population) and slightly greater than that in the controls. Two lines of evidence suggest that this inflation in σ_A^2 was largely, if not entirely, due to the conversion of additive \times additive epistatic variance. First, the absence of any significant change in mean adult weight throughout the period of inbreeding implies that directional dominance is negligible for this trait. Second, previous QTL analysis of this experimental population had revealed pervasive epistatic interactions between loci influencing body size (Routman and Cheverud 1997; Kramer et al. 1998). As a caveat, however, it must be emphasized that this study is quite artificial, in that by constructing a base population with intermediate gene frequencies, the epistatic genetic variance was maximized at the outset. We now consider the few results that have emerged for more naturally derived populations.

Bryant et al. (1986b) put populations of houseflies (*Musca domestica*) through single-generation bottlenecks of 1, 4, and 16 pairs, and then rapidly expanded them for several generations prior to the measurement of the additive genetic variance (to reduce the variation in the within-line variance caused by gametic-phase disequilibrium). Analyses of several morphological characters suggested an increase in σ_A^2 in the bottlenecked lines relative to a control (Figure 11.4), which the authors surmised to be a consequence of the conversion of epistatic to additive genetic variance. Although this study has become something of a flagship example of bottleneck-induced increases in genetic variance, it also serves to highlight the extreme difficulties that exist in interpreting the dynamics of genetic variance in inbred populations.

First, only four replicate populations were maintained at each population density in this study, so there is a substantial chance that the average within-line variance may have increased entirely by chance, even in the absence of nonadditive genetic variance. Second, some characters exhibited a five-fold inflation in the additive genetic variance over the control, and based on the considerations outlined above, this is hard to accept as a real consequence of inbreeding in the essentially non-inbred ($f \simeq 0.03$) 16-pair lines (traits IE and SW in Figure 11.4). In contrast, although the evidence that inbreeding created a real increase in additive genetic variance in these lines is not very compelling, it is equally true that there

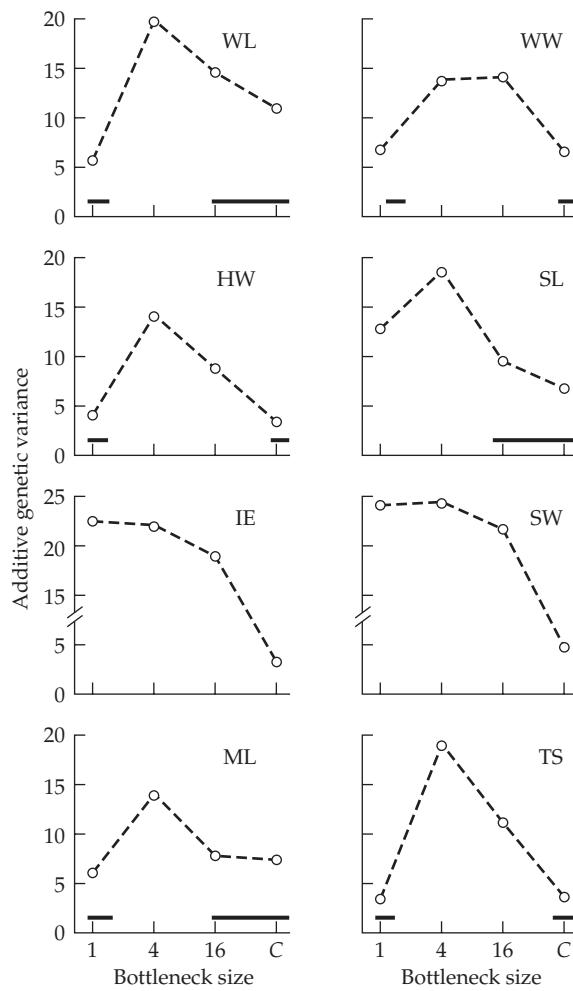

Figure 11.4 Additive genetic variances for eight morphometric traits averaged over four replicate lines of bottlenecked housefly (*Musca domestica*) populations. Horizontal lines (along the bottom axes) connect variances that were not significantly different at the 0.05 level. *C* denotes a large randomly mating control population, whereas the remaining populations were propagated through single-generation bottlenecks of 1, 4, and 16 pairs. WL denotes wing length; WW, wing width; HW, head width; SL, scutellum length; IE, inner-eye separation; SW, scutellum width; ML, metafemur length; and TS, thoracic-suture length. (From Bryant et al. 1986b.)

is no evidence of a substantial erosion in additive genetic variance following inbreeding. In subsequent studies involving single-generation bottlenecks of four individuals, Meffert (1995) did not detect any overall change in the additive genetic variance for various aspects of courtship behavior (six replicate populations), and Bryant and Meffert (1996) observed increases in σ_A^2 for two morphological characters but decreases for two others (two replicate populations) thought to have had relatively high levels of additive \times additive epistatic variance in the base population.

Replication is less of a problem in a few other recent studies. For example, starting from a large base population of *D. melanogaster*, Whitlock and Fowler (1999) subjected 52 lines to a single generation of full-sib mating ($f = 0.25$) and then expanded them to a large size. Within each line, the additive genetic variance for various aspects of wing structure was estimated by parent-offspring regressions involving 90 families, and a similar procedure was applied to a large control population; see also Example 11.2. No evidence

for an increase in the additive genetic variance emerged from this well-designed study, and a similar conclusion was reached in a study on sternopleural bristles in bottlenecked populations of *D. bunnanda* (van Heerwaarden et al. 2008). Although a few individual lines exhibited moderate increases in σ_A^2 , these increases were always compatible with the expectations of additive genetic theory (i.e., consistent with the predicted sampling variance), as was the average reduction in σ_A^2 across all lines.

In a smaller study with the flour beetle (*Tribolium castaneum*), involving three inbreeding levels ($f = 0, 0.375$, and 0.672 , with five replicates each), Wade et al. (1996) also observed average changes in the additive genetic variance for pupal weight that were entirely compatible with expectations of the additive model. Likewise, changes in the additive genetic variance of wing pigmentation patterns in bottlenecked populations of the butterfly *Bicyclus anynana* (Saccheri et al. 2001), sternopleural bristle number in *Drosophila* (Kristensen et al. 2005), and flower size in *Nigella degenerii* (Andersson et al. 2010) were all consistent with expectations of the additive model. However, a meta-analysis dominated by morphological traits led to a slightly different conclusion (Taft and Roff 2012). In order to compare the results of a number of different studies, Taft and Roff considered the log of the ratio of the estimated additive variance in a bottlenecked population to the estimated variance in the control. Under the additive model (Equation 11.7a), one expects that

$$R = \ln \left(\frac{V_A(\text{bott})}{V_A(\text{cont})} \right) = \ln(1 - f)$$

in which case the regression of R on $\ln(1 - f)$ would have a slope of one and an intercept of zero. More generally, one could fit $R = a + b \ln(1 - f)$ to look for departures from the predictions of the additive model. While the slope of this regression was not significantly different from its expected value ($b = 1$), Taft and Roff observed a significant nonzero intercept. They interpreted this as arising from trying to force a linear relationship onto a collection of response curves, some of which were nonlinear (i.e., with the additive variance increasing over some initial range in f). A simple alternative explanation is that estimation error could generate a nonzero intercept (especially considering that variance estimators have highly asymmetric confidence intervals; see Figure 12.1). Taken together, these diverse studies provide little justification for the view that the *expected* additive genetic variance for *morphological* traits commonly increases during early phases of inbreeding, although transient increases associated with sampling are certainly expected in some replicates.

These results are in striking contrast to those from studies on fitness-related traits. For example, in a parallel study of offspring production in *Tribolium*, Wade et al. (1996) observed no significant decline in additive genetic variance at inbreeding levels up to $f = 0.672$. Likewise, López-Fanjul and Villaverde (1989) took 16 replicate populations of *D. melanogaster* through single generations of full-sib mating and assayed them for egg-to-pupa viability. The average additive genetic variance in the control lines was not significantly different from zero, whereas that in lines inbred to $f = 0.25$ was five-fold (and significantly) higher. In a study involving 32 lines of *D. melanogaster*, again inbred to $f = 0.25$, Fernández et al. (1995) observed a ten-fold increase in the additive genetic variance for viability, whereas that for fecundity remained approximately equal to that of the control; and a similar increase in additive genetic variance for viability following inbreeding was seen in still another study by García et al. (1994). In each of these studies, the characters of interest exhibited significant inbreeding depression.

This dichotomy between the behavior of additive variance under inbreeding for metric traits versus those more directly related to fitness is predicted from theoretical results. As discussed in Chapter 6, we expect a higher fraction of nonadditive variance in fitness-related traits. Assuming dominance (but no epistasis), Zhang et al. (2004b) noted that the equilibrium distribution of allele frequencies for a nearly neutral trait is very different from that for a fitness-related trait under mainly purifying selection. In the latter, deleterious alleles tend to be rare and at least partly recessive (Chapter 7), exactly the condition that facilitates an increase in additive variance under inbreeding. In contrast, no such association

in the joint distribution of allelic frequencies and effect sizes is expected for a nearly neutral trait, and thus no increase in σ_A^2 is expected.

If any general message can be taken from these limited results, it is that increases in additive genetic variance following a population bottleneck are largely restricted to fitness characters harboring substantial dominance genetic variance, with morphological and behavioral traits exhibiting genetic-variance dynamics that are not greatly different from expectations based on the additive model (Wang et al. 1998; Van Buskirk and Willi 2006). Moreover, there is, as yet, no firm empirical evidence that population bottlenecks create significant levels of *adaptive* variation. With the exception of the intentionally artificial setting used by Cheverud et al. (1999), all observed increases in additive variation following inbreeding have been accompanied by substantial inbreeding depression—while the variance increased, the mean changed in a direction contrary to high fitness.

Might the creation of new additive genetic variance nevertheless compensate for slippage in the mean via inbreeding depression? In the two *D. melanogaster* studies in which selection for increased fitness was imposed on inbred lines, a substantial increase in the response to selection (relative to the controls) was observed, but this was more than offset by the loss of fitness due to inbreeding depression (López-Fanjul and Villaverde 1989; García et al. 1994), i.e., there was an overall reduction in viability even after selection utilized the released genetic variance. In another study, involving bottlenecked populations of *Drosophila bunnanda*, van Heerwaarden et al. (2008) found that although inbreeding resulted in an inflation of the additive genetic variance for desiccation resistance, there was no increase in the response to selection relative to control populations. The same pattern was seen in selected populations of the mustard plant *Brassica rapa*—bottlenecking led to a significant increase in additive genetic variance for cotyledon size, apparently via a release from the dominance component, but a reduction in the long-term response to selection (Briggs and Goldman 2006).

Example 11.2. The significance of the problem of the variance of the within-population variance is highlighted by a massive experiment performed by López-Fanjul et al. (1989). Starting from a large random-bred base population of *D. melanogaster*, 304 non-inbred lines were constructed, and another 300 inbred lines were produced by four generations of full-sib mating followed by population expansion for six generations. The components of variance for abdominal bristle number were evaluated for the initial 304 lines ($f = 0$) and for the fourth and tenth generations after the bottleneck/expansion treatment (both $f = 0.5$) by several techniques including sib analysis. Consistent with the view that this character has a largely additive genetic basis (LW, pp. 171–172), the mean (\bar{z}) was unaffected by inbreeding (table below). Moreover, averaging over all of the inbred lines, there was an approximately 50% reduction in the additive genetic variance, as predicted by additive theory.

The data from this experiment are in excellent accord with the sampling theory for the additive genetic variance presented above. Summing the expected variances contributed by Hardy-Weinberg and gametic-phase disequilibria, $\sigma_A^4(0)/N_e + \sigma_A^4(0)/N_e$, the expected coefficient of variation for the additive genetic variance in the non-inbred lines (random populations with $N_e \approx 8$ and $t = 0$) is $(2/N_e)^{1/2} = 0.50$, which is reasonably close to the observed value 0.35 (table below).

Generation	f	\bar{z}	$\text{Var}(A)$	$\text{CV}[\text{Var}(A)]$
1	0.0	41.4	5.2	0.35
4	0.5	41.4	2.5	1.05
10	0.5	41.4	1.8	1.15

In addition, for both of the inbred generations, the observed values of the coefficient of variation for $\text{Var}(A)$, $\text{CV}[\text{Var}(A)]$, are close to the theoretical minimum $\sqrt{8/(3N_e)} = 1.04$ (using $N_e = 2.5$ for full-sib mating). In principle, several generations of random mating would be expected to cause a reduction in $\text{CV}[\text{Var}(A)]$ through the elimination of

gametic-phase disequilibrium if significant numbers of linked loci contributed to the genetic variance, but a comparison of results for $t = 4$ and 10 shows that this was not observed.

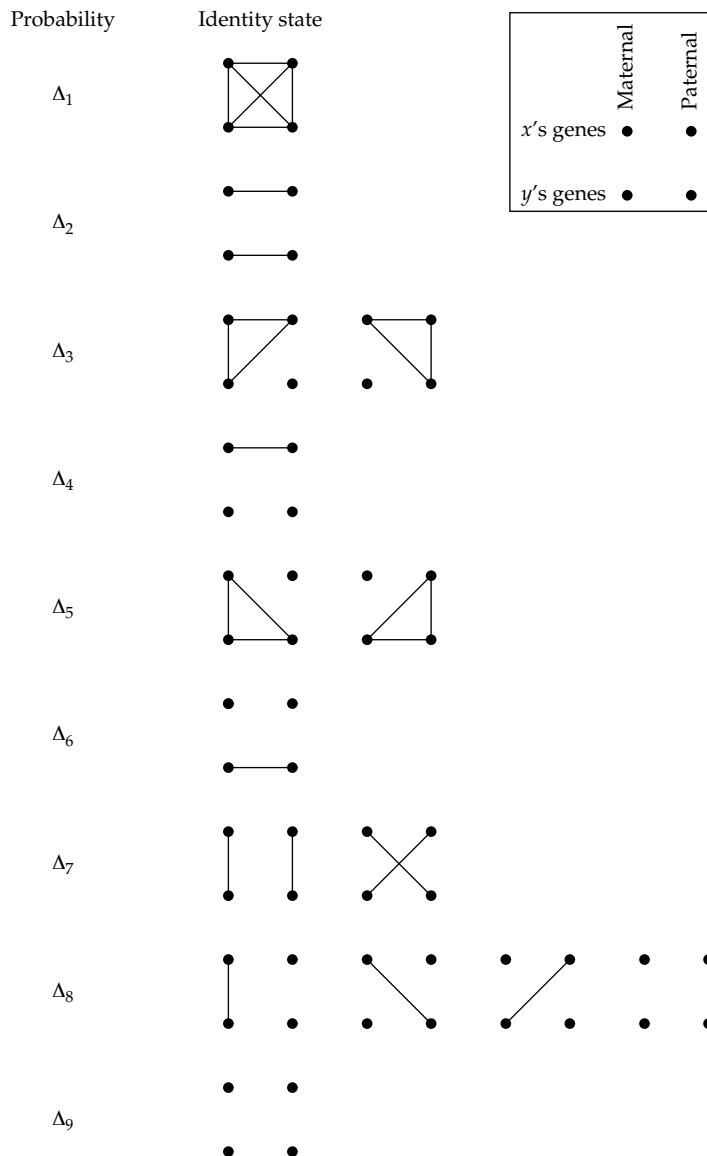

Figure 11.5 The 15 possible states of identity by descent for a locus in individuals x and y ; condensed into nine classes. Alleles that are identical by descent are connected by lines, with horizontal lines indicating an inbred individual (Δ_1 through Δ_6). Note that Δ_4 , Δ_6 , and Δ_9 involve unrelated individuals (there are no lines between any gene of x to any gene of y).

COVARIANCE BETWEEN INBRED RELATIVES

In the preceding sections, we assumed there was a parallel series of small populations, each being propagated across generations as progeny derived from randomly mating populations of size N_e . Even in the simplest case of no epistasis, we found that the dynamics of the genetic variance within populations is a potentially complex function of six quadratic

parameters of gene effects in the base population (Table 11.1). What remains to be considered is how these contributions can be estimated in a practical sense. Not surprisingly, the key strategy is the usual one in quantitative genetics—the resemblance between relatives (LW Chapter 7).

When individuals are inbred with respect to the base population, the expressions for the genetic covariance between relatives become functions of all of the parameters outlined in Table 11.1, not just the usual σ_A^2 and σ_D^2 . On the other hand, with inbreeding there are also many more potential types of relationships than in the conventional case, as the latter are supplemented by inbred relatives. One can imagine, for example, a multigenerational series of individuals resulting from continuous selfing, full-sib mating, or both. Given phenotypic information on these additional types of relatives, it should be possible to estimate several different factors contributing to phenotypic covariance (as many as the number of observed relationships). The little experience we have gained in this area, however, indicates that the statistical difficulties in achieving accurate estimates are still quite formidable, even in the absence of epistasis, which we will assume in the following.

Three new issues arise in considering the sources of phenotypic resemblance between inbred relatives. First, inbreeding causes a statistical dependence between alleles within individuals (generating an excess of homozygotes), and this creates a covariance between the additive effects, α_i , in one relative and the dominance effects, δ_{ii} in the other, as represented by $\sigma(\alpha_i, \delta_{ii}) = \sigma_{ADI}$ (Table 11.1). Second, if two individuals have identical genotypes by descent, their dominance covariance will differ depending on whether they are inbred or outbred (because inbred individuals cannot be heterozygous), and this will generally vary from locus to locus. Third, with dominance, the mean phenotype of inbred individuals will generally differ from that of non-inbred individuals, and this can inflate the covariance between certain types of relatives by breaking the population up into classes of inbred vs. non-inbred individuals.

The one- and two-locus identity measures (Figure 11.1) used to examine the within- and among-genetic variances in a random-mating population undergoing drift are insufficient to describe all of the potential relationships among two diploids when generalized inbreeding is occurring. To do so, we need the nine **condensed coefficients of identity**, Δ_i , between two individuals (Figure 11.5). Introduced in LW Chapter 7, these coefficients sum to one and have a natural connection to the quadratic components in Table 11.1. As shown in the figure, three situations (Δ_4 , Δ_6 , and Δ_9) correspond to comparisons between unrelated individuals (although one or both may be inbred), and hence do not contribute to the genetic covariance between relatives.

Harris (1964) and Gillois (1965) first derived an expression for the covariance between inbred relatives, assuming gametic-phase equilibrium and an absence of epistasis, and Cockerham (1984a) extended their analyses to allow for gametic-phase disequilibrium, showing that the genetic covariance between individuals x and y is

$$\begin{aligned}\sigma_G(x, y) = & 2\Theta_{xy}\sigma_A^2 + \Delta_{7xy}\sigma_D^2 + \Delta_{1xy}\sigma_{DI}^2 + (2\Delta_{1xy} + \Delta_{3xy} + \Delta_{5xy})\sigma_{ADI} \\ & + (\Delta_{2xy} - f_x f_y)\iota^* + (\tilde{\Delta}_{xy} - f_x f_y)(\iota^2 - \iota^*)\end{aligned}\quad (11.13)$$

where $\tilde{\Delta}_{xy}$ indicates our previous two-locus identity measure (Figure 11.1), applied to individuals x and y (as opposed to randomly drawn gametes).

To see how the Δ_i enter into the covariance expressions, consider the coefficient of coancestry Θ_{xy} , the probability that two genes, one drawn from x and the other from y are identical by descent. In terms of the condensed coefficients of identity,

$$\Theta_{xy} = \Delta_{1xy} + \frac{1}{2}(\Delta_{3xy} + \Delta_{5xy} + \Delta_{7xy}) + \frac{1}{4}\Delta_{8xy}\quad (11.14)$$

(LW Chapter 7), where each condensed coefficient of identity is weighted by the conditional probability that a gene that is randomly drawn from x is identical by descent with a gene that is randomly drawn from y . There are four different ways to randomly choose an allele from

Table 11.5 The expected genetic covariance generated by each Δ_i relationship.

Δ_1	Δ_2	Δ_3, Δ_5	Δ_7	Δ_8	$\Delta_4, \Delta_6, \Delta_9$
$2\sigma_A^2 + \sigma_{DI}^2 + 2\sigma_{ADI}$	$(1 - f_x f_y / \Delta_2) \iota^*$	$\sigma_A^2 + \sigma_{ADI}$	$\sigma_A^2 + \sigma_D^2$	$\sigma_A^2 / 2$	0

each of two diploids. In each case, with a probability of Θ_{xy} the two chosen alleles are IBD, in which case their contribution to the genetic covariance is $\sigma_A^2 / 2$. Hence, the contribution to the additive variance resulting from shared additive effects is $4\Theta_{xy}\sigma_A^2 / 2 = 2\Theta_{xy}\sigma_A^2$.

Similarly, Δ_{7xy} and Δ_{1xy} account for the probabilities that the two individuals share identical genotypes by descent, in the absence or presence of inbreeding, respectively, so the dominance genetic covariance is $(\Delta_{7xy}\sigma_D^2 + \Delta_{1xy}\sigma_{DI}^2)$. The term $(2\Delta_{1xy} + \Delta_{3xy} + \Delta_{5xy})$ is a measure of the expected number of ways in which three alleles in the two individuals are identical by descent, and when multiplied by σ_{ADI} , it yields the expected covariance between individuals resulting from the covariance between additive and homozygous dominance effects. Finally, $(\Delta_{2xy} - f_x f_y)$ is the probability that the two individuals are inbred at the same locus in excess of that expected for random members of the population ($f_x f_y$), whereas $(\tilde{\Delta}_{xy} - f_x f_y)$ is the excess joint inbreeding at one locus in x and another in y . These latter two coefficients are multiplied, respectively, by the quadratic terms describing inbreeding depression at the same and at different loci. Table 11.5 summarizes the expected genetic covariance contributed by the various relationships.

One conclusion that can be drawn immediately from Equation 11.13 is that with inbreeding, dominance can contribute to the covariance between many types of inbred relatives. All of the quadratic components in this equation are necessarily positive except σ_{ADI} , which can be positive or negative (Example 11.1). Thus, while it is likely that inbreeding will inflate the covariance between relatives, this cannot be stated with certainty.

Example 11.3. Consider the situation in which fathers are mated to their daughters. What is the genetic covariance between the offspring (y) of such matings and their fathers (x)?

Assuming the father is not inbred (there is no line connecting the maternal and paternal alleles of x in Figure 11.5), $\Delta_{1xy} = \Delta_{2xy} = \Delta_{3xy} = f_x = \tilde{\Delta}_{2xy} = 0$, so to complete the solution of Equation 11.13, we only require values for the coefficients Θ_{xy} , Δ_{7xy} , and Δ_{5xy} . The inbreeding coefficient of y is the same as the coefficient of coancestry between the parents (the father and his daughter), $f_y = 1/4$. Moreover, because y inherits only one gene from x directly, if y is inbred, then identity relationship 5 must hold, so $\Delta_{5xy} = f_y \cdot 1 = 1/4$. A gene in x can be identical with one in y by direct descent from the father or by indirect descent from the father through his first daughter (the mother of y), so $\Theta_{xy} = (1/4) + (1/8) = 3/8$. Finally, given that y has inherited one gene directly from x , the probability that x 's other gene has been transmitted through his first daughter is $1/4$. Thus, $\Delta_7 = 1/4$. Substituting into Equation 11.13,

$$\sigma_G(x, y) = \frac{3}{4}\sigma_A^2 + \frac{1}{4}\sigma_D^2 + \frac{1}{4}\sigma_{ADI}$$

This may be contrasted with $\sigma_G(x, y) = \sigma_A^2 / 2$, the expectation for the parent-offspring covariance under random mating (the mother of y and its father, x , are unrelated).

Some attention has been given to the contribution of additive \times additive genetic variance to the resemblance between inbred relatives (Cockerham 1984b; Cockerham and Tachida 1988; Tachida and Cockerham 1989). In this case, Equation 11.13 requires an additional term,

$$\left(\tilde{f}_{xy} + \tilde{\gamma}_{\bar{x}y} + \tilde{\gamma}_{x\bar{y}} + \tilde{\Delta}_{\bar{x}\bar{y}} \right) \sigma_{AA}^2$$

Table 11.6 Coefficients for the components of genetic covariance for an equilibrium population undergoing mixed selfing and random mating (in proportions of β and $1 - \beta$, respectively). The equilibrium variance in the inbreeding coefficient among individuals is $\sigma_f^2 = f(1 - f^2)/(2 + f)$, with $f = \beta/(2 - \beta)$. (From Cockerham and Weir 1984.)

Relationship	σ_A^2	σ_D^2	σ_{ADI}	σ_{DI}^2	ι^*	$\iota^2 - \iota^*$
Parent and outcrossed offspring	$\frac{1+f}{2}$	0	$\frac{f}{2}$	0	0	0
Parent and selfed offspring	$1+f$	$\frac{1-f}{2}$	$\frac{1+7f}{4}$	f	$\frac{f(1-f)}{2}$	$\frac{\sigma_f^2}{2}$
Parent and mixed offspring	$\frac{1+3f}{2}$	$\frac{2f(1-f)}{2(1+f)}$	$\frac{f(1+3f)}{1+f}$	$\frac{2f^2}{1+f}$	$\frac{f^2(1-f)}{1+f}$	$\frac{f\sigma_f^2}{1+f}$
Selfed sibs	$1+f$	$\frac{1-f}{2}$	$\frac{1+3f}{2}$	$\frac{1+7f}{8}$	$\frac{f(1-f)}{4}$	$\frac{\sigma_f^2}{4}$
Selfed sib and outcrossed sib	$\frac{1+f}{2}$	0	$\frac{1+3f}{8}$	0	0	0
Full sibs	$\frac{1+f}{2}$	$\frac{(1+f)^2}{4}$	0	0	0	0
Half sibs	$\frac{1+f}{4}$	0	0	0	0	0

Here, the double identity measures are analogous to those described in Figure 11.1, with the overbars (on gamete subscripts) denoting that the two gametes contributing to that individual are involved. These coefficients depend upon the previous inbreeding in the population and the amount of recombination that occurs between individuals x and y . The algebraic details may be found in the references given above.

Equation 11.13 provides a practical way to obtain estimates of the quadratic components described in Table 11.1 from estimates of the phenotypic covariances between various types of inbred relatives and solution of the resultant set of equations (the usual method-of-moments approach). An optimal design for such an analysis employs a number of very small populations in order to maximize the temporal change in the identity coefficients and to allow a high degree of replication. For systems of selfing and full-sib mating, there is an added advantage of simplicity in formulating the identity coefficients, as we will now show, while Table 11.6 gives the genetic covariances in populations undergoing mixed selfing and random mating.

If we assume there is negligible linkage, all identity coefficients under obligate self-fertilization can be expressed in terms of the inbreeding coefficient (Cockerham 1983; Wright and Cockerham 1986a; Wright 1988), a point that will be quite useful in Chapter 23, when we examine the response to selection under selfing. For a set of selfed lines derived from a random-mating base population existing in generation 0, the covariance of relatives in generations (of selfing) i and j whose last common ancestor occurred in generation t is

$$\begin{aligned}\sigma_G(x_i, y_j, t) &= (1 + f_t) \sigma_A^2 + \left(\frac{(1 - f_i)(1 - f_j)}{1 - f_t} \right) (\sigma_D^2 + f_t \iota^*) + \left(\frac{f_i + f_j + 2f_t}{2} \right) \sigma_{ADI} \\ &\quad + \left(f_t + \frac{(f_i - f_t)(f_j - f_t)}{2(1 - f_t)} \right) \sigma_{DI}^2 + (1 + f_t)^2 \sigma_{AA}^2\end{aligned}\quad (11.15)$$

where $f_k = 1 - (1/2)^k$. For example, the covariance of a parent in generation t and a descendant in generation j is

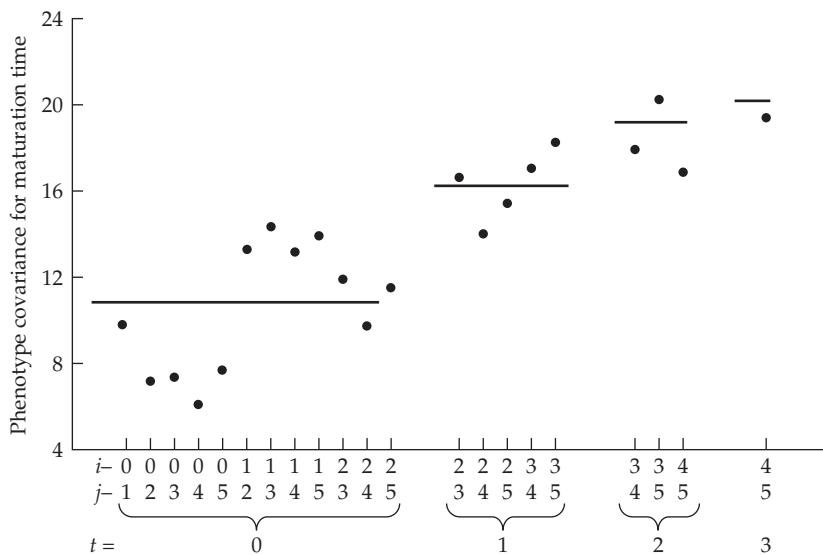

Figure 11.6 Observed covariances between relatives in a selfing series starting from a highly heterozygous F_2 synthetic population (i.e., that formed by all pairwise crosses among a set of lines) of soybeans ($t = 0$). Here i and j denote the generations of the individuals under consideration, and t is the generation of their last common ancestor. For example, the covariance between individuals in generations 2 and 3 with a last common ancestor at generation 0 is indicated by $i = 2$, $j = 3$, $t = 0$. The lines represent the expectations (for a given value of t) under the assumption of an additive model, $(1+f_t)\sigma_A^2$ with $f_t = 1-(1/2)^t$ and $\sigma_A^2 = 10.9$. (Data are from Horner and Weber 1956.)

$$\begin{aligned}\sigma_G(x_t, y_j, t) = & (1 + f_t)\sigma_A^2 + (1 - f_j)(\sigma_D^2 + f_t \iota^*) + \frac{f_j + 3f_t}{2} \sigma_{ADI} \\ & + f_t \sigma_{DI}^2 + (1 + f_t)^2 \sigma_{AA}^2\end{aligned}\quad (11.16)$$

For a parent-offspring analysis, $j = t + 1$. Additional terms involving σ_{AA}^2 and $(t^2 - t^*)$ are required if there are pairs of linked loci with major effects (Cockerham 1983, 1984b).

Although Equation 11.15 applies to an *entire collection* of selfed lines, *within* a single selfed line (from the F_1 of pure-line cross), there are two equally frequent alleles per polymorphic locus, which leads to $\sigma_{ADI} = \sigma_{DI}^2 = 0$ and $\iota^* = \sigma_D^2$. The expected covariance between relatives *within lines* then becomes

$$\sigma_G(x_i, y_j, t) = (1/2)^t \sigma_A^2 + (1/2)^{i+j-t} \sigma_D^2 + (1/2)^{2t} \sigma_{AA}^2 \quad (11.17)$$

(Wright and Cockerham 1986a), which will also prove very useful in Chapter 23 when examining within-line selection. Note that for $t > 5$, the within- and among-population components of variance are very close to 0 and $2\sigma_A^2 + 2\sigma_{ADI}^2 + \sigma_{DI}^2 + 4\sigma_{AA}^2$, respectively. Wright (1987) extended Equation 11.17 to include additive \times dominance and dominance \times dominance epistasis, but even in the absence of linkage, 12 terms are necessary to define the genetic covariance in this case.

An example of the utility of the selfing theory is provided by a study with soybeans, a predominantly self-fertilizing species (Horner and Weber 1956). Two inbred varieties were crossed to produce a uniform F_1 population, which was then selfed to produce a segregating F_2 population. Random F_2 plants were then selfed to produce F_3 plants, and so on down to the F_7 . The covariances between many possible types of relatives for the timing of seed maturation were then assessed. Under a simple additive genetic model, Equation 11.15 reduces to

$$\sigma_{G_i}(x_i, y_i, t) = (1 + f_t)\sigma_A^2$$

which indicates that the genetic covariances of all types of direct descendants from generation t plants should be independent of i and j . The observed covariances are in fair accord with these expectations with $\sigma_A^2 = 10.9$ (Figure 11.6). Although there is a certain amount of noise in the data, the inclusion of other base-population properties does not significantly improve the fit, and it is likely that some of the scatter in the data is caused by year-to-year differences in growth conditions.

For the special case of full-sib mating, Cornelius and Dudley (1975) provided a general solution (ignoring epistasis and linkage) for the covariance between parents and descendants, full-sibs, and uncle (or aunt) and niece (or nephew). They presented tables of the coefficients needed for Equation 11.13 for the first eight generations of consanguineous mating. Cockerham (1971) derived a transition matrix that allows the computation of all of the coefficients for the covariance between full-sibs,

$$\begin{pmatrix} 1 - \Delta_1 \\ 1 - \Delta_3 \\ 1 - \Delta_7 \\ 1 - \Delta_2 \\ 1 - f \\ 1 - \Theta \end{pmatrix}_{t+1} = \begin{pmatrix} 1/4 & 1/2 & 0 & 0 & 0 & 1/4 \\ 0 & 1/2 & 0 & 0 & 0 & 1/2 \\ 0 & 1/4 & 1/8 & 1/8 & 1/4 & 1/8 \\ 0 & 1/2 & 1/4 & 0 & 0 & 1/4 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 1/4 & 1/2 \end{pmatrix} \begin{pmatrix} 1 - \Delta_1 \\ 1 - \Delta_3 \\ 1 - \Delta_7 \\ 1 - \Delta_2 \\ 1 - f \\ 1 - \Theta \end{pmatrix}_t \quad (11.18)$$

where in this case $\Delta_3 = \Delta_5$.

In closing, it needs to be emphasized that all of the expressions developed above have been written in terms of the quadratic components for the random-mating base population. Provided that mating remains random in a small population, there is no reason why the simpler and more familiar expressions of LW Chapter 5 cannot be relied upon, provided it is understood that the variance and covariance components apply to the *current population*. For example, the expected genetic covariance between half-sibs in generation t may be written either as $\sigma_A^2(t)/4$ or in terms of base-population properties with Equation 11.13. The advantage of interpreting the covariance between relatives in terms of the base population properties is that it provides a mechanistic explanation for the temporal changes in the usual components of variance, $\sigma_A^2(t)$ and $\sigma_D^2(t)$.

REML Estimates

As with all approaches to variance-component estimation, comparisons among appropriate sets of relatives (to provide the correct independent contrasts) can be used to estimate σ_{ADI} , σ_{DI}^2 , and ι^* . One can use specific crossing designs to ensure that modest to large numbers of the correct types of relatives are included. More generally, one can potentially use pedigree data, provided there is sufficient inbreeding. Both of these settings can be handled under the very flexible mixed-model framework offered by REML variance estimation (Chapters 19, 20, and 22; LW Chapter 27). The basic idea is that the covariance matrix, \mathbf{V} , for the vector, \mathbf{y} , of observations (sets of relatives, where $V_{ij} = \sigma[y_i, y_j]$) can be decomposed into the sum of the products of appropriate relationship matrices times their associated quadratic components. From Equation 11.13, and ignoring epistasis,

$$\mathbf{V} = \text{Cov}(\mathbf{y}) = \sigma_A^2 \mathbf{A} + \sigma_D^2 \mathbf{D} + \sigma_{DI}^2 \mathbf{M}_1 + \sigma_{ADI} \mathbf{M}_2 + \iota^* \mathbf{M}_3 + \sigma_e^2 \mathbf{V}_e \quad (11.19a)$$

where $\mathbf{A}_{ij} = 2\Theta_{ij}$ is the (additive) relationship matrix (Chapters 19, 20, and 22; LW Chapters 26 and 27), $\mathbf{D}_{ij} = \Delta_{7ij}$ is the dominance relationship matrix, \mathbf{V}_e is the residual covariance structure (often assumed to be $\mathbf{V}_e = \mathbf{I}$, implying independent and homoscedastic residuals), and the elements of the other three relationship matrices are given by

$$\mathbf{M}_{1ij} = \Delta_{1ij}, \quad \mathbf{M}_{2ij} = 2\Delta_{1ij} + \Delta_{3ij} + \Delta_{5ij}, \quad \mathbf{M}_{3ij} = \Delta_{2ij} - f_i f_j \quad (11.19b)$$

as obtained by Smith and Mäki-Tanila (1990), de Boer and Hoeschele (1993), Shaw and Woolliams (1999), and Abney et al. (2000). This approach is computationally demanding,

Table 11.7 Average values for all nine Δ_i coefficients for all 324,415 pairwise combinations of a measured set of 806 individuals from a 13-generation pedigree of South Dakota Hutterites. A religious sect originally from the Tyrolean Alps, Hutterites are well-studied by human geneticists as all extant individuals can be traced by genealogical records back to less than 90 ancestors from the 1700s to the early 1800s. This table shows the power (or lack thereof) for computing the various genetic components that appear in Equation 11.13. For example, information to estimate σ_{DI}^2 comes from the roughly 70 pairs ($324,415 \cdot 0.000217$) that are expected to involve Δ_1 . (From Abney et al. 2000.)

Δ_1	Δ_2	Δ_3, Δ_5	Δ_4, Δ_6	Δ_7	Δ_8	Δ_9
0.000217	0.000993	0.00411	0.0283	0.00444	0.141	0.788

as the standard iterative approach used to obtain the REML estimates must invert the \mathbf{V} matrix following each update of its component variances (LW Chapter 27).

Two historical approaches have been used to obtain the simplest relationship matrix, \mathbf{A} , given a pedigree. Wright (1921a) used path analysis (counting all paths connecting two individuals within a pedigree), while Emik and Terrill (1949) and Crudent (1949) introduced the **tabular method**, a quicker approach that starts with the founding relatives and tabulates the relationships forward in each generation. Extensions of both approaches have been proposed to calculate the more general relationships, Δ_i , needed for the matrices in Equation 11.19: path analysis approaches were proposed by Jacquard (1966) and Nadot and Vaysseix (1973), and tabular methods by Smith and Mäiki-Tanila (1990). Issues with pedigree-free (i.e., marker based) estimates of the Δ_i are examined by García-Cortés et al. (2014) and Ackerman et al. (2017).

The central issue of whether a pedigree/designed cross is able to uniquely estimate each quadratic component is the concept of **identifiability** (Rothenberg 1971; Jiang 1996), discussed in Chapter 22. This is the random-effects counterpart of the concept of estimability for fixed effects (LW Chapter 26). Basically, variance components can be uniquely estimated, *provided* the relationship matrices are sufficiently independent of each other. For example, from Equation 11.16, the among-(selfed)-line variation for $t > 5$ is essentially $2\sigma_A^2 + 2\sigma_{ADI} + \sigma_{DI}^2$, so that these three components are fully confounded and not separable if the data consist of only the between-line variance for a series of lines with (say) 5, 10, and 15 generations of selfing. Power is another issue. If a relationship matrix is sparse (contains mostly zeros), then even a large dataset may not have much power, as the numbers in the required identity classes may be quite small (Table 11.7).

Empirical Observations

Unfortunately, data on the parameters σ_{DI}^2 , σ_{ADI} , and ι^* are scant, although some progress has been made with annual plants. Starting from a random-mating base population of maize, Cornelius (1988) produced a series of selfed and full-sib mated lines, all of which were assayed in a common-garden experiment. The parameter estimates given in Table 11.8 best describe the overall set of observed covariances. Except for yield, all of the characters exhibit significant additive genetic variance, and four of the six traits exhibit significant squared inbreeding effects, ι^* . However, nearly all of the estimates for σ_D^2 , σ_{DI}^2 , and σ_{ADI} are nonsignificant. In part, this is clearly a power issue, as the significant inbreeding depression implies the presence of dominance.

The few other attempts to estimate quadratic components involving inbreeding have yielded mixed results. For example, starting with 300 inbred lines of the monkeyflower (*Mimulus guttatus*), Kelly and Arathi (2003) crossed triplets of lines to create outbred full-sib and half-sib families, allowing a joint analysis of σ_A^2 , σ_D^2 , σ_{DI}^2 , and σ_{ADI} for six floral traits. Although each character exhibited significant inbreeding depression, and σ_D^2 was significant for two traits and σ_{DI}^2 was significant for six traits, σ_{ADI} was significant in only one case. In a study of another flowering plant, *Nemophila menziesii*, >1000 plants with f up to 0.75 were

Table 11.8 Estimates of the quadratic components of Equation 11.13 from phenotypic data on selfed and full-sib mated lines derived from a panmictic base population of maize. The parameter estimates, which were obtained by a maximum-likelihood procedure, are those that give the overall best fit to a large number of observed relationships. (From Cornelius 1988.)

evaluated in a common garden for two morphological and two floral traits (Shaw et al. 1998). A REML analysis revealed significant inbreeding depression for all traits, but σ_{DI}^2 was significant only for the floral traits, and σ_{ADI} was uniformly nonsignificant.

Approaches based entirely on pedigree data (as opposed to defined crossed populations) have been much less successful. Hoeschele and Vollema (1993) obtained inconsistent estimates of the inbreeding quadratic terms for milk and fat yield in Holsteins, using least-squares on subsets of the data. Shaw and Woolliams (1999) used REML to study a pedigree of 2000 sheep with variable inbreeding up to a high of $f = 0.6$, but found no evidence for significant σ_{DI}^2 or σ_{ADI} for body weight or fleece quality, despite the presence of significant inbreeding depression for both. The application of REML to humans by Abney et al. (2000) found no significant inbreeding quadratic components for a cholesterol measure (HDL) in a population of Hutterites, but this may have been a consequence of lack of power. Table 11.7 makes the key point that the effective numbers of individuals in these relationship classes needed to estimate σ_{DI}^2 , σ_{ADI} , and ι^* are expected to be small in most pedigrees, even those that are rather inbred. By contrast, a controlled crossing design can generate large numbers of the appropriate sets of relatives.

Kelly (1999c) suggested a selection-based approach to estimate the ratio of σ_{ADI}/σ_A^2 as a test for rare recessives. His motivation can be seen in the figure for Example 11.1, where $\sigma_{ADI}/\sigma_A^2 > 1$ for a rare recessive (allele frequency, p , is small), while for intermediate allele frequencies, this ratio is close to zero, or even negative. Kelly's idea (examined more fully in Chapter 28) is to compare the change in mean, ΔM , and the change in the inbreeding depression coefficient, ΔB , following selection, as he noted that $\Delta B/\Delta M$ tracks σ_{ADI}/σ_A^2 . Significant, and negative, estimates of this ratio were seen following artificial selection experiments on flower size in *Mimulus guttatus* (Kelly and Willis 2001), and in female fecundity in *Drosophila melanogaster* (Charlesworth et al. 2007), suggesting significant, and negative, estimates of σ_{ADI} , as well as the presence of recessive alleles at intermediate frequencies in these traits.

Although these limited surveys do not rule out important contributions from quadratic inbreeding components in some cases, combined with the observations on the dynamics of genetic variance described above, they do raise questions about the general necessity of incorporating such complexities into expressions for genetic variances and covariances. Again, this is not to deny an important role for dominance and epistasis in the expression of complex traits, for which the evidence is substantial (Wolf et al. 1980; Lynch and Walsh 1998). However, despite arguments to the contrary (Templeton 1980; Nelsen et al. 2013), there is little compelling evidence that we need to abandon the existing theoretical framework for quantitative-trait evolution, even in the presence of substantial physiological epistasis. Although substantial progress has been made in incorporating the complexities of nonadditive gene action into the theory of quantitative traits in finite populations, the limited empirical evidence to date implies a second-order nature of such effects.

DRIFT-MUTATION EQUILIBRIUM

The models introduced in the previous sections predict that finite populations eventually lose all of their genetic variation, at which point the genotypic means of isolated populations will have attained a maximum level of divergence. These results arose because we assumed there was an absence of significant evolutionary forces countering the loss of variance caused by random genetic drift. In reality, however, there is one such force that cannot be prevented—the continual input of new variation by polygenic mutation. When this is accounted for, we can expect neutral quantitative traits to approach an equilibrium level of within-population variance as a balance is struck between the opposing forces of drift and mutation. The means of such characters should also continue to diverge as isolated populations become fixed for unique mutations, a subject that will be dealt with in detail in Chapter 12. We also explore the within-population drift-mutation variance in more detail in Chapter 28, as part of a larger discussion on what forces account for the observed levels of quantitative-genetic variation.

Consider a character with a purely additive genetic basis in a population with a constant effective size. In each generation, a fraction $1/(2N_e)$ of the genetic variation is lost by drift, while new variation in the amount σ_m^2 is introduced by mutation. In mechanistic terms, σ_m^2 is defined as $2 \sum_{i=1}^n \mu_i E(a_i^2)$, where μ_i denotes the per-locus mutation rate for gene i , n denotes the number of loci contributing to the trait, and $E(a_i^2)$ is the average squared heterozygous effect of a new mutation on the phenotypic value (LW Chapter 12). This leads to the simple recursion equation,

$$\sigma_A^2(t) = \left(1 - \frac{1}{2N_e}\right) \sigma_A^2(t-1) + \sigma_m^2 \quad (11.20a)$$

(Clayton and Robertson 1955), which has the approximate solution

$$\sigma_A^2(t) = 2N_e\sigma_m^2 + [\sigma_A^2(0) - 2N_e\sigma_m^2] \exp(-t/2N_e) \quad (11.20b)$$

Thus, the equilibrium (obtained as $t \rightarrow \infty$) genetic variance for a neutral quantitative trait with an additive genetic basis is simply

$$\sigma_A^2(\infty) = \tilde{\sigma}_A^2 = 2N_e\sigma_m^2 \quad (11.20c)$$

(Lande 1976; Chakraborty and Nei 1982; Lynch and Hill 1986). Starting from a completely homozygous base population, the times to 50% and 95% of the equilibrium variance are approximately $1.4N_e$ and $6.0N_e$ generations, respectively (Lynch and Hill 1986). Note that this time to converge to the equilibrium is *independent* of the mutational variance, σ_m^2 . Because $\sigma_A^2(0)$ will typically be greater than zero, small isolated populations can be expected to reach the equilibrium quite rapidly. On the other hand, if a population is suddenly reduced to an unusually small N_e , such that $\sigma_A^2(0) \gg 2N_e\sigma_m^2$, for the several generations immediately following the bottleneck, $\sigma_A^2(t) \simeq \sigma_A^2(0)e^{-t/2N_e}$, justifying the use of Equation 11.2 for the short term.

If we let $h_m^2 = \sigma_m^2/\sigma_E^2$, where σ_E^2 is the environmental variance of the trait, be the **mutational heritability** and again assuming additivity of genetic effects, the expected equilibrium heritability for a neutral character under the model given by Equation 11.20b is

$$\tilde{h}^2 = \frac{\tilde{\sigma}_A^2}{\tilde{\sigma}_A^2 + \sigma_E^2} = \frac{2N_e\sigma_m^2}{2N_e\sigma_m^2 + \sigma_E^2} = \frac{2N_e h_m^2}{2N_e h_m^2 + 1} \quad (11.21a)$$

Almost all estimates of h_m^2 are in the range of 0.01 to 0.0001 with a median value near 0.001 (LW Chapter 12). Thus, populations with $N_e \simeq 100$ are expected to have small to moderate levels of heritability for neutral characters, but nearly all of the phenotypic variation for neutral characters is expected to have a genetic basis if $N_e > 10^4$ (Figure 11.7).

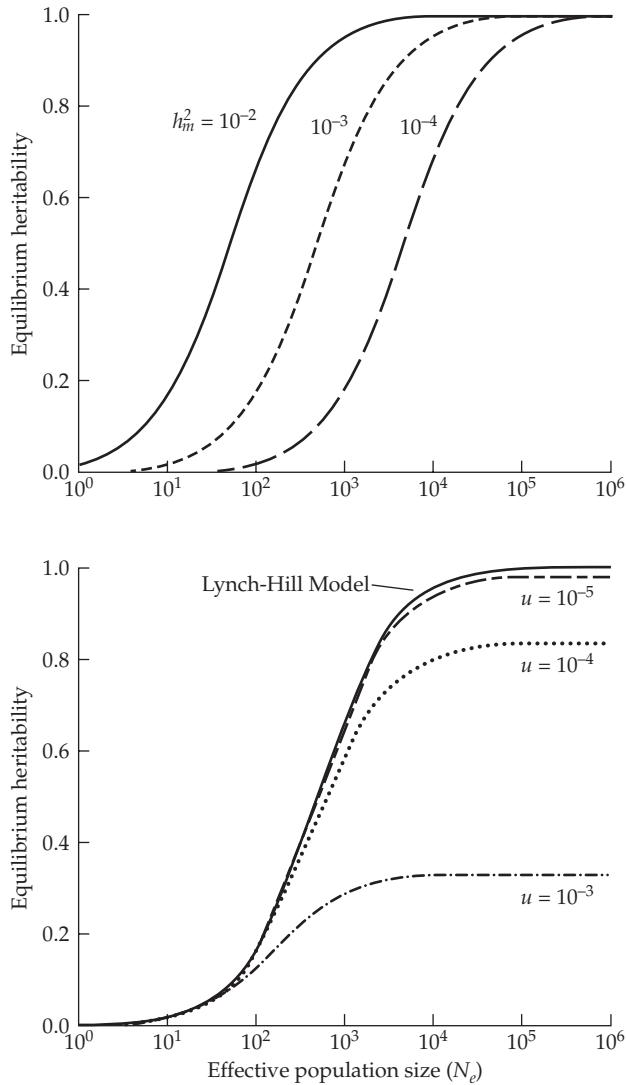

Figure 11.7 (Top) Levels of heritability expected for neutral characters with an additive genetic basis under drift-mutation equilibrium, assuming the Lynch-Hill (1986) incremental (i.e., Brownian-motion) model. The three levels of mutational heritability, σ_m^2/σ_E^2 , span the range of observed values. (Bottom) Comparison of the predictions of the Lynch-Hill model (solid line) with that of the Cockerham-Tachida model for three different gametic mutation rates for the trait (dotted and dashed lines), with $h_m^2 = 0.001$ in both cases.

It is informative to note the similarity of Equation 11.21a with the expected heterozygosity for sites in drift-mutation equilibrium

$$E(H) = \frac{4N_e\mu_0}{1 + 4N_e\mu_0} \quad (11.21b)$$

where μ_0 is the per nucleotide mutation rate (derived in Chapter 2). A comparison of these two expressions shows that because μ_0 is on the order of 10^{-9} to 10^{-8} (Chapter 4) while $h_m^2 \approx 10^{-3}$, substantial heritability can exist for quantitative traits in populations with low or undetectable levels of molecular heterozygosity.

Lynch and Hill (1986) generalized the preceding results to allow for dominance and linkage. Let $a(1 + k)$ denote the value of a heterozygote. If we assume a population size small enough that no more than two alleles are likely to be segregating simultaneously per

locus, and letting \bar{k} and σ_k^2 be the mean and variance of dominance effects, with $k = 0$ implying additivity, the equilibrium levels of additive and dominance genetic variance are

$$\tilde{\sigma}_A^2 \simeq \frac{2N_e\sigma_m^2(3 + 2\bar{k})}{3} \quad (11.22a)$$

$$\tilde{\sigma}_D^2 \simeq \frac{2N_e\sigma_m^2(\bar{k}^2 + \sigma_k^2)}{3} \quad (11.22b)$$

Thus, unless new mutations tend to be highly dominant, highly recessive, or highly variable in their dominance effects, most of the genetic variation will be additive in nature. If we assume that there is no overdominance, the bounds on $\tilde{\sigma}_A^2$ are $(2/3)N_e\sigma_m^2$ and $(10/3)N_e\sigma_m^2$. Although these formulae ignore the fact, discussed above, that dominant mutations in gametic-phase disequilibrium can inflate the genetic variance, this effect only magnifies the variance by a factor of approximately $0.02\bar{a}\bar{k}/\bar{a}^2$, which is unlikely to be very large (Lynch and Hill 1986).

The preceding results were obtained by use of Kimura and Crow's (1964) **infinite-alleles model**, which postulates that although a large number of alleles need not be segregating at a particular locus at any point in time, each new mutation gives rise to a novel allele. From a quantitative-genetic perspective, the additive effect of each new mutant allele is assumed to equal to that of the ancestral allele plus a random deviate with a mean of zero. Under this **Brownian-motion (or incremental)** model of mutational effects, there is no directional change of the mean but also no upper or lower bound on the range of mutational effects. This implies that $\sigma_A^2 \rightarrow \infty$ as $N_e \rightarrow \infty$.

Taking exception to this assumption, Cockerham and Tachida (1987) assumed a finite number of possible additive allelic states, with new (mutant) allelic effects following the so-called **house-of-cards model** of Kingman (1977, 1978). Under this model, each new mutant allele has a new effect drawn randomly from the distribution of possible effects and independent of the prior state (so that new mutations collapse the previous allelic values like a house of cards). Hence, unlike under the Brownian motion model, allelic effects remain bounded, rather than wandering off to infinity. Under these conditions, the equilibrium genetic variance within a finite population becomes $\tilde{\sigma}_A^2 = E(H)\sigma_A^2(\infty)$, where $\sigma_A^2(\infty)$ is the equilibrium level of genetic variance expected in a hypothetical population of infinite size, and $E(H)$ is the equilibrium heterozygosity for the loci underlying the trait. Under the Cockerham-Tachida model, $\sigma_A^2(\infty) = nE(a^2)$, and $E(H)$ is defined by Equation 11.21b. Thus, when $4N_e\mu \ll 1$ (with μ being the per-locus rate at which new alleles appear, with $\mu = L\mu_0$ for a locus of length L nucleotides, where μ_0 is the per-nucleotide mutation rate), the Cockerham-Tachida expression for the equilibrium variance is very close to $4N_e\mu nE(a^2) = 2N_e\sigma_m^2$, which is identical to the Lynch-Hill expression.

As it is not likely that mutant alleles will have effects that are entirely independent of their ancestral alleles, nor that mutational effects can grow without bounds, reality must lie between these two extremes. Zeng and Cockerham (1993) presented a **regression model** approach that joins these two limiting cases. They imagined a situation in which the effect of a mutant allele (a_m) is that of a random deviate around a linear regression on the ancestral state (a_0), i.e.,

$$a_m = \tau a_0 + e_a \quad (11.23)$$

where e_a denotes the deviation around the expectation. When $\tau = 1$, Equation 11.23 is equivalent to the Lynch-Hill (incremental) model, whereas when $\tau = 0$, it is equivalent to the Cockerham-Tachida (house-of-cards) model. The general solution to the equilibrium additive genetic variance under this model is

$$\tilde{\sigma}_A^2 = \frac{2N_e\sigma_m^2}{1 + 4N_e\mu(1 - \tau)} \simeq \begin{cases} 2N_e\sigma_m^2 & \text{for } 4N_e\mu \ll 1 \\ \frac{\sigma_m^2}{2\mu(1 - \tau)} & \text{for } 4N_e\mu \gg 1 \end{cases} \quad (11.24)$$

Thus, both the house-of-cards and regression models predict a linear increase in the equilibrium genetic variance with population size so long as N_e is smaller than the reciprocal of the mutation rate to alleles affecting quantitative-trait expression ($4N_e\mu \ll 1$). As noted in Chapter 4, when defined at the nucleotide level, $4N_e\mu$ is generally in the range of 0.001 to 0.05 in eukaryotes. Because a typical protein-coding locus contains ~ 1000 sites where a nucleotide substitution can result in an amino acid replacement, and regulatory sequences may comprise another 100 to 2000 sites per gene (Lynch 2007), then if we assume that a moderate fraction of such sites yield mutations with phenotypic effects, a typical mutational target size per locus will be on the order of $L \sim 10^3$ sites. Recalling the survey in Chapter 4, the mutation rate per site per generation is $\mu_0 \sim 10^{-9}$ in microbes and a high of 10^{-8} in humans: thus $\mu = L\mu_0$ for a quantitative-trait locus is expected to be in the range of 10^{-6} to 10^{-5} . We revisit these mutational models in detail in Chapter 28.

Finally, due to the randomness of both the drift and mutation processes, the within-population genetic variance is expected to vary considerably around its expectation both among populations of the same size and from generation to generation in the same population. Assuming that there is a large number of unlinked loci, the coefficient of variation of the average within-population genetic variance under the infinite-alleles model is

$$\text{CV}(\tilde{\sigma}_A^2) \simeq \left[\frac{1}{L} \left(\frac{E(a^4)}{12N_e U [E(a^2)]^2} + \frac{2}{3N_e} + \frac{2}{s} \right) \right]^{1/2} \quad (11.25)$$

where $U = n\mu$ is the gametic mutation rate for the trait, L is the number of lines examined, and s is the sample size per line (Lynch and Hill 1986; Keightley and Hill 1989; Zeng and Cockerham 1991). If the effects of new mutations are approximately normal, with an average of zero, then $E(a^4) = 3[E(a^2)]^2$. Further considering only the true evolutionary variance, and assuming $\mu \ll 1$, the CV for a single line reduces to $\simeq (4N_e U)^{-1/2}$, or the inverse of the square root of twice the effective number of new mutations entering the population per generation. Bürger and Lande (1994) further considered the temporal correlation in σ_A^2 over consecutive generations.

Subdivided Populations

In closing, we emphasize that the results given in the previous section apply to the ideal situation in which individual demes are completely isolated from each other. In nature, however, it is common for a total metapopulation to be fragmented into multiple demes held together in a genealogical sense by restricted gene flow. Borrowing from results presented in Chapter 3, we now explore the quantitative-genetic consequences of population subdivision. Throughout, it will be assumed that there is some possible migratory route, either direct or indirect, between all pairs of demes under consideration. In other words, even if two particular demes are incapable of directly exchanging genes, they are assumed to be connected by a corridor through other subpopulations. In this case, at least for characters with an additive genetic basis following the Lynch-Hill model, the average within-deme genetic variance exhibits some remarkably general behavior, although the results for traits with a nonadditive genetic basis remain to be worked out.

Recall Wright's (1951) ideal island model, discussed in Chapter 2, in which the metapopulation consists of d demes, each comprised of an equivalent number (N) of (ideally) randomly mating individuals, with each deme contributing an identical fraction, m , of its genes to a pool of migratory genes. Under this model, with equal exchange rates between all deme pairs, the migration rate from any subpopulation to any other is $m/(d-1)$. In Chapter 2, we noted the geographic invariance principle for this model under neutrality, which indicates that the mean coalescence time between random alleles within a deme is simply equal to $2dN$, independent of the migration rate (Li 1976; Slatkin 1987b; Strobeck 1987; Nagylaki 2000). If we let μ be the per-locus mutation rate, it then follows that the mean number of mutations separating two random alleles is $4dN\mu$, or more generally $4N_T\mu$ with unequal deme sizes (Slatkin 1987b; Strobeck 1987), where $N_T = \sum_{i=1}^d N_i$ is the sum of effective sizes of the individual demes. If we note that the contribution of each haploid mutational change

to the genetic variance is $E(a^2)/2$, with $2n$ genes contributing to the character, the average within-deme additive genetic variance is

$$\sigma_A^2 = 4N_T\mu \cdot 2n \cdot E(a^2)/2 = 2N_T\sigma_m^2 \quad (11.26)$$

which is identical in form to the expectation for a single isolated deme, $2N_e\sigma_m^2$, but with N_T being substituted for the N_e of a single deme. Depending on the exact population structure, individual demes may have higher or lower equilibrium variances than this quantity, but Equation 11.26 gives the expectation over all demes.

That the preceding result was obtained by a much more detailed route by Lynch (1988b) for two demes and Lande (1992) for an arbitrary number of demes illustrates the substantial utility of results from coalescence theory (Chapter 2) for problems in quantitative genetics involving traits with an additive-genetic basis. As anticipated from the coalescent, with an ideal island structure, the equilibrium additive-genetic variance is not only completely independent of the migration rate (provided that it is nonzero), but most remarkably, it behaves as though the average deme were panmictic, with an effective size of N_T . Although lower migration rates imply a lower rate of replenishment of alleles lost locally by random genetic drift, a greater degree of isolation also increases the level of the interpopulation divergence of alleles, so that a rare immigration event will likely introduce a more substantial allelic variant. Under the ideal island model, these two opposing effects perfectly compensate for each other.

Because the expected coalescence time, $2Nd$, applies to all types of population structures, so long as they allow for migratory routes between all pairs of subpopulations, this result generalizes to situations well beyond the ideal island model, including the **stepping-stone model**, in which migration events are restricted to adjacent demes. Slatkin and Voelml (1991) evaluated the genealogical properties of a population with a hierarchical metapopulation where there are k neighborhoods, each containing d demes, and even this structure yields a result analogous to that presented above. Again, provided that there are potential migratory routes between demes within neighborhoods as well as between neighborhoods, the expected genetic variance within a deme can be shown to be $\sigma_A^2 = 2Nkd\sigma_m^2$, where Nkd is the sum of demic effective population sizes (over all neighborhoods). Thus, we again see that provided the trait has an additive genetic basis, the expected within-population additive variance under neutrality (and assuming the Lynch-Hill model) is $2N_T\sigma_m^2$. This result does assume that gametic-phase disequilibria do not substantially influence the expected standing level of variation, but this is reasonable for a neutral trait, as there will be no tendency for disequilbria to favor coupling over repulsion effects.

These results apply to the variation within single demes, and it is of additional interest to determine the equilibrium features of the entire metapopulation. This requires a measure of among-deme divergence in addition to the within-deme variance, as the total genetic variation in the metapopulation is the sum of the two. This matter is also readily resolved using results from coalescence theory, again assuming a neutral character with an additive genetic basis. Consider, for example, Wright's island model. If two genes are randomly drawn from an entire metapopulation, they will be derived from the same subpopulation with a probability of $1/d$, in which case they will have an average coalescence time of $2Nd$ generations, and from different subpopulations with a probability of $(d-1)/d$, in which case they will have an elevated average coalescence time of $2Nd + [(d-1)/(2m)]$ as a consequence of divergence during isolation (Li 1976). Weighting these two coalescence times by their respective probabilities yields the average coalescence time given, as Equation 2.45b. Again noting that the expected number of mutations separating two alleles is 2μ times the average coalescence time, and that there are $2n$ genes involved, each with respective contributions to the variance of $E(a^2)/2$, the total additive genetic variance for the metapopulation is

$$\sigma_{A,T}^2 = \left(2Nd + \frac{(d-1)^2}{2dm} \right) \sigma_m^2 \quad (11.27)$$

Again, essentially the same result was obtained by Lande (1992) by a more circuitous route.

Thus, for the island model, the within- and among-deme components of additive-genetic variance are equal to $2Nd\sigma_m^2$ and $[(d - 1)^2/(2dm)]\sigma_m^2$, respectively. Recalling that $m/(d - 1)$ is the genic migration rate per deme, this shows that the among-deme component of genetic variance is inversely proportional to the exchange rate among demes. It is also notable that the among-deme component of genetic variance is completely independent of the sizes of the individual demes. If we assume that there is a large d , the fraction of the total genetic variance associated with the interdemic component is $1/(1 + 4Nm)$, showing that under this type of population structure, the relative contribution from interdemic variance is low unless the expected number of migrants per deme per generation (mN) is less than one.

Note that Equation 11.27 can be obtained directly from our general expression for the equilibrium additive-genetic variance, $2N_e\sigma_m^2$, using the coalescent-based definition of N_e for the entire metapopulation under the island model, Equation 2.45b. Using this general strategy, the expressions for N_e given in Chapter 3 can be used to obtain results for a variety of other types of population structures. Moreover, as summarized in Lynch (1994), coalescent results can also be used to estimate the genetic variances and covariances for pairs of populations separated by various distances for assessing situations in which migration is spatially restricted. Provided there are possible migratory routes between demes, the expected excess variance between any pair of demes is simply the product of the coalescence time (in excess of the within-deme expectation) and the rate of polygenic mutation, σ_m^2 .

12

The Neutral Divergence of Quantitative Traits

From the perspective of the evolutionary biologist, missing or incomplete null or neutral models for many omics data (for example, transcriptome and metabolome data) limit our understanding of how selection has shaped their evolution. Leinonen et al. (2013)

In the preceding chapter, we learned how the opposing forces of random genetic drift and mutation lead to an equilibrium level of within-population genetic variance. In contrast, the phenotypic variance among isolated populations may continue to increase nearly indefinitely for neutral characters, as isolated demes or species recurrently acquire and become fixed for independent mutations. Here, we explore neutral factors that can drive the evolutionary dynamics of the among-population variance. As in Chapter 11, we will start with the situation in which the time span is short enough that most of the change in population-mean phenotypes is driven by drift acting on existing variation rather than by new alleles introduced by mutation. We then explore the consequences of longer-term divergence, with mutation playing an increasingly dominant role, and show that eventually, the rate of divergence for neutral characters may become essentially independent of local effective population sizes. We conclude by using this theory to develop statistical tests of whether an observed pattern of phenotypic divergence is consistent with a model of strict neutral drift and mutation.

Although few quantitative traits may actually evolve in a purely neutral fashion, a more compelling case for selection can always be made if the hypothesis of neutrality can be formally rejected. For example, an observed divergence of isolated lines that is significantly less than the neutral expectation provides evidence of stabilizing selection, whereas the reverse supports a role for diversifying selection. In addition, as populations become diminishingly small in size, drift begins to overwhelm selection, promoting nearly neutral patterns of evolution.

Tests for departures from neutral-trait divergence come in several different forms. First, one can compare the observed rate of divergence in the trait mean with the rate that would be expected given estimates of the effective population size, time, and genetic variation. Second, one may have a time series of data (such as a fossil record sequence) and test whether the observed pattern is more consistent with a neutral random walk, a biased random walk, or stasis. Third, one can compare the within- and between-population structure of the genetic variance of a candidate trait (measured by Q_{ST}) against a genome-wide estimate based on markers that are presumed neutral (F_{ST}). Finally, a number of **trait-augmented marker-based approaches** have been proposed. These use markers from either a QTL or a GWAS study (and hence require a candidate trait to chose the set of markers being examined). Examples include tests based on the distribution of QTL effects detected by crossing two divergent lines and tests using GWAS marker information (such as comparing marker-allele frequencies between two populations).

This highly diverse collection of neutral divergence tests has been applied to an equally diverse collection of traits, ranging from studies of morphological changes in the fossil record to evaluations of evolutionary forces shaping omics data. To highlight the latter, we conclude the chapter by applying several of these approaches to examine if (and if so, how) divergence in gene expression departs from neutrality. Chapters 8–10 considered the complementary topic of tests for departures from neutrality at specific *loci*, as opposed to our focus here, which is specific *traits*.

SHORT-TERM DIVERGENCE

We start with the special case in which all gene action is additive and random genetic drift is the only evolutionary force. Most of the predictions of this model can be expressed in terms of two observable quantities: the additive genetic variance in the base population, $\sigma_A^2(0)$, and the effective population sizes, N_e , of the isolated lineages. The expected among-population genetic variance, $\sigma_B^2(t)$, under neutrality is obtained by noting that the mean genotypic value at a diallelic locus i is $2a_i p_i$ (there being two genes per locus, each with additive effect a_i with probability of p_i , and effect 0 with probability $1 - p_i$). The variance among populations for this locus is (from the definition of the variance), $E\{[2a_i p_i(t)]^2\} - \{E[2a_i p_i(t)]\}^2$, which simplifies to

$$4a_i^2 (E\{[p_i(t)]^2\} - \{E[p_i(t)]\}^2) = 4a_i^2 \sigma_{p_i}^2(t),$$

where $\sigma_{p_i}^2(t)$ is the expected among-population variance in allele frequency. Summing over all loci, assuming negligible gametic-phase disequilibrium, and substituting from Equation 2.14a yields

$$\sigma_B^2(t) = 4 \sum_{i=1}^n a_i^2 p_i(0)[1 - p_i(0)] \left\{ \frac{1}{N_{fo}} + \left[1 - \left(1 - \frac{1}{2N_e} \right)^t \right] \right\} \quad (12.1a)$$

$$= \left(\frac{1}{N_{fo}} + 2f_t \right) \sigma_A^2(0) \quad (12.1b)$$

where N_{fo} is the effective number of founders per line, the inbreeding coefficient (f_t) follows from Equation 2.4c, and the time index is defined such that $t = 0$ denotes the final generation of the base population and $t = 1$ denotes the founding generation for the isolated lines. Equation 12.1 shows that, under the assumptions of this ideal model, the expected variance among genotypic means of isolated populations increases linearly with the inbreeding coefficient, asymptotically approaching a limit (as $f_t \rightarrow 1$) that is very close to twice the additive genetic variance in the base population (Wright 1951). Under the assumption of additivity, Equation 12.1b holds regardless of the number of alleles at the underlying loci.

If we ignore the generally minor contribution (N_{fo}^{-1}) from the baseline founder effect, this limiting result may be obtained in a simpler manner. Because the probability of fixation of a neutral allele is equal to its initial frequency, when the process of random drift is completed, a proportion $p_i(0)$ of the populations will have genotypic value $2a_i$, while the remaining proportion, $1 - p_i(0)$, will have genotypic value 0. The mean genotypic value is, therefore, $2a_i p_i(0)$ and the mean squared value is $(2a_i)^2 p_i(0)$, which yields the among-population variance, $4a_i^2 p_i(0)[1 - p_i(0)] = 2\sigma_{A_i}^2(0)$.

The expression for $\sigma_B^2(t)$ given by Equation 12.1 only considers the true genetic divergence among lines (the **evolutionary variance**), which can, in principle, be obtained by an analysis of variance of phenotypic variation within and among lines. If, however, one simply focuses on the raw variance of the observed means, additional sources of variation associated with finite sample sizes also contribute to the observed divergence (Hill 1972a; Lynch 1988a). For example, when the mean phenotype of each line is estimated using n progeny from $N/2$ matings (involving $N/2$ males and females, for a total parental sample size of N), there can be three additional sources of variance to add to Equation 12.1:

- (i) The **segregational variance**, $(1 - f_{t-1})\sigma_A^2(0)/(Nn)$, of the mean offspring value about the mean breeding value of their parents resulting from the sampling of $Nn/2$ individuals. This follows because the segregational variance (in the absence of linkage disequilibrium) equals half the additive variance (Chapters 16 and 24);
- (ii) The **maternal sampling variance**, $\sigma_{E_m}^2/(N/2)$, associated with any maternal effects resulting from the sampling of $N/2$ mothers;
- (iii) The **residual variance**, $\sigma_{E_s}^2/(Nn/2)$, associated with special environmental effects averaged over the entire progeny pool.

Finally, the among-line variances in consecutive generations will be correlated as a consequence of shared ancestry,

$$\sigma_B(t, t') = \left(\frac{1}{N_{fo}} + 2f_t \right) \sigma_A^2(0) \quad \text{for } 0 < t < t' \quad (12.2)$$

Equation 12.2 assumes no transmission of maternal effects across generations, which, if present, would further inflate this covariance.

A few words should also be said about the potential importance of nonadditive gene action. From Table 11.3, it can be seen that in the presence of dominance, the among-population variance (in the absence of any new mutation) eventually asymptotes at $\sigma_B^2 = 2\sigma_A^2 + 2\sigma_{ADI} + \sigma_{DI}^2$. Thus, dominance can magnify or reduce the among-population variance depending upon the magnitudes of σ_{DI}^2 and σ_{ADI} and on the sign of the latter. In addition, the asymptotic contribution from epistatic interactions involving additive effects is equal to $2^n \sigma_{An}^2$ for n -locus epistasis, i.e., $4\sigma_{AA}^2$ for additive \times additive epistasis, and $8\sigma_{AAA}^2$ for additive \times additive \times additive epistasis (again, all based on the base-population values). Thus, epistasis involving large numbers of loci can, in principle, greatly magnify the among-population variance, even if it appears to be of relatively minor importance within the populations.

Sampling Error

We now consider the sampling properties of the among-population genetic variance by reference to a particular experimental design, again assuming a character with a strictly additive basis (Hill 1972a; Lynch 1988a). Starting from a base population with additive genetic variance, $\sigma_A^2(0)$, L replicate lines are isolated and subsequently maintained in each generation with $N/2$ random monogamous matings. Due to the fact that only a finite number of lines is studied, the among-population variance that actually develops in any particular experiment (the **realized variance**), $\hat{\sigma}_B^2(t)$, will deviate from the expectation (the evolutionary variance), $\sigma_B^2(t)$, given by Equation 12.1b. Moreover, due to finite sample sizes within populations, the among-population variance estimated by the investigator, $V_B(t)$, will further deviate from $\hat{\sigma}_B^2(t)$. This first source of variation, $\sigma^2[\hat{\sigma}_B^2(t) - \sigma_B^2(t)]$, is a function of population-genetic structure and, for a fixed system of mating, is largely beyond the control of the investigator. The second source of variation, the **sampling variance**, $\sigma^2[V_B(t) - \hat{\sigma}_B^2(t)]$, arises in estimating $\hat{\sigma}_B^2(t)$ from the among-line sample variance $V_B(t)$. Its contribution can be minimized by the use of large sample sizes.

Because our concern here is variation in divergence due to genetic changes generated by random drift, we focus on the situation in which the among-line divergence has been measured in such a way as to eliminate nongenetic causes (such as a common-garden experiment designed to remove any environmental trends). Suppose that the same experiment has been repeated many times, on each occasion starting with L lines from the same base population. Due to the variation in the drift process and the finite number of observed lines, each set of experimental lines will develop its own temporal pattern of realized among-population variance. The expected variation in the realized variance among these hypothetical replicate experiments provides a measure of confidence that one can have in the results of any single experiment. If we let $\hat{\sigma}_B^2(t)$ be the realized among-population variance at generation t for a particular experiment, the expected variance of this quantity among replicate experiments is

$$\sigma^2[\hat{\sigma}_B^2(t)] \simeq \frac{4\sigma_A^4(0)}{L-1} \left[\frac{1}{2N_{fo}^2} + 2 \left(1 + \frac{1}{N_{fo}} \right) f_t^2 + \sigma_f^2(t) \right] \quad (12.3)$$

Although, in practice, one generally performs a divergence experiment only once, the utility of Equation 12.3 is that it is entirely expressed in terms of observable parameters, so that some idea of the reliability of estimates of $\sigma_B^2(t)$ can be determined in advance. In most situations, the terms in Equation 12.3 involving the founder number (N_{fo}) will be of second or third order and can be ignored.

The variance, $\sigma_f^2(t)$, in the amount of actual inbreeding between individuals in the population requires additional comments. This has been examined in detail in Lynch (1988a), drawing heavily from the results of Weir et al. (1980) and Cockerham and Weir (1983). The theoretical value of $\sigma_f^2(t)$ under different systems of mating is of special interest because empirical studies usually do not record the essential pedigree information for its computation. For freely recombining loci, σ_f^2 is zero when the pedigree structure is fixed, e.g., for obligate selfing, full-sib mating, the maximum avoidance systems of Wright (1921b), and the circular systems of Kimura and Crow (1963a); and even with fairly tightly linked loci, $\sigma_f^2(t)$ is generally negligible in any generation under selfing or full-sib mating. However, under most natural mating schemes, some individuals mate by chance with closer relatives than do others. This results in variation in f among members of the same population, which, because of sampling, accumulates as the among-population variance in f (different lines stochastically accumulate different amounts of inbreeding). For larger population sizes, even with unlinked loci, if the sexes are separate and matings are monogamous, the squared coefficient of variation of $f(t)$, $[\text{CV}(f_t)]^2 = \sigma_f^2(t)/f_t^2$, can attain values of 0.1 to 1.0 in the first two to four generations of isolation, which is enough to contribute significantly to $\sigma^2[\hat{\sigma}_B^2(t)]$. However, after six or so generations have passed, $\sigma_f^2(t)$ can be safely ignored, regardless of the population size, even with tightly linked loci.

Ignoring the initial founder effect, these results indicate that the coefficient of variation of the among-population variance is $\sqrt{2\{1 + [\text{CV}(f_t)]^2\}/(L - 1)}$, which is generally on the order of $\sqrt{2/L}$, although in some cases may be as high as $2/\sqrt{L}$. Thus, studies of phenotypic divergence *need to have very large number of replicates to be statistically reliable*. For example, if it is desirable to reduce the standard error of the among-line variance to 10% of the expectation under the null hypothesis of neutrality and additivity ($\sqrt{2/L} = 0.1$), a minimum of 200 lines should be studied.

One can assess the fit of the additive theory to actual data under two different settings. In the first, we have a single estimate of the among-line variance, and we compare this result to the value expected from theory (as later illustrated in Example 12.2). In the second, we have a series of among-line estimates at different time points, allowing us to consider the temporal pattern of increase in σ_B^2 , which, as noted above, should eventually reach a constant (in the absence of mutational input) as $f \rightarrow 1$. When a temporal series of $V_B(t)$ is available, these may be regressed on f_t . Under the null hypothesis of neutral additive genes, from Equation 12.1b, the expected slope of such a regression is $2\sigma_A^2(0)$. However, because of shared ancestry, consecutive estimates of mean phenotypes obtained from the same lines are nonindependent (Equation 12.2). This violates a fundamental assumption of ordinary least-squares (OLS) regression analysis, and generalized least-squares (GLS) must be used instead (Chapter 18; LW Chapter 8). For example, once the lines have become completely inbred (and ignoring mutation), all future values of $\hat{\sigma}_B^2(t)$ must be fixed, and therefore they should not be given equal weight with earlier time points in the regression analysis. The expected covariance of $\hat{\sigma}_B^2$ between generations with inbreeding levels of f_t and $f_{t'}$ is

$$\sigma[\hat{\sigma}_B^2(t), \hat{\sigma}_B^2(t')] \simeq \frac{4\sigma_A^4(0)}{L - 1} \left[\frac{1}{2N_{fo}^2} + 2 \left(1 + \frac{1}{N_{fo}} \right) f_t f_{t'} + \lambda_1^{t'-t} \sigma_f^2(t) \right] \quad \text{for } t < t' \quad (12.4)$$

where $\lambda_1 = 1 - 1/(2N)$. Lynch (1988a) provided approximate expressions for the standard errors of the slope and intercept that account for the intrinsic correlations in the data, assuming measurements of $V_B(t)$ in progressive generations. Chapter 18 also considers this problem, but in the context of the response in a selection experiment. The variance of the regression coefficient increases with the duration of the experiment, but it is essentially constant after the fourth generation of inbreeding. At that point, the standard error ranges from approximately $4\sigma_A^2(0)/\sqrt{L}$ under obligate self-fertilization to $3\sigma_A^2(0)/\sqrt{L}$ with larger N_e , implying coefficients of variation in the range of $1.5/(f\sqrt{L})$ to $2/(f\sqrt{L})$. For large values of f , these are not greatly different from the sampling variances of single-point estimates noted above.

Sample Variance Confidence Intervals

Given the critical role played by the sample variance in empirical tests of the additive-drift model, we digress here to briefly consider a few statistical issues (construction of confidence intervals and power) related to estimating a variance from a sample, which are used throughout the rest of the chapter. This section may be skipped by both the statistically sophisticated and the casual reader.

Let z_i be the trait value in individual i , with population mean μ and variance σ^2 . Provided that individual observations used to estimate a sample variance are uncorrelated and normally distributed with $z_i \sim N(\mu, \sigma^2)$, then (LW Equation A5.14c) for a sample of size n , for the sample estimator $\text{Var} = \sum(z_i - \bar{z})^2/(n - 1)$, we have that

$$(n - 1)\text{Var} \sim \sigma^2 \chi_{n-1}^2 \quad (12.5a)$$

namely, that the variance estimator, Var , is distributed as a scaled chi-square random variable with $n - 1$ degrees of freedom. As a result, confidence intervals for the true variance, σ^2 , based on the observed sample variance, Var , follow from critical values for a χ^2 distribution. Letting $X_{p,n}$ satisfy $\Pr(\chi_n^2 \leq X_{p,n}) = p$, then

$$\Pr(X_{\alpha/2,n} \leq \chi_n^2 \leq X_{1-\alpha/2,n}) = 1 - \alpha \quad (12.5b)$$

From Equation 12.5a, substituting $(n - 1)\text{Var}/\sigma^2$ for χ_{n-1}^2 , we have

$$\Pr\left(X_{\alpha/2,n-1} \leq \frac{(n - 1)\text{Var}}{\sigma^2} \leq X_{1-\alpha/2,n-1}\right) \quad (12.6a)$$

$$= \Pr\left(\frac{1}{X_{\alpha/2,n-1}} \geq \frac{\sigma^2}{(n - 1)\text{Var}} \geq \frac{1}{X_{1-\alpha/2,n-1}}\right) = 1 - \alpha \quad (12.6b)$$

yielding

$$\Pr\left[\left(\frac{n - 1}{X_{1-\alpha/2,n-1}}\right)\text{Var} \leq \sigma^2 \leq \left(\frac{n - 1}{X_{\alpha/2,n-1}}\right)\text{Var}\right] = 1 - \alpha \quad (12.6c)$$

This motivates a $(1 - \alpha)100\%$ confidence interval for the true variance, σ^2 , given the observed sample variance, Var . As shown in Figure 12.1, confidence intervals for σ^2 are asymmetrical about the estimated value, Var , and tend to be quite large, even for modest sample sizes.

A second important issue is power: how likely are we to declare the variance to be statistically distinct from some hypothesized null value, σ_0^2 ? Intuitively, power increases with both the sample size (n) and the difference between the true and null values. To formally develop this relationship, note from Equation 12.6a that the upper and lower critical values for a $100(1 - \alpha)\%$ confidence interval on the value of Var when the true variance is σ_0^2 are

$$\left(\frac{\sigma_0^2}{n - 1}\right)X_{\alpha/2,n-1} \leq \text{Var} \leq \left(\frac{\sigma_0^2}{n - 1}\right)X_{1-\alpha/2,n-1} \quad (12.7a)$$

If Var falls outside this interval, we declare that the true variance is statistically different (at level α) from the assumed value, σ_0^2 . If β denotes the probability that a sample value of Var falls *within* this internal, namely the probability of a type-II error (failing to declare a test significant when the null is false, i.e., when the true variance is σ_1^2), then the power is $1 - \beta$. We can obtain β by noting that the true distribution is given by $[(n - 1)/\sigma_1^2]\text{Var} \sim \chi_{n-1}^2$. Multiplying all terms of Equation 12.7a by $(n - 1)/\sigma_1^2$ gives the probability β of a sample variance failing to be declared significant as

$$\begin{aligned} \beta &= \Pr\left[\left(\frac{\sigma_0^2}{n - 1}\right)\left(\frac{n - 1}{\sigma_1^2}\right)X_{\alpha/2,n-1} \leq \chi_{n-1}^2 \leq \left(\frac{\sigma_0^2}{n - 1}\right)\left(\frac{n - 1}{\sigma_1^2}\right)X_{1-\alpha/2,n-1}\right] \\ &= \Pr\left[\left(\frac{\sigma_0^2}{\sigma_1^2}\right)X_{\alpha/2,n-1} \leq \chi_{n-1}^2 \leq \left(\frac{\sigma_0^2}{\sigma_1^2}\right)X_{1-\alpha/2,n-1}\right] \end{aligned} \quad (12.7b)$$

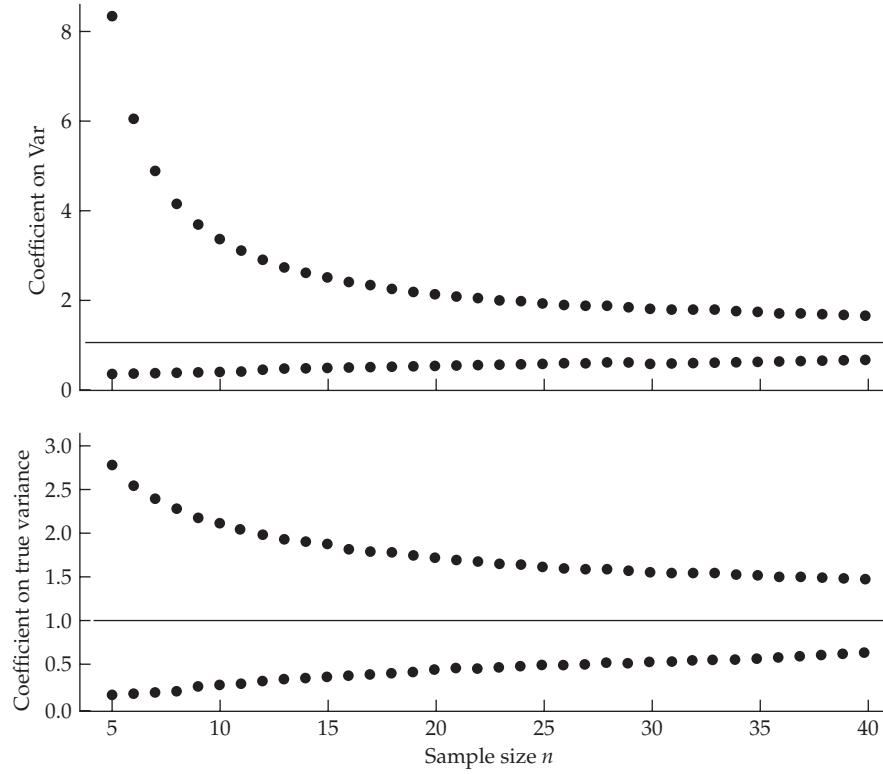

Figure 12.1 Confidence limits and critical values for σ^2 estimated from a sample of n observations. Define $X_{p,n}$ as satisfying $\Pr(\chi^2_{n-1} \leq X_{p,n}) = p$. (**Top**) Upper and low values correspond to $[(n-1)/X_{0.025,n-1}]$ and $[(n-1)/X_{0.975,n-1}]$, respectively, the coefficients that multiply the estimated sample variance, Var , to yield a 95% confidence interval for σ^2 (Equation 12.6c). For example, for $n = 10$, the 95% confidence interval for σ^2 is $0.44 \cdot \text{Var}$ to $3.33 \cdot \text{Var}$. (**Bottom**) Upper and low values correspond to $X_{0.975,n-1}/(n-1)$ and $X_{0.025,n-1}/(n-1)$, respectively, the coefficients that multiply the assumed variance, σ_0^2 , to yield upper and lower 2.5% critical values for an observed sample variance (Equation 12.7a). For example, for $n = 10$, 95% of the values of Var are expected to fall within the interval of $0.30 \cdot \sigma_0^2$ to $2.11 \cdot \sigma_0^2$.

The complement of this event (namely, either less than the lower critical value or greater than the upper critical value) is the power

$$1 - \beta = \Pr \left[\chi^2_{n-1} \leq \left(\frac{\sigma_0^2}{\sigma_1^2} \right) X_{\alpha/2,n-1} \right] + \Pr \left[\chi^2_{n-1} \geq \left(\frac{\sigma_0^2}{\sigma_1^2} \right) X_{1-\alpha/2,n-1} \right] \quad (12.7c)$$

Example 12.1. Consider a sample variance estimated from $n = 10$ observations. Because $\Pr(\chi^2_9 \leq 2.700) = 0.025$ and $\Pr(\chi^2_9 \leq 19.023) = 0.975$, Equation 12.6c gives the 95% confidence interval ($\alpha = 0.05$) for the true variance σ^2 as between $(9/19.023)\text{Var}$ and $(9/2.7)\text{Var}$, or $0.473 \cdot \text{Var}$ to $3.333 \cdot \text{Var}$, implying an uncertainty in σ^2 spanning almost a full order of magnitude.

What observed values of the sample variance are unlikely given an assumed true variance of σ_0^2 ? From Equation 12.7a, the upper and lower critical values (for a two-sided test with $\alpha = 0.05$) are $(2.700/9)\sigma_0^2 = 0.3 \cdot \sigma_0^2$ and $(19.023/9)\sigma_0^2 = 2.11 \cdot \sigma_0^2$.

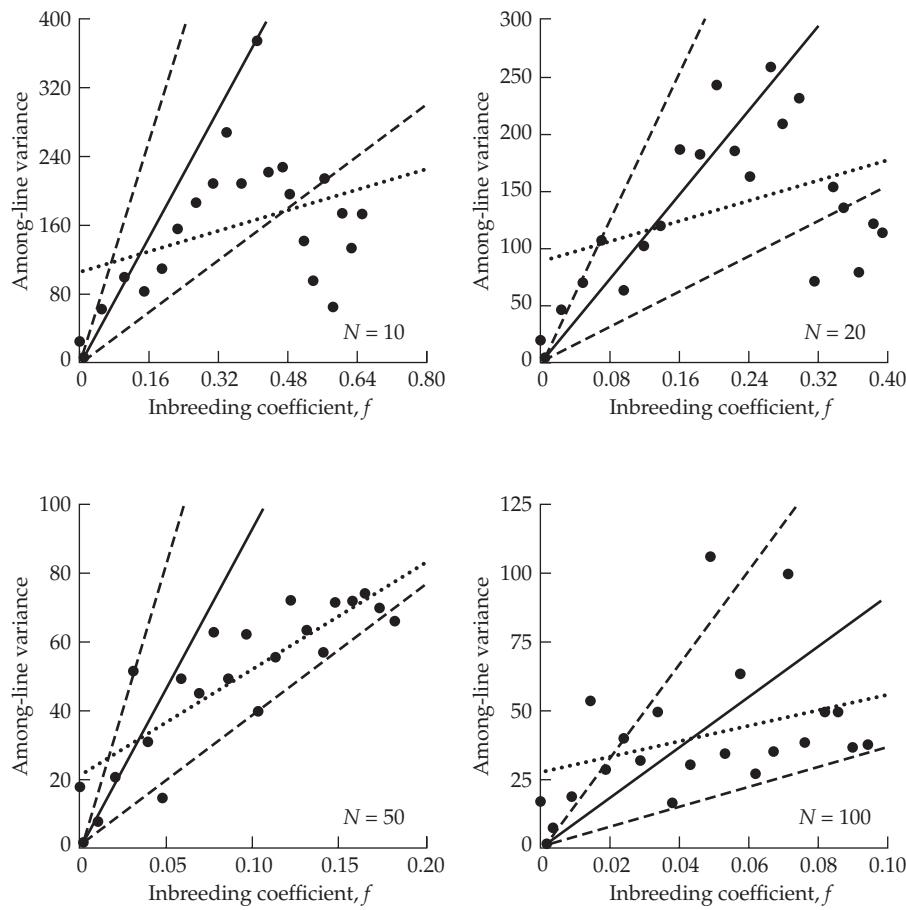

Figure 12.2 Observed and expected levels of the among-population variance for pupal weight in a divergence experiment with the flour beetle *Tribolium*. Solid lines are the expected divergence ($2\sigma_A^2(0)f_t = 920f_t$), dotted lines are the least-squares regressions of the observations, and the paired dashed lines give the approximate 95% confidence interval. (Data from Rich et al. 1984.)

Finally, what is the power of this design to declare the null model (the true variance is σ_0^2) false when the correct variance is $\sigma_1^2 = 2\sigma_0^2$? Taking $\alpha = 0.05$, Equation 12.7b (with $\sigma_0^2/\sigma_1^2 = 1/2$) gives the power as

$$\Pr \left(\chi_9^2 \leq \frac{2.700}{2} \right) + \Pr \left(\chi_9^2 \geq \frac{19.023}{2} \right) = 0.39$$

and hence a type II error rate of 61% when the true variance is twice the assumed variance. A similar calculation assuming $\sigma_1^2 = \sigma_0^2/2$ gives a power of 0.20, or a type II error rate of 80%. Useful R commands are (i) `pchisq(x,n)`, which returns $\Pr(\chi_n^2 \leq x)$, and hence $1 - \text{pchisq}(x,n)$, which returns $\Pr(\chi_n^2 \geq x)$; and (ii) `qchisq(p,n)`, which returns $X_{p,n}$.

Empirical Observations

As an example of the application of the preceding theory, consider the results from a large drift experiment with laboratory cultures of the flour beetle *Tribolium castaneum* (Rich et al. 1984). The authors followed 12 replicate populations at four population sizes (1:1 sex ratio, random mating) over 20 consecutive generations. In each generation, the mean pupal weight (in μg) of each population was obtained from a bulk sample of 100 random individuals.

The additive genetic variance was estimated to be 460 in the base population. The observed values of $V_B(t)$ are plotted as a function of f_t in Figure 12.2, along with the expected divergence, $2\sigma_A^2(0)f_t = 920f_t$ (solid lines). The dashed lines, which were obtained by using Equation 12.3 for the expected variance and substituting this into Equation 12.6c (using $\alpha = 0.05$ and $n = 12$), give the limits of the among-population variance beyond which there is less than a 5% chance for the realization of the drift process under the null to generate these values. Because these bounds ignore measurement error and hence are too narrow, they may be regarded as conservative confidence limits. Nevertheless, almost all of the observations, with the exception of the clusters of the late generations (which are expected to have the largest sampling variances) at $N = 10$ and 20, lie within these limits. The least-squares regressions of the data are given by the dotted lines (more formally, a GLS regression would be used to account for correlated and heteroscedastic residuals; see Chapter 18). The slope of each regression is less than the expected 920, but all slope estimates are within two standard errors of the expectation. Thus, the observed patterns are fairly consistent with a hypothesis of random drift of neutral additive genes. The observed declines in $V_B(t)$ late in the experiment at the two smallest population sizes may have simply arisen by chance and remained there due to intergenerational correlations (Equation 12.2). The results of some other short-term divergence experiments previously given in Figure 11.3 show no evidence for nonlinear increases in the among-population variance with inbreeding.

Eisen and Hanrahan (1974) have argued that the divergence of growth and reproductive rates in inbred lines of mice is more rapid than can be accounted for by the additive genetic variance in the base population, and Bryant et al. (1986a) suggested the same for morphological traits in bottlenecked housefly lines. The implication of these authors is that some nonadditive variance is converted by inbreeding into σ_A^2 (Chapter 11), leading to a faster among-line divergence. However, their designs have low power and in neither case was it verified that the departures from expectations were significant.

Estimating the Among-group Variance

With L replicate populations, a common estimate in the literature for $\sigma_B^2(t)$ is

$$V_B(t) = \frac{1}{L-1} \sum_{i=1}^L [\bar{z}_i(t) - \bar{z}_.(t)]^2 \quad (12.8a)$$

the sample variance among the sample means, $\bar{z}_1, \dots, \bar{z}_L$, of the replicate population. When just two populations are being considered (as in some of the tests developed below), their squared difference

$$d^2(t) = [\bar{z}_1(t) - \bar{z}_2(t)]^2 \quad (12.8b)$$

is often used. This is easily related to Equation 12.8a by noting for $L = 2$ that

$$V_B = \frac{1}{2-1} \sum_{i=1}^2 \left(\bar{z}_i - \frac{\bar{z}_1 + \bar{z}_2}{2} \right)^2 = \frac{(\bar{z}_1 - \bar{z}_2)^2}{4} + \frac{(\bar{z}_2 - \bar{z}_1)^2}{4} = \frac{d^2}{2} \quad (12.8c)$$

These expressions for V_B overestimate the true among-line variance σ_B^2 , as the sample means are measured with error. In particular, $\bar{z}_i = \mu_i + e_i$, so that

$$\sigma^2(\bar{z}_i) = \sigma^2(\mu_i) + \sigma^2(e_i) = \sigma_B^2 + \frac{\sigma_z^2}{n} \quad (12.8d)$$

where σ_z^2 is the trait variance and n is the sample size used to estimate μ_i . When $\sigma_B^2 = 2f_t\sigma_A^2 \gg \sigma_z^2/n$ (which is equivalent to $2f_t h^2 \gg 1/n$), the difference between $\sigma^2(\bar{z}_i)$ and σ_B^2 is small.

As suggested by a number of authors (Lynch 1988a, 1990; Turelli et al. 1988; Bjöklund 1991; Savalli 1993), a simple way to avoid this issue is to estimate the among-group variance from a standard one-way ANOVA, with

$$V_B(t) = \frac{MS_B - MS_W}{n_0} \quad (12.8e)$$

using the among- and within-group mean squares (MS_B and MS_W , respectively), with n_0 being a measure of the average sample size per group (see LW Table 18.1).

Lande's Constant Variance Test, F_{CV}

Is an observed divergence over a modest amount of time significantly different than that expected by drift? For the case in which one has only a single estimate of the among-population divergence, Lande (1977b) suggested the statistic

$$F_{CV} = \frac{V_B(t)}{t \cdot V_A(0)/N_e} \quad (12.9a)$$

as a test for neutrality, where $V_A(0)$ is an estimate of the base-population additive variance, and t is the number of generations of divergence among the replications. This is the **constant variance** version of Lande's test, as it assumes that the additive variance remains unchanged over the time period being followed (Turelli et al. 1988). As noted by Lande, under approximate assumptions, his test statistic F_{CV} follows an F distribution (LW Appendix 5), which can be shown as follows. If we assume the trait is normally distributed, then so is the sample mean $\bar{z}_i \sim N[\mu(0), \sigma_B^2(t)]$, where we have assumed that terms associated with the sampling variance of the mean are small enough to be ignored (i.e., $\sigma_B^2 \gg \sigma_z^2/n$). With L independent lines drawn from a common population at the same time (i.e., a star phylogeny), Equation 12.5a yields

$$V_B(t) = \frac{1}{L-1} \sum_{i=1}^L (\bar{z}_i - \bar{z}_.)^2 \sim \frac{\sigma_B^2(t)}{L-1} \chi_{L-1}^2 \quad (12.9b)$$

If we ignore the (usually) small founder effect, Equation 12.1b returns

$$\sigma_B^2(t) \simeq 2f_t \sigma_A^2(0) = 2 \left[1 - \left(1 - \frac{1}{2N_e} \right)^t \right] \sigma_A^2(0) \simeq t\sigma_A^2(0)/N_e \quad \text{for } t \ll N_e \quad (12.9c)$$

and hence

$$V_B(t) \sim \left(\frac{t\sigma_A^2(0)}{N_e[L-1]} \right) \chi_{L-1}^2 \quad (12.9d)$$

Assuming that $\text{Var}_A(0)$ is a good estimate of $\sigma_A^2(0)$, substitution of Equation 12.9d into Equation 12.9a yields

$$F_{CV} \sim \frac{\chi_{L-1}^2}{L-1} \sim F_{L-1,\infty} \quad (12.9e)$$

The last step follows from the definition of an F distribution (LW Appendix 5). Hence, Lande's F_{CV} statistic follows an F distribution with $L-1$ numerator and infinite denominator degrees of freedom. More generally, because $\sigma_A^2(0)$ is estimated by $\text{Var}_A(0)$, the denominator degrees of freedom are those associated with this estimate (e.g., $F_{CV} \sim F_{L-1,df}$, where df is the degrees of freedom associated with the estimate of $\sigma_A^2[0]$). As noted in the previous section, Lande's original test statistic can be improved by using Equation 12.8e to estimate $V_B(t)$.

A couple of approximations were required to reach Equation 12.9e. One check of their validity is that if the distribution of some summary statistic x is given by a scaled- χ^2 , with $x \sim \sigma^2 \chi_n^2/n$, then the variance of x should equal $2\sigma^4/n$ (as $\sigma^2(\chi_n^2) = 2n$; LW Equation A5.15b). Hence, the numerator of Equation 12.9a should have a variance approximately equal to $2[2f_t \sigma_A^2(0)]^2/(L-1)$. Ignoring the added contribution from sampling error, note that this last result matches Equation 12.3 when N_{fo} is large and $\sigma_f^2(t)$ is small. Thus, Lande's approach should be restricted to lines with at least moderate effective population size. Moreover, as we will see below, all of the preceding formulae for σ_B^2 become questionable for $t > N_e$ because they ignore the contribution from new mutations. Hence, Lande's F_{CV} test is best thought of as one for *short-term divergence*, such as would be seen in a laboratory experiment or, at most, a modest amount of time in a set of natural populations.

Example 12.2. Lande (1977b) used Equation 12.9a to evaluate the results of a 12-year divergence experiment involving five populations of *Drosophila pseudoobscura* (Anderson 1973). Two of the populations had been maintained at 25°C, two at 27°C, and one at 16°C. They were then raised in two common environments (16 and 25°C) and measured for wing length. Estimates of the additive genetic variance for these two environments were 0.88 and 0.77, respectively, while the among-population variances were approximately 6.62 and 4.37, respectively. An approximate upper bound for the number of generations of divergence is $t = 150$, whereas the effective population size probably always exceeded $N_e = 1000$. The use of these extreme bounds gives conservative estimates of F_{CV} , making it more difficult to demonstrate diversifying selection on wing length. The resulting values (for the two environments) were

$$F_{CV,1} = \frac{6.62}{150 \cdot 0.88/1000} = 50.15, \quad \text{and} \quad F_{CV,2} = \frac{4.37}{150 \cdot 0.77/1000} = 37.84$$

Given that $\Pr(F_{4,\infty} > 4.6) = 0.001$, both values are highly significant. Thus, the hypothesis that the observed line divergence is solely attributable to random genetic drift can be rejected confidently. More likely, the different thermal conditions resulted in selection for different wing lengths.

LONG-TERM DIVERGENCE

Our previous results were simply concerned with how any initial variation is partitioned among lines during drift/inbreeding. While this is occurring, new variation is constantly being generated by mutation, further driving divergence (Haldane 1949). Polygenic mutation was first incorporated into the theory of population divergence by Dempster (in the appendix to Bailey 1959) and was subsequently studied by Lande (1976), Chakraborty and Nei (1982), and Lynch and Hill (1986). As noted in Chapter 11, the assumed mutational model generating the new mutational effect (a_m) given the ancestral allelic effect (a_0) is critical. The standard model is a version of the infinite-alleles approach, where each new mutation gives rise to a new allele, with $a_m = a_0 + e_a$, namely, the ancestral value plus a random increment, e_a . To distinguish this from the standard infinite-alleles model of Chapter 2 (where the allelic effect of a mutation were not a concern), this approach is also known as the **incremental** or **Brownian-motion** mutational model in the literature; it is examined more fully in Chapter 28.

Again focusing on a character with a purely additive genetic basis, starting with an ancestral-population genetic variance of $\sigma_A^2(0)$, and assuming the infinite-alleles model, the expected variance of genotypic means for replicate populations isolated t generations in the past is

$$\sigma_B^2(t) = 2\sigma_m^2 t + 2(\sigma_A^2(0) - 2N_e\sigma_m^2) \left(1 - e^{-t/(2N_e)}\right) \quad (12.10)$$

where σ_m^2 is the per-generation mutational rate of input of genetic variance, as described in Chapter 11. This expression shows that as t becomes large, the expected rate of increase of the among-population variance for a neutral quantitative trait becomes a constant $2\sigma_m^2$ per generation. The same formulation applies to the among-species genetic covariance for a pair of traits, if the mutational rate of production of covariance between the traits is substituted for σ_m^2 (Lande 1979a).

Thus, under the infinite-alleles model, the asymptotic divergence rate is independent of the population size, just as it is in the neutral theory of molecular evolution (Chapter 7; Kimura 1983). Although the expected number of new mutations entering a population in each generation is $2Nu$ per locus, the probability of fixation of a new mutation is its initial frequency $1/(2N)$, so (at equilibrium), the expected number of mutations that is fixed per locus,

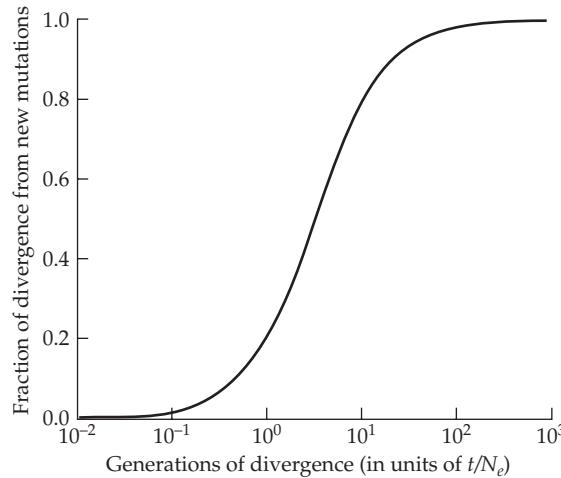

Figure 12.3 The expected fraction of neutral among-population variance attributable to mutations arising subsequent to the isolation event. It is assumed that the base population is in drift-mutation equilibrium, $\sigma_A^2(0) = 2N_e\sigma_m^2$, with the same effective size as the daughter species, so that from Equation 12.1b, the divergence due to base-population variance is $4N_e\sigma_m^2[1 - e^{-t/(2N_e)}]$. To obtain the actual number of generations of divergence for any population size, the horizontal axis is multiplied by N_e .

per population, per generation is simply the mutation rate, u . With each fixed mutation causing an increase in expected among-population variance of $\sim E[(2a)^2]$, and n loci contributing, the asymptotic divergence rate is $nuE[(2a)^2] = 2\sigma_m^2$.

Under the assumptions of the infinite-alleles model, the asymptotic divergence rate of $2\sigma_m^2$ is a fairly general result. It is independent of the degree of dominance of new mutations, the linkage relationships of the constituent loci, and the mating system (Lynch and Hill 1986). This is because both dominance and gametic-phase disequilibrium are transient properties of alleles en route to loss or fixation, and not cumulative phenomena, and because the probability of fixation of a new neutral mutation is equal to its initial frequency regardless of the breeding system.

How long should populations be isolated before one should start to worry about the contribution of new mutations to divergence? From Equation 12.10, it can be seen that this depends on the initial level of genetic variance and on the effective sizes of the derived isolates. In Figure 12.3, it is assumed that the initial base population is in drift-mutation equilibrium, so that $\sigma_A^2(0) = 2N_e\sigma_m^2$, and that the isolated lineages have rapidly attained the same effective sizes (N_e). Under these circumstances, by the time N_e generations have elapsed, polygenic mutation subsequent to the isolation event has caused about 20% of the divergence, whereas for $t > 3N_e$ generations, the majority of the divergence is due to new mutations.

Note that $\sigma_B^2(t)$ is unbounded in t under the infinite-alleles model. However, as emphasized in the preceding chapter (and in Chapter 28), alternatives exist to this mutational model, raising questions about the appropriate structure of a neutral null model. For example, Cockerham and Tachida's (1987) model, which assumes that there are a finite number of alleles with each new allelic state being independent of the prior allelic state (the house-of-cards model), yields a bounded equilibrium among-population variance

$$\tilde{\sigma}_B^2 = 2[1 - E(H)]\sigma_A^2(\infty) \quad (12.11)$$

where $E(H)$ is the expected heterozygosity per locus, and $\sigma_A^2(\infty) = 2nE(a^2)$ is the expected additive genetic variance in a population of infinite size (Chapter 11). Note that under this model, not only does the among-population variance not build up indefinitely, but because $E[H] = 4N_eu/(1 + 4N_eu) \rightarrow 1$ as $N_e \rightarrow \infty$, the among-population component of variance

asymptotically approaches zero as populations become progressively larger. This is because under the house-of-cards model, replicate populations that are each effectively infinite in size eventually will harbor the same alleles with the same frequency spectrum defined by the mutational interconversion rates.

If nothing else, these dichotomous results indicate that although neutral models are essential to demonstrating the necessity of invoking natural selection to explain an observed pattern of divergence, the actual *construction* of the null model depends on unresolved biological issues. Recall from Chapter 11 that Zeng and Cockerham (1993) proposed a model bridging the infinite-alleles (incremental) and house-of-cards approaches, wherein the effect of a mutant allele is given by $a_m = \tau a_o + e_a$. Taking $\tau = 1$ recovers the incremental (Lynch-Hill) model, while $\tau = 0$ recovers the house-of-cards (Cockerham-Tachida) model. With τ being a measure of the dependency of the mutational effect on the current allelic value, this **regression model** (see Chapter 28 for more details) yields an equilibrium among-population variance of

$$\tilde{\sigma}_B^2 = \frac{4E(a^2)}{(1-\tau)^2[1+4N_e u(1-\tau)]} \quad (12.12)$$

For $\tau < 1$, the temporal approach to the equilibrium level of divergence is defined by the mutation rate (u), assuming an identical N_e in the base and descendant populations,

$$\sigma_B^2(t) = [1 - (1-u)^{2t}] \tilde{\sigma}_B^2 \quad (12.13)$$

and hence is quite slow (approximately $2u$ per generation).

Finally, we note that the expression for the variance of the among-population variance (i.e., the variance of $\sigma_B^2(t)$ among replicate experiments with mutational input) is algebraically complex, and it has only been worked out for the infinite-alleles model (Lynch and Hill 1986). However, if it is assumed that the number of loci is large and the distribution of mutational effects is normal with a mean of zero, the variance of the realized among-population variance approaches $2(2\sigma_m^2 t)^2/L$ for large values of t . This is simply twice the square of the expected among-population variance. Thus, for large t , the coefficient of variation of a realized among-population variance based on L lines is expected to be on the order of $\sqrt{2/L}$, and, we have noted before, unless L is quite large, estimates of $\sigma_B^2(t)$ can deviate quite far from their expectation.

Effectively Neutral Divergence and the Estimation of Rates of Mutational Variance

As discussed in detail in LW Chapter 12, the theoretical expectations of the neutral model provide the basis for estimating the rates of polygenic mutation. Starting from an inbred base population, experimental lines with known times of divergence can be used to estimate the amount of polygenic mutation necessary to account for the distribution of the resultant mean phenotypes. In one of the earliest applications of this approach, Russell et al. (1963) started with several lines of maize that had been maintained by prolonged self-fertilization. They then performed a dichotomous branching experiment for five generations in which each plant was self-fertilized to produce two new daughter sublines. Seed was saved from each generation, so that at the end of the experiment members of all generations could be assayed simultaneously in a common environment, and then sib analysis was used to estimate the additive genetic variance for the *total* population in each generation. Assuming the within-population variance to be in drift-mutation equilibrium, this type of population expansion should give rise to an average rate of increase in the total genetic variance of $2\sigma_m^2$ per generation. In accordance with this prediction, the regressions of the genetic variance on time were positive for every character investigated (Figure 12.4). The rate of polygenic mutation for each of the traits is estimated by one-half the slopes of these regressions.

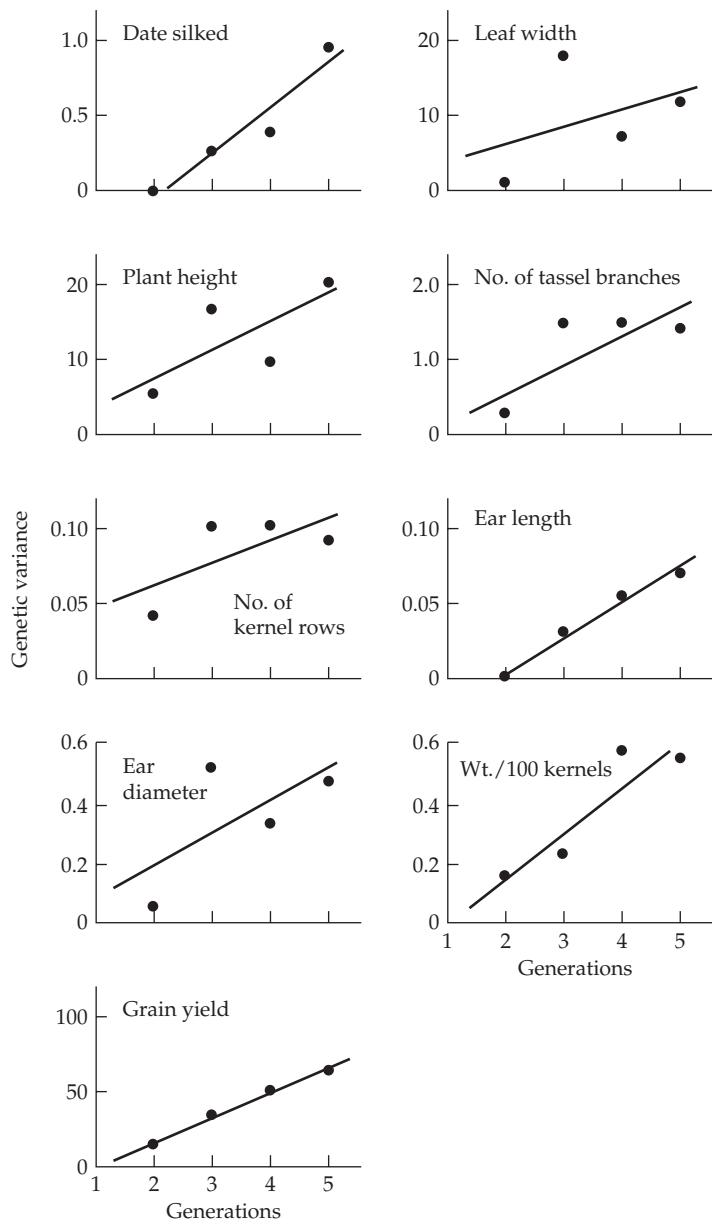

Figure 12.4 The increase in total additive genetic variance (within- plus among-population components) from new mutational variance in an expanding set of lines of corn. See text for details. (After Russell et al. 1963.)

Results from many other experiments of this sort were reviewed in LW Chapter 12. Although a number of additional results have emerged since then, most of these are confined to a small number of model systems, and the conclusions reached in our earlier review remain unaltered. Here, we simply give a brief update, providing references only to post-1998 papers. Most estimates are framed in terms of the mutational heritability, $h_m^2 = \sigma_m^2 / \sigma_e^2$. Estimates of h_m^2 for a diversity of morphological, physiological, and life-history traits in *D. melanogaster* are consistently in the range of 0.001 to 0.005. Mutational heritabilities for body

size and life-history traits in nematodes fall in the range of 0.001 to 0.008 (Vassilieva et al. 2000; Baer et al. 2006; Ostrow et al. 2007), and the same is true for life-history traits in the microcrustacean *Daphnia pulex* (Lynch et al. 1998; Latta et al. 2013) and in the grape phylloxera insect *Daktulosphaira vitifoliae* (Downie 2003). Thus, essentially all studies with invertebrates imply $0.001 < h_m^2 < 0.01$ for complex traits.

Although the numbers of studies are still rather limited, estimates of h_m^2 for some land plants and vertebrates appear to be several-fold higher than those noted above. Mutational heritabilities for growth and reproductive traits in *Arabidopsis thaliana* are in the range of 0.001 to 0.008 (Schultz et al. 1999; Shaw et al. 2000; Chang and Shaw 2003; Kavanaugh and Shaw 2005), but the average h_m^2 for maize, from the study of Russell et al. (1963), is 0.0092. In addition, mutational heritabilities for morphological and reproductive traits in mice fall in the range of 0.003 to 0.023 (Casellas and Medrano 2008). Thus, there is at least a rough indication that mutational heritabilities are increased in organisms with longer life spans, which might in principle be a consequence of elevated rates of mutation per generation (Chapter 4).

Finally, it should be emphasized that in all mutation-accumulation experiments, fitness declines in the vast majority of lines, indicating that mutations are, on average, deleterious, although the fraction of mutations that are beneficial remains unclear (Shaw et al. 2002; Keightley and Lynch 2003; Charlesworth and Eyre-Walker 2007; Eyre-Walker and Keightley 2007; Dickinson 2008; Hall et al. 2008). Equally important, for characters that influence fitness only indirectly (e.g., morphology), the fraction of new mutations with negative pleiotropic effects on fitness remains unclear (Chapter 28). Hence, estimates of h_m^2 from mutation-accumulation experiments with their very small effective population sizes may *overestimate, perhaps significantly*, the actual *usable* amount of h_m^2 for most populations. Even if the focal trait is neutral, if some of its underlying mutants have deleterious pleiotropic effects on fitness (i.e., fitness impacts *independent* of the actual value of the focal trait), then the effective number of neutral mutations in the trait changes with effective population size. As N_e increases, this fraction decreases, so that the effective value of h_m^2 is likely a decreasing function of N_e . What is unclear is whether this decline plateaus out fairly quickly or continues to decrease over a large range of N_e . Resolving these issues is critical to any attempts to utilize estimates of mutational heritability to infer long-term mechanisms of evolution, as illustrated in the following sections.

TESTING THE NULL HYPOTHESIS OF NEUTRAL PHENOTYPIC DIVERGENCE: RATE-BASED TESTS

One of the enduring problems in evolutionary biology is the struggle to demonstrate that various aspects of biodiversity are products of diversifying selection. It is one thing to concoct plausible adaptive scenarios to explain patterns of morphological, physiological, or behavioral divergence, but quite another to formally demonstrate that an observed level of divergence cannot simply be explained by a null model of random genetic drift. This is especially the case with the massive volume of omics data flooding out of large-scale functional genomics studies.

Four broad classes of tests for departures from neutral divergence have been proposed, each requiring successively more information. The first (**rate tests**) simply require the means of divergent populations, and ask (given N_e , t , and either h^2 or h_m^2) whether the rate of divergence is consistent with drift. A second approach is based entirely on the internal information in a temporal sequence of trait values, typically from the fossil record. A third class requires information on the additive variation of a trait and the frequencies of a set of markers in a subdivided population. Such tests compare the within- and among-population structure of the additive variation of a trait (measured by Q_{ST}) with that from some presumably neutral set of markers (measured by F_{ST} ; Chapter 2). The final class, trait-augmented marker-based tests, examine patterns in the set of markers associated with a

specified trait detected using either a QTL (fixed differences) or GWAS (segregating alleles) study.

A genomics-focused researcher may (incorrectly) get the impression that despite the use of marker information in some of these tests, none of these four approaches are relevant to their work. Nothing could be further from the truth. For example, methods initially developed to test for neutrality in changes in morphology (often over a fossil record) are now widely applied to omics data. To highlight this transition from morphology to molecules, we conclude this chapter by applying these tests to gene-expression data to examine if such divergence is largely governed by neutral drift, stabilizing selection, or directional selection.

Rate Tests

Lande's F_{CV} (Equation 12.9a) is one example of a rate test, comparing the amount of divergence across a set of lines or populations with the expected among-population variance (σ_B^2). As mentioned, this test is best applied over short time scales ($t \ll N_e$), as in a selection experiment or over a short to modest amount of time in nature.

Here we focus on tests over potentially much longer time scales and ask whether an observed amount of total divergence, $d = |\mu(t) - \mu(0)|$, within a single lineage is excessively large (or small) relative to drift. Tests for unusual amounts of divergence (either too much, or too little) are framed by asking what critical values for an effective population size (N_e) or mutation variance (σ_m^2) are consistent with the amount of divergence and whether these values are biologically reasonable. For example, a smaller effective population size and/or higher mutation variance results in increased divergence. Based on the observed rate of divergence, rate tests return either a critical effective population size $N_e(d)$, above which the divergence is unlikely due to drift, or a critical mutational variance, $\sigma_m^2(d)$, below which divergence is unlikely from drift. Likewise, either large population size or small mutation variance will constrain neutral divergence, yielding a critical value of $N_e(s)$ below which the lack of divergence observed is unlikely, and conversely a critical mutation variance, $\sigma_m^2(s)$, above which lack of divergence is unlikely. Hence, if $N_e > N_e(d)$ or $\sigma_m^2 < \sigma_m^2(d)$, the amount of divergence is excessive relative to drift, consistent with directional selection; while if $N_e < N_e(s)$ or $\sigma_m^2 > \sigma_m^2(s)$, there is too little divergence relative to the drift prediction, consistent with stabilizing selection. If none of these conditions is satisfied, the hypothesis of drift alone accounting for the pattern is not rejected. It should be stressed that situations exist in which considerable selection shapes the observed pattern, and yet we can still fail to reject the drift model.

While these tests are widely used, they have several important caveats. For any analysis of this sort to be meaningful, one must be confident that the majority of population divergence is genetic, and not inflated by environmental effects on phenotypes. This is clearly problematical when populations cannot be assayed in a common-garden environment, as is the case with data from the fossil record. A further complication is that expressions for critical effective population sizes or mutational variances ignore the sampling error of all other terms. Finally, as we have discussed, the infinite-alleles model for neutral-trait evolution (where σ_B^2 is an ever-increasing function of time; Equation 12.10) may be too extreme, as the usable amount of σ_m^2 likely decreases with increasing N_e . The among-population divergence under mutation might be better described by either the House-of-cards (Equation 12.11) or the regression (Equation 12.12) models, that by the incremental model. Given all these considerations, it should be clear that the following tests for neutrality cannot be regarded as being very rigorous in a statistical sense. As is the case for most of the tests for selection on specific genes covered in Chapters 9 and 10, tests of neutral phenotypic evolution are best employed as diagnostic guides to prioritize traits for further study.

Lande's Brownian-motion Model of Neutral Trait Evolution

The basic structure of tests for neutral trait divergence have the form of $\mu_t \sim (\mu_0, \sigma_B^2[t])$, namely, the mean phenotype at time t has an expected value equal to the initial mean

μ_0 and variance $\sigma_B^2(t)$. To proceed further, we need additional assumptions about the actual *distribution* from which the means are sampled, which is generally assumed to be Gaussian (normal). Support for this assumption traces back to Lande (1976), who framed mean divergence in terms of a **Brownian-motion process** (Appendix 1). Under the simplest Brownian-motion model, the expected change in value over a small time interval is zero with a constant variance of b . Under this model, the distribution of values at time t is normal with mean x_0 (the initial value) and variance $\sigma_t^2 = bt$ (Equation A1.31b). Assuming a strictly additive model with no environmental trends, Lande noted that if we sample N_e individuals, their mean breeding value (i.e., the trait mean) will have a sampling variance in each generation of σ_A^2/N_e , which is used for b . Hence, at generation t , the distribution of phenotypic means is approximately normal with mean μ_0 (the initial mean) and variance

$$\sigma_t^2 = t\sigma_A^2/N_e \quad (12.14a)$$

This approach assumes a constant additive genetic variance as well as a constant effective population size during the period of divergence being considered. Because drift can also change σ_A^2 , the assumption of a constant σ_A^2 is reasonable only for $t \ll N_e$, unless the initial variance is close to its mutation-drift equilibrium value ($2N_e\sigma_m^2$; see Equation 11.20b). More generally, if the additive variance and N_e are both changing in each generation, then under the Brownian-motion model (taking the first time point at $i = 0$ and the last at $i = t - 1$, bringing us up to generation t),

$$\sigma_t^2 = \sum_{i=0}^{t-1} \left(\frac{\sigma_A^2(i)}{N_e(i)} \right) \quad (12.14b)$$

For example, assuming a constant effective population size, the additive genetic variance at time t under drift and mutation is given by Equation 11.20b. Substituting this into Equation 12.14b yields

$$\begin{aligned} \sigma_t^2 &= \frac{1}{N_e} \sum_{i=0}^{t-1} \left[2N_e\sigma_m^2 + (\sigma_A^2(0) - 2N_e\sigma_m^2) e^{-i/2N_e} \right] \\ &= 2\sigma_m^2 t + (\sigma_A^2(0) - 2N_e\sigma_m^2) \left(\frac{1}{N_e} \sum_{i=0}^{t-1} e^{-i/2N_e} \right) \end{aligned} \quad (12.14c)$$

By noting that

$$\frac{1}{N_e} \sum_{i=0}^{t-1} e^{-i/2N_e} \simeq 2 \left(1 - e^{-t/2N_e} \right) \quad (12.15a)$$

recovers the previous expression (Equation 12.10) for σ_B^2 under drift and mutation. This useful identity follows by recalling that the partial sum of a geometric series is

$$\sum_{i=0}^{k-1} x^i = \frac{1 - x^k}{1 - x}. \quad (12.15b)$$

Taking $x = e^{-1/2N_e}$ and noting from a first-order Taylor series that

$$1 - e^{-1/2N_e} \simeq 1 - \left(1 - \frac{1}{2N_e} \right) = \frac{1}{2N_e} \quad (12.15c)$$

returns Equation 12.15a.

Thus, as expected, the variance (σ_t^2) of the Brownian-motion process corresponds to the among-group drift variance $\sigma_B^2(t)$ in population means. The notion that (under a pure drift model) the additive variance within populations reaches a drift-mutation equilibrium value has resulted in different parameterizations of σ_t^2 in tests of drift (Lande 1976; Turelli et

al. 1988). Lande assumed a constant variance, $\sigma_t^2 = t\sigma_A^2/N_e$, but because part of his concern was evolution in the fossil record, he replaced σ_A^2 by $h^2\sigma_z^2$, yielding

$$\sigma_t^2 = h^2\sigma_z^2 t/N_e \quad (12.16a)$$

His logic was that σ_z^2 could be estimated directly from a sample in the fossil record, while h^2 values for many morphological traits fall within a relatively narrow range. Hence, either a representative value for h^2 could be used, or different values of h^2 could be explored to examine the robustness of any conclusions. This results in a test based on joint considerations of N_e and h^2 .

Conversely, Turelli et al. (1988) noted that if the population has been at its current size sufficiently long enough that the additive genetic variance is at its mutation-drift equilibrium value, then (assuming the infinite-alleles model) $\sigma_A^2 = 2N_e\sigma_m^2$, yielding

$$\sigma_t^2 = 2tN_e\sigma_m^2/N_e = 2t\sigma_m^2, \quad (12.16b)$$

Under this setting, N_e does not appear in σ_t^2 and tests are based on whether the values of σ_m^2 required to be consistent with drift are plausible. This is the quantitative-trait analog of the divergence ($d = tu$) between two neutral sequences separated by t total generations (Chapter 7), with the *allelic* mutation rate (u) replaced by twice the *trait* mutational variance, $2\sigma_m^2$. It needs to be stressed, however, that this apparent independence of N_e is a bit misleading. As mentioned previously, some fraction of its underlying variation may be due to alleles with deleterious pleiotropic effects on fitness (Chapter 28). Any such alleles are expected to have ever-decreasing frequencies (and hence less impact on h_m^2) as N_e increases. Hence, the evolutionary relevant fraction of h_m^2 very likely declines with N_e , even for a neutral trait, resulting in less neutral divergence than expected.

Tests Based on the Brownian-motion Model

Under the Brownian-motion model, the mean phenotype $\mu_t \sim N(\mu_0, \sigma_t^2)$, providing the basis for tests of either too much, or too little, divergence based on simple normal theory. Suppose an absolute divergence of $d = |\mu(t) - \mu(0)|$ is observed, where $\mu(t)$ and $\mu(0)$ are the means from two samples from the same population taken t generations apart. The probability of this level of divergence under drift alone is given by

$$\Pr(|\mu(t) - \mu(0)| \leq d) = \Pr\left(\frac{|\mu(t) - \mu(0)|}{\sigma_t} \leq \frac{d}{\sigma_t}\right) = \Pr\left(|U| \leq \frac{d}{\sigma_t}\right) \quad (12.17)$$

where U is a unit normal random variable. Lande's (1976) original test (distinct from his 1977 F_{CV} test; Equation 12.9a) was based on the constant variance assumption, $\sigma_t^2 = th^2\sigma_z^2/N_e$. Recalling that $\Pr(|U| \leq 1.96) = 0.95$, Lande's critical effective population size below which there is a < 5% probability of an absolute deviation as large as d satisfies

$$1.96 = \frac{d}{\sqrt{th^2\sigma_z^2/N_e}}, \quad \text{implying} \quad (1.96)^2 th^2\sigma_z^2 = N_e d^2 \quad (12.18a)$$

Equation 12.18a allows one to determine critical values for either divergence time, t , heritability, h^2 , or N_e that are consistent with drift. For example, solving for the upper bound, $N_{e,u}$ on the effective population size that is compatible with drift yields

$$N_{e,u} = \frac{t \cdot h^2 \cdot 1.96^2}{d_*^2} = 3.84 \cdot \frac{t h^2}{d_*^2} \quad (12.18b)$$

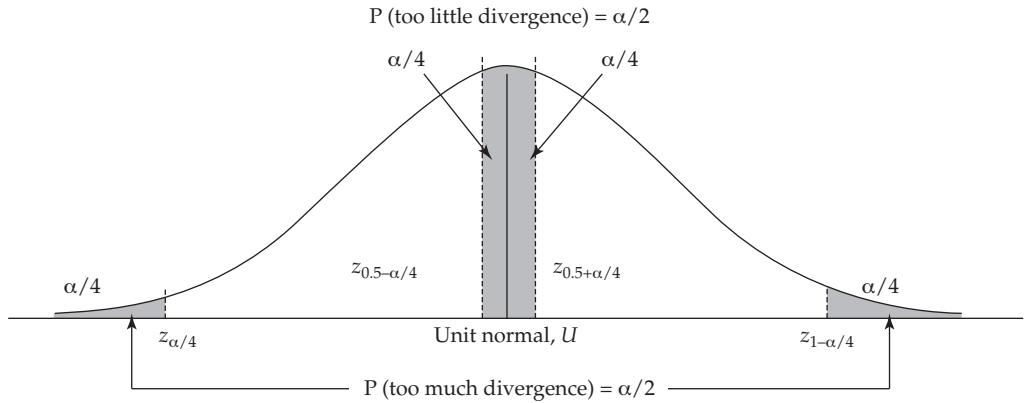

Figure 12.5 Critical values for an α -level test of a departure from drift having either too little, or too much, absolute divergence. Too much absolute divergence occurs when the unit-normal scaled test score is either in the lower $\alpha/4$ or upper $\alpha/4$ tail (for a total probability of $\alpha/2$). Too little absolute divergence occurs when the unit-normal scaled test score is too close to zero, namely, a region of probability $\alpha/4$ below zero and a region of probability $\alpha/4$ above zero (for a total probability of $\alpha/2$). Here, z_p satisfies $\Pr(U \leq z_p) = p$, where U is a unit-normal random variable. See the text for further details.

where $d_* = d/\sigma_z$ is the divergence scaled in phenotypic standard deviations. Drift with $N_e > N_{e,u}$ is unlikely to generate the observed amount of divergence. For a test with an arbitrary α , one replaces 1.96 by $z_{1-\alpha/2}$, where z_p satisfies $\Pr(U \leq z_p) = p$ for a unit normal U ($\alpha/2$ is used, as we are considering an absolute difference). Likewise, if one is comparing the means of two species with a common ancestor τ generations ago, then $t = 2\tau$ and d is the absolute difference between their means. For historical reasons, the above discussion has been framed in terms of d^2 . Recalling Equation 12.8e, more generally, the ANOVA-based estimate V_B of the between-group variance can be used in place of $d^2/2$.

As noted by Turelli et al. (1988), the population-size test for departures from drift given by Equation 12.18b is really *two-sided*. Lande's original test examines whether N_e is too large to account for the observed divergence (as might occur if directional selection was changing the mean). However, any formal test of departures from neutral trait drift must also inquire as to whether the *stability* of population means is too great to be compatible with neutrality (too little divergence). For a two-tailed test of neutrality with an $\alpha = 5\%$ overall significance level, we use a 2.5% probability cutoff for the observed divergence being too small to be consistent with drift and a 2.5% cutoff for excessively high divergence. Because $\Pr(|U| \geq 2.24) = 0.025$ for a unit-normal random variable U , the critical upper bound, $N_{e,u}$, on population size in a test that evolution has been too fast for drift is

$$N_{e,u} \leq \frac{t \cdot h^2 \cdot 2.24^2}{d_*^2} = 5.02 \cdot \frac{t h^2}{d_*^2} \quad (12.19a)$$

Because populations with smaller N_e should show more drift (and divergence), Equation 12.19a gives the largest value of N_e that is consistent with drift generating the observed amount of divergence. If the assumed N_e exceeds $N_{e,u}$, we reject the hypothesis that drift can account for this fast a divergence. Likewise, because $\Pr(|U| < 0.03) = 0.025$, the critical lower-bound population size $N_{e,l}$ in a test that evolution has been too slow (support for stabilizing selection) is

$$N_{e,l} \geq \frac{t \cdot h^2 \cdot 0.03^2}{d_*^2} = 0.0009 \cdot \frac{t h^2}{d_*^2} \quad (12.19b)$$

If our assumed N_e is less than $N_{e,l}$, we reject the hypothesis that drift can account for this slow a divergence.

More generally, for a two-sided test at overall significance level α ($\alpha/2$ for too much absolute divergence and $\alpha/2$ for too little absolute divergence), the above values of 2.24 and 0.03 are replaced by $z_{1-(\alpha/4)}$ and $z_{0.5+\alpha/4}$ (Figure 12.5). To see how these critical values arise, first consider the probability of excessive absolute divergence, which means that either the difference between means is too negative or too positive. Because $\alpha/2$ is the critical value for either of these two events occurring, we set the negative lower limit (the difference between means is too negative) to occur with probability $(\alpha/2)/2 = \alpha/4$ (i.e., the probability of divergence in the lower tail is less than $\alpha/4$), and likewise set the upper positive limit (the difference between means is too positive) also at $\alpha/4$. Given the symmetry of the normal, we can compactly express the total probability for excessive divergence in either direction as

$$\Pr(|U| \geq z_{1-(\alpha/4)}) = \alpha/2$$

Turning to tests of too little divergence, instead of focusing on the tails of the normal, we focus around its mode (its mean, which corresponds to $z_{0.5}$), with a section of probability $\alpha/4$ below the mean and a corresponding section above the mean, where the total area in the region of too little divergence corresponds to $\alpha/2$. Putting these together,

$$\Pr(|U| \leq z_{0.5+\alpha/4}) = \alpha/2$$

Figure 12.5 illustrates this logic.

Example 12.3. Reymert (1982) observed a change of $1.49\sigma_z$ in the size of a Cretaceous foraminifer over roughly $5 \cdot 10^5$ generations. Taking a typical heritability value of 0.3, Equation 12.18b (i.e., assuming a one-sided test, namely, a test only for excessive divergence) gives the upper bound, $N_{e,u}$, on population size consistent with this amount of divergence as

$$N_{e,u} = 3.84 \cdot \frac{t h^2}{d_*^2} = 3.84 \cdot \frac{5 \cdot 10^5 \cdot 0.3}{1.49^2} \simeq 260,000$$

However, paleontological data suggest that the census population size $N \gg 10^6$, implying that drift was unlikely to account for such a rapid divergence (of course, caveats from Chapter 3 apply in that usually $N_e \ll N$). Assuming h^2 values of 0.5, 0.7, and 1.0 yields $N_{e,u}$ values of 433,000, 607,000, and 867,000 respectively, so that only for assumed h^2 values close to one does the critical N_e under drift approach the assumed size of $N_e > 10^6$.

Using the two-sided test (strict departure from drift, either too little or too much absolute divergence), the value of the 3.84 used above is replaced by 5.02 (Equation 12.19a), resulting in an $\sim 31\%$ ($5.02/3.84 = 1.307$) increase in $N_{e,u}$ value, with critical values of $\sim 340,000$, 566,000, 794,000, and 1,133,000 for h^2 values of 0.3, 0.5, 0.7, and 1.0, respectively. Similarly, the lower critical $N_{e,l}$ (the size below which the lack of divergence is too improbable under drift) is 61 (using Equation 12.19b with $h^2 = 0.3$).

The structure of the tests given by Equations 12.17 through 12.19 depends on N_e and h^2 . A second approach is to instead base tests on the mutational variance, σ_m^2 , alone. The idea is that if N_e has been roughly constant for a sufficient amount of time, then the additive-genetic variance for a neutral trait approaches its mutation-drift equilibrium value, $2N_e\sigma_m^2$ (Equation 11.20c). Under this condition, Equation 12.16b shows that the among-group variance becomes $\sigma_B^2 = 2t\sigma_m^2$, giving the MDE (mutation-drift equilibrium) version of Lande's F test (Equation 12.9a) as

$$F_{MDE} = \frac{V_B(t)}{2t\sigma_m^2} \tag{12.20a}$$

We can also arrive at this test by substituting $2N_e\sigma_m^2$ for $V_A(0)$ in Equation 12.9a. As above, V_B is best estimated from the among-group variance in a one-way ANOVA (Equation 12.9f).

When V_B is based on more than two lineages, Equation 12.20a assumes a star phylogeny (Chapter 8). If the phylogeny is more complex, one has to place the lineage relationships into a phylogenetic framework to account for the covariance structure imparted by shared common ancestry (Felsenstein 1985, 2004, 2008; Lynch 1991; Gu 2004). Using the same logic leading to Equation 12.9e with L lineages (under a star phylogeny), Equation 12.5a gives $(L - 1)V_B(t) \sim 2t\sigma_m^2\chi_{L-1}^2$, and Equation 12.6c yields

$$\Pr \left[\left(\frac{L-1}{X_{1-\alpha/2,L-1}} \right) V_B(t) \leq 2t\sigma_m^2 \leq \left(\frac{L-1}{X_{\alpha/2,L-1}} \right) V_B(t) \right] = 1 - \alpha \quad (12.20b)$$

where $X_{p,n}$ satisfies $\Pr(\chi_n^2 \leq X_{p,n}) = p$. Thus, if an estimate of t is available, one can test the neutral hypothesis without an estimate of N_e by inquiring whether there has been too little or too much divergence given some assumed value of σ_m^2 (Turelli et al. 1988). We can also frame the test in terms of the mutational heritability $h_m^2 = \sigma_m^2/\sigma_e^2$ by dividing all terms in Equation 12.20b by $2t\sigma_e^2$, yielding

$$\Pr \left[\left(\frac{L-1}{X_{1-\alpha/2,L-1}} \right) \frac{V_B(t)}{2t\sigma_e^2} \leq h_m^2 \leq \left(\frac{L-1}{X_{\alpha/2,L-1}} \right) \frac{V_B(t)}{2t\sigma_e^2} \right] = 1 - \alpha \quad (12.20c)$$

A slightly different formulation of this test is based in terms of the observed rate of divergence (Lynch 1990). Letting $\Delta = (V_B/t)/\sigma_e^2$ be the estimated rate of divergence scaled in units of the environmental variance, Equation 12.20c becomes

$$\Pr \left[\left(\frac{(L-1)/2}{X_{1-\alpha/2,L-1}} \right) \Delta \leq h_m^2 \leq \left(\frac{(L-1)/2}{X_{\alpha/2,L-1}} \right) \Delta \right] = 1 - \alpha \quad (12.20d)$$

yielding the upper and lower bounds on the mutational heritability h_m^2 consistent with drift. For $\alpha = 0.05$ and $L = 2$, Equation 12.20b becomes

$$\Pr(0.10 \cdot \Delta \leq h_m^2 \leq 509 \cdot \Delta) = 0.95 \quad (12.20e)$$

Thus, the hypothesis of drift is rejected (at $\alpha = 0.05$) if the mutational heritability is too small to account for the observed divergence rate, namely

$$h_m^2 < 0.10 \cdot \Delta \simeq 0.10 \cdot \frac{d_*^2}{t} \quad (12.21a)$$

Just as a smaller N_e allows for more divergence (and hence we set a critical *upper* value for N_e in Equation 12.18a), so does a larger mutational heritability, h_m^2 , and we set a critical *lower* value, above which drift can account for the observed divergence. Given that a typical upper-range value is $h_m^2 = 0.05$ (LW Table 12.1), if $0.05 < 0.10 \cdot \Delta$ (i.e., $\Delta > 0.5$), the rate of divergence is too high to reasonably be accounted for by drift.

Conversely, the divergence is too slow to be accounted for by drift if the assumed mutational heritability is too high to account for the observed divergence rate, or when

$$h_m^2 \geq 509 \cdot \Delta \simeq 509 \cdot \frac{d_*^2}{t} \quad (12.21b)$$

A mutational heritability above this value would lead to significantly more divergence than observed. There is one minor bookkeeping detail with both Equations 12.21a and 12.21b. The careful reader might recall Equation 12.8c, where we showed that $V_B = d^2/2$. So why did we assume that $\Delta \simeq d_*^2/t$ in these two equations? Recalling that $\sigma_e^2 = (1 - h^2)\sigma_z^2$, we have

$$\Delta = \frac{V_B}{t\sigma_e^2} = \frac{d^2}{2t(1 - h^2)\sigma_z^2} = \frac{1}{2(1 - h^2)} \frac{d_*^2}{t} \simeq \frac{d_*^2}{t} \quad (12.21c)$$

with the last step following when $h^2 \simeq 1/2$.

One important caveat for σ_m^2 -based tests of stabilizing selection is that estimates of h_m^2 are obtained using very small effective population sizes, and hence most mutations are likely effectively neutral in these settings (Chapter 7). Because even a completely neutral trait may have underlying loci with deleterious pleiotropic fitness effects, the evolutionarily relevant fraction of h_m^2 may be far less than that suggested from laboratory experiments. Hence, using laboratory estimates for the polygenic mutation rate may generate a considerable number of false positives for stabilizing selection (the mutation rate is too large relative to the small amount of divergence), so this test should be used with considerable caution.

Example 12.4. We now return to Reymert's foraminifer data from Example 12.3. Using the original Lande model (Equation 12.18b), we rejected the hypothesis that drift could have accounted for the divergence. Applying Equation 12.21a, the hypothesis of drift accounting for excessive divergence is not rejected when

$$h_m^2 > 0.10 \cdot \frac{d_*^2}{t} = 0.10 \cdot \frac{1.49^2}{5 \cdot 10^5} = 4.4 \cdot 10^{-7}$$

This critical value of the mutational heritability is several orders of magnitude lower than typical values of this parameter, implying that this pattern of divergence is not too excessive for drift.

Thus, we reach two very different conclusions depending on whether the constant variance (Example 12.3) or equilibrium variance (Example 12.4) assumption is used. Which is the better choice? In our view, the constant variance assumption (Equation 12.16a) is less problematic, as the usable amount of σ_m^2 and h_m^2 may decrease with increasing N_e . In such cases, $2N_e\sigma_m^2/N_e$ may not be a constant over N_e , complicating tests based on critical mutational variances. Conversely, most trait heritabilities typically fall within a modest window of values, and one can vary the assumed value of h^2 in Equation 12.16a to examine its consequences.

Ornstein-Uhlenbeck Models

As developed in Appendix 1, the **Ornstein-Uhlenbeck (OU) process** provides a model of Brownian motion drift coupled with a restoring force back to some optimal value (θ), as might be expected with drift and stabilizing selection. This process has been used to model the divergence of traits over a phylogeny (Felsenstein 1988, 2004, 2008; Garland et al. 1993; Martins 1994; Hansen and Martins 1996; Hansen 1997; Martins and Hansen 1997; Butler and King 2004; Beaulieu et al. 2012), including gene-expression data (Bedford and Hartl 2009; Kalinka et al. 2010; Brawand et al. 2011; Rohlf et al. 2014).

Under the OU model, the expected change in the mean value of a process at a value of x is $a(\theta - x)$ with $a > 0$, so that if $x < \theta$, it increases, while it decreases for $x > \theta$. The parameter a , which measures the strength of the restoring force, is a measure of the strength of stabilizing selection. Under the standard model of Gaussian stabilizing selection (Example 5.6; Equation 16.17), where ω^2 measures the strength of selection (smaller ω^2 implies stronger selection), Example A1.13 shows that

$$a = \frac{\sigma_A^2}{\sigma_z^2 + \omega^2} \quad (12.22a)$$

As with Brownian motion, the value of the process at time t is normally distributed (Equation A1.33b), but now with mean and variance

$$\mu_t = \theta + [x_o - \theta]e^{-at} \quad (12.22b)$$

$$\sigma_t^2 = \frac{b}{2a}[1 - e^{-2at}] \quad (12.22c)$$

where $b = \sigma_A^2/N_e$ under the constant-variance model. For large t , the mean value approaches the optimal value (θ), while the divergence variance approaches an asymptotic value of

$$\frac{b}{2a} = \frac{\sigma_z^2 + \omega^2}{2N_e} \quad (12.22d)$$

Initially, the among-population divergence increases linearly with divergence time t under both the pure drift (e.g., Equation 12.10) and OU models. However, unlike pure drift (which retains its linear divergence over all time), the between-lineage variance under an OU eventually asymptotes at a fixed level of divergence after sufficient time. Thus, while initially both models have very similar behavior, they become increasingly distinct as time progresses. It should be noted that divergence approaching an asymptotic variance can also occur under the purely neutral house-of-cards (Equation 12.11) and regression (Equation 12.12) mutational models, mimicking a process under stabilizing selection.

Divergence in Morphological Traits

Numerous attempts have been made to apply the above procedures, or variants of them, to data from the fossil record to test the hypothesis that levels of morphological divergence over geological time scales have been driven by directional selection. In the first such study, Lande (1976) showed that changes in tooth-size dimensions over a 42 million year period in early horse evolution are consistent with the hypothesis of random genetic drift if the heritabilities of the traits had been near 0.5 and the long-term effective population size was smaller than 60,000 or so individuals. Given the generally high levels of heritability observed for mammalian morphological traits (Lynch and Walsh 1998), an assumption of $h^2 = 0.5$ is not unreasonable, and the argument that the long-term N_e in such lineages could be smaller than the critical value of $N_e^* = 60,000$ is also plausible (Chapter 4). Analyses of tooth morphometrics in two additional lineages of extinct mammals (condylarths and oreodonts) suggested critical effective sizes of 80,000 to 120,000, below which the observed changes would be compatible with a neutral hypothesis (Lande 1976). Thus, only if the effective sizes of these ancient mammalian taxa were actually in excess of 10^5 , a matter that remains unclear, would the observed changes require some mechanism of directional selection.

Several other studies of this nature have been applied to aspects of mammalian skull evolution. For example, by setting the upper and lower limits to mutational heritability, σ_m^2/σ_e^2 , at 10^{-2} and 10^{-4} , Lynch (1990) found that the rates of evolution of cranial morphology in a wide array of placental mammalian lineages are one to two orders of magnitude *below* the minimum neutral rate, and Lemos et al. (2001) observed a similar pattern in marsupials. The only exception to this general trend concerns the races of modern man, which appear to have diverged at a rate slightly above the minimum neutral expectation (Lynch 1990; Ackermann and Cheverud 2004; Roseman 2004). Although they leave many questions unanswered, these kinds of results put in perspective previous arguments that rates of morphological evolution are exceptionally high in mammals, and especially so in the great apes (e.g., Cherry et al. 1982; Wyles et al. 1983; Van Valen 1985). Clearly, the predominant mode of evolution in mammalian skeletal morphology has been one of stabilizing selection, not of strong diversifying selection. Similarly, Spicer (1993) found widespread evidence of stabilizing selection in a variety of morphological traits in *Drosophila*, but some caution is in order here as the tests were based on critical mutation variances (Equation 12.21b). As mentioned, this approach likely generates many spurious calls of too little divergence (because h_m^2 estimates are likely inflated by inclusion of deleterious mutations), hence biasing tests toward inferring stabilizing selection.

TIME SERIES DIVERGENCE TESTS

The methods discussed above are based on *external comparisons*—one has information from two time points and examines whether the observed amount of divergence is consistent with some external information (either estimated or assumed), such as effective population size (N_e), time of divergence (t), and a measure of genetic variation (h^2 or σ_m^2). Conversely, starting with Raup (1977; Raup and Crick 1981), a number of methods have been proposed (largely from paleontology) to detect departures from drift entirely from observations on

the *internal* characteristics of a series of trait values over time (no external information, such as an estimate of N_e or h^2 , is required by the test). The sequence of trait data from a set of subsamples within a stratigraphic column has been called a **stratophenetic series** (Gingerich 1979). This is not a new enterprise. Almost a century ago, Ronald Brinkmann (1929) published morphological information on close to 3,000 ammonites in the genus *Kosmoceras* from a 14-meter stratigraphic section from the Middle Jurassic. The number of available stratophenetic series is considerable, and growing. A recent review by Hunt et al. (2015) examined 709 such series from roughly 200 lineages. The number of samples per sequence (populations measured from different locations within the same stratigraphic column) ranged from 7 to 114 (with a median of 14), covering approximate time ranges from 5000 to more than 50 million years, with most between 10^5 and 10^7 years in duration. Such a temporal series of data makes it possible to look for statistical trends in mean phenotypes or for correlations in rates of change in adjacent intervals, neither of which are expected in a strictly neutral model (under the strong assumption of no environmentally influenced change in mean phenotype). The motivation for many of these tests is to provide a statistical framework to examine fossil data in the context of the **punctuated equilibrium** debate, which postulates directional selection to be rare in the fossil record, with a pattern of **stasis** (very little change) being predominant (Eldredge and Gould 1972; Gould and Eldredge 1977; Eldredge et al. 2005).

There are two important caveats with random-walk models. First, any observed phenotypic trend could be entirely environmental, with changes in the mean being independent of any underlying genetic change. Second, as highlighted by Raup (1977), a pattern indistinguishable from a random walk can mask significant underlying selection, such as short, episodic bursts of directional selection in shifting directions or stabilizing selection with drift occurring in the optimal value. These are examples of **hierarchical models** of random change, wherein selection is driving the generational change, but the focus of selection (either directional or stabilizing) is randomly changing, generating an random walk.

Tests for Departures From Symmetric Random Walks

A number of tests of departure from a symmetric random walk have been proposed. All assume uncorrelated changes over time increments and an equal chance of positive and negative increments (with the mean incremental change equaling zero). Raup (1977) and Raup and Crick (1981) proposed using the **Wald–Wolfowitz runs test** (under the null hypothesis of an equal number of positive and negative changes). Here the test statistic, R_n , for the number of runs (changes in the direction of the walk) in a sample of size n is approximately normally distributed with mean $n/2 + 1$ and variance $n/4$. A sequence showing excessive runs of the same sign is consistent with directional selection, while a sequence with an excessive number of sign reversals is consistent with stabilizing selection (as might be expected for a population mean fluctuating around an optimum). Similarly, one could simply test the number of positive increments against the value expected from a binomial with success parameter $1/2$ and sample size n . Both the runs and binomial tests do not use any information on the *size* of any jump, but rather simply test against a null of equally likely up versus down change over any given time point.

A more sophisticated approach was taken by Bookstein (1987, 1988), who used results from the theory on the maximal excursion of a symmetric random walk. The sequence of measured phenotypes is scaled so that the initial mean is zero, with x_i denoting the mean of the i th sample. The standard error for the expected divergence over the entire sequence (n steps) of a symmetric random walk is $\sigma\sqrt{n}$, where σ^2 is the variance in change per increment. Assuming roughly equal time intervals between samples, this standard error can be estimated as

$$\widehat{\sigma}^2 = \frac{1}{n} \sum_i^n (x_i - x_{i-1})^2 \quad (12.23a)$$

Further, define S_k as the sum of the first k increments (the displacement of the mean from its original value after k steps). Bookstein obtained a large- n expression for the distribution

of the largest scaled excursion,

$$\gamma = \frac{\max_k |S_k|}{\hat{\sigma}\sqrt{n}} \quad (12.23b)$$

Namely, the largest absolute value of the walk ($\max_k |S_k|$) over any of the sampled times, expressed in terms of the expected standard error of the walk value at the final sample time ($\sigma\sqrt{n}$). For $\gamma > 1$, critical values (the upper p in the tail of the null distribution) are very closely given by the corresponding $p/4$ critical values for a unit normal. For example, the upper 5% tail corresponds to $\gamma = 2.25$, consistent with the value of 2.24 for a normal with $p/4 = 0.0125$. The upper 1% and 0.1% upper tail probabilities correspond to γ values of 2.8 and 3.5, respectively. Series with values exceeding these critical values are said to be **improbably directional**, consistent with directional selection (or an environmental trend). Conversely, a series that does not vary enough is said to be **improbably constrained**, consistent with some sort of stabilizing selection or other cause of stasis. The lower 5%, 1%, and 0.1% values correspond to γ values of 0.62, 0.49, and 0.41, respectively. Failure to reject the null of a random walk still allows for considerable selection, either due to a lack of power or randomness in the direction of selection over time. Multivariate random-walk tests are discussed by Bookstein (2013).

Another widely used test for departures against the null of a symmetric random walk (closely related to Bookstein's approach), called **scaled range analysis**, is based on **Hurst exponents** (Hurst 1951). The idea behind this approach is that the absolute difference of a symmetric random walk $|x_t - x_0|$ scales as $\sigma\sqrt{t}$ (which can be estimated from Equation 12.23a). Defining the **standardized range**, $R(\tau)$, for a time interval (τ) as

$$R(\tau) = \frac{|x_\tau - x_0|}{\sigma} \quad (12.24a)$$

one then regresses $R(\tau)$ on ever-increasing values of τ , fitting the log-log regression

$$\ln[R(\tau)] = H \ln(\tau) + \epsilon \quad (12.24b)$$

where the slope (H) is the Hurst exponent (i.e., $R \propto \tau^H$). Under a symmetric random walk with uncorrelated increments, absolute trait divergence is expected to scale with the square root of time, giving $H = 0.5$. As increments become more positively correlated, H increases to 1.0 (**directional persistence**), consistent with directional selection. As adjacent increments become increasingly negatively correlated, H decreases to zero (**anti-persistence**), consistent with stabilizing selection or some other form of stasis. Roopnarine (2001) discussed permutation tests for the significance of $H \neq 0.5$. Gingerich's (1993) *LRI* (log rate versus log interval) method is a version of this test, where the slope (G) of his *LRI* regression is simply $G = H - 1$ (Roopnarine et al. 1999).

While straightforward and widely applied in the early literature, these methods typically have low power, meaning that the null hypothesis of a symmetric random walk is hard to reject (Roopnarine et al. 1999; Roopnarine 2001; Sheets and Mitchell 2001). This is especially the case with stratophenetic series, with their usual incompleteness and sporadic coverage due to the vagaries of the fossilization process. Further, as noted by Sheets and Mitchell (2001), there is an asymmetry of detection in that stabilizing selection is easier to detect than directional selection. They showed that the Hurst exponent (and, by extension, the *LRI* method) has the highest power to detect stabilizing selection, followed by Bookstein's approach, and then the runs test. Conversely, for detecting directional selection, the runs test is often the most powerful, followed by the Hurst exponent, and then Bookstein's approach.

Hunt's Approach for Comparing Different Models

Hunt (2006, 2007, 2008a, 2008b; Hunt and Carrano 2010) noted that the low power for tests of departures from symmetric random walks creates a “tyranny of the null hypothesis,” potentially overinflating the role of drift. He suggested that instead of testing against

Table 12.1 Summary of the 251 fossil sequences examined by Hunt (2007), each fit using three models of divergence: random walk, directional selection, and stasis. Counts given under the Trait and Fossil group categories are the numbers of times a model had the highest Akaike weight (Example 12.5) for a fossil sequence. For example, 13 of the 251 sequences (0.052) had directional selection as the model with the highest support, while 5 of 114 (0.044) size-related traits had directional selection as the most-supported model. Values under the Median column correspond to the median fraction of support over all sequences for a given model. For example, half of all sequences had a support for directional change model of 0.06 or less, while 95% of all sequences have a fractional support for directional selection in the 0.04 to 0.08 range. The fossil groups are planktonic and benthic microfossils (Plank and Benth) and macrofossils (Macro).

Model	Median, 95% CI	Trait			Fossil group			
		All	Size	Shape	Other	Plank	Benth	Macro
Directional	0.06 (0.04, 0.08)	13	5	4	4	5	3	5
Random	0.47 (0.39, 0.56)	123	67	43	13	24	57	42
Stasis	0.34 (0.20, 0.50)	115	42	68	5	12	37	66
		251	114	115	22	41	97	113

the random null, one should examine a set of candidate models, using Akaike weights (Anderson et al. 2000) to indicate support for each (see Example 12.5 for details). The Akaike weights for a set of competing models sum to one, providing a useful indicator of their relative support.

Hunt initially considered three basic models: a symmetric random walk (with an incremental mean value of zero); a directional (or generalized) random walk (mean increment $\neq 0$); and stasis. For the two random walks, he modeled the incremental δ (the change over an interval) with normal random variables. For the symmetric random walk, $\delta \sim N(0, \sigma_\delta^2)$, while for the general random walk, $\delta \sim N(\mu_\delta, \sigma_\delta^2)$, with parameters fit by maximum likelihood. For stasis, he assumed a simple model initially suggested by Sheets and Mitchell (2001). Instead of constructing likelihood models around increments (so that $z_t = z_0 + \sum \delta_i$), they simply took the trait value at time t to be $z_t \sim N(\mu, \sigma^2)$, namely a constant variance (σ^2) over all time (rather than the linear increased under Brownian motion). While at first glance this appears to be an OU process at stationarity ($t \rightarrow \infty$), this is not the case, as an Ornstein-Uhlenbeck process has correlated means (reflecting the shared history on a common evolutionary path). Akaike weights allow for a more nuanced interpretation of model fits (see Figure 12.6), and are based on the relative likelihoods among a set of candidate models, summing to one over all the models considered (Example 12.5). For example, suppose the Akaike weights for a fossil sequence are 0.50, 0.48, and 0.02 for the random, directional, and stasis models, respectively. Clearly, stasis and a random walk are almost equally likely explanations in this case, but the support for a directional model is very slim.

It should be stressed that the power of this approach is not the initial small set of candidate models, but rather that it serves as a much more general framework for examining an ever richer set of models. Indeed, Hunt et al. (2015) examined more complex models that allow for the sequence of mean phenotypes to shift between modes (e.g., random vs. stasis) over the time sampled. One could also use the Akaike weights strategy to contrast the simple stasis model used by Hunt with the Ornstein-Uhlenbeck or other competing models of stabilizing selection (Estes and Arnold 2006; Uyeda et al. 2011), as well as considering other models of directional evolution (e.g., Charlesworth 1984b).

Using this approach, Hunt (2007), Hopkins and Lidgard (2012), and Hunt et al. (2015) examined an evergrowing number of stratophenetic series (251, 635, and 709 studies, respectively). The basic conclusions from Hunt et al. (2007), which hold for these larger (and more recent) studies as well, are given in Table 12.1. For each fossil series, the fraction of support for the three models was computed using Akaike weights. In only 13/251 (5.2%) of the sequences was directional selection (a generalized random walk with $\mu_\delta \neq 0$) the most

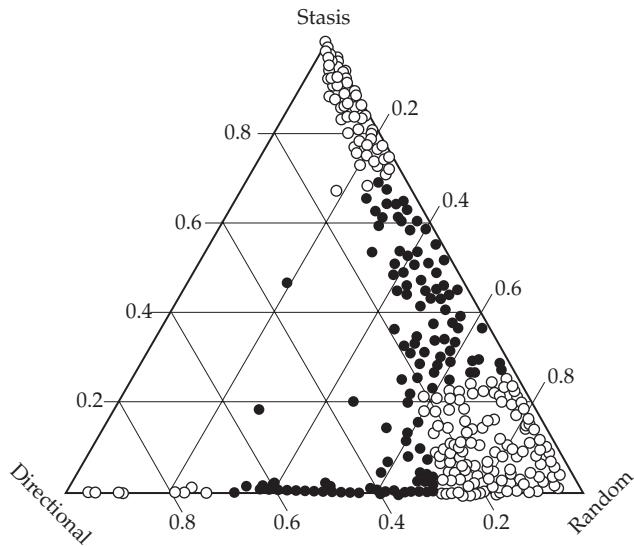

Figure 12.6 A De Finetti diagram of the support for the random walk, directional walk, and stasis models. Each point corresponds to the coordinates of the Akaike weights for these three models (which sum to one) for a single stratophenetic series. Points near vertices correspond to almost 100% support for a particular model, hence the labels at the vertices. Points along an edge of the triangle indicate very little support for the model perpendicular to that edge. Unfilled points indicate strong support (weight for most supported model at least 2.7 times the weight of any other model). (After Hopkins and Lidgard 2012.)

strongly supported model (had the largest Akaike weight). The random walk model was the most supported overall (49% of the time), while 46% of the fossil series had stasis as the most supported model. Figure 12.6 presents the relative support for all three models from the analysis of Hopkins and Lidgard (2012), presented as a **De Finetti diagram** (or **De Finetti triangle**). Values in the middle of the triangle have roughly equal support for all three models (which was rarely seen). Values near the edges of the triangle have very weak support for at least one model, and values near the vertices correspond to very high support for a single model. Note that there is little support along the directional selection axis for any sequence, with most of the support lying along the stasis-random walk axes.

An interesting perspective on the rates of macroevolution was offered by Uyeda et al. (2011), who examined a vast data set of traits followed over time, with time-span ranging from fractions of years to over 350 million years. For periods of a million years or less, rapid evolution was seen to occur, but it is constrained, and does not accumulate over time. This matches the earlier observation by Estes and Arnold (2007) that the expected magnitude of divergence over samples is largely time-independent up to about a million generations. However, as Figure 12.7 illustrates, Uyeda et al. observed an accumulation of cases of rapid divergence starting at $\sim 10^6$ year intervals, generating what they called a **blunderbuss pattern**, as the spread of values resembles the flared muzzle of the seventeenth-century firearm of the same name.

While Estes and Arnold (2007) were able to account for their observed pattern in terms of stabilizing selection with a fluctuating optimum, this model did not fit the data of Uyeda et al. (2011) presented in Figure 12.7. Rather, the best fit was a model of essentially stasis (the Sheets-Mitchell model), coupled with rare random bursts of significant change (with an average waiting time of $\sim 10^7$ years). The model allowing for multiple (as opposed to single) bursts fit the data best. While this pattern is striking and reproducible over the several different taxonomic data sets used by the authors, the underlying mechanism is unclear. Uyeda et al. suggested that this pattern might be correlated with the opening of new niches following species turnover (as species life spans are typically in the million-year range).

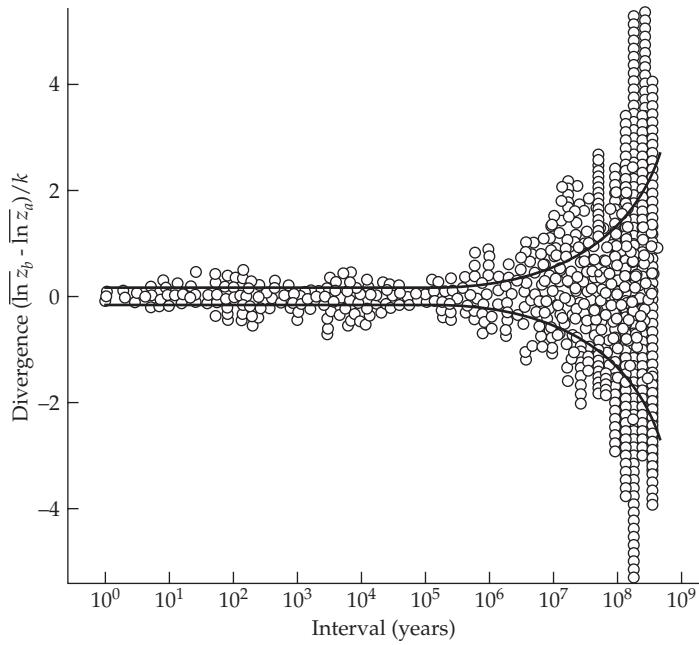

Figure 12.7. The blunderbuss pattern of divergence observed by Uyeda et al. (2011). Bounded variation is seen over the first 10^6 years, after which considerable divergence can occur. Divergence is scored as the log difference between means (at time points a and b , for an interval of $b - a$), scaled by the dimension k of the data ($k = 2$ for area, $k = 3$ for mass). (After Uyeda et al. 2011.)

Example 12.5. Anderson et al. (2000) proposed that a series of candidate models can be compared via their **Akaike weights**, an approach used by Hunt (2007) to assess the relative fit of a series of candidate models for long-term evolution (Figure 12.6). Suppose one has a series of models that were fit using maximum likelihood. If these models are not nested (so that likelihood-ratio tests for comparing fit are not available; LW Appendix 4), then comparison statistics, such as the **Akaike information criterion** (AIC; Akaike 1974) can be used to rank them. AIC rewards goodness of fit (higher log-likelihood, L), while penalizing for the number of parameters (k) with smaller AIC values implying a better model. With $n < 40k$ observations, Anderson et al. suggested that a corrected version of AIC should be used,

$$AIC_c = -2 \ln(L) + 2k + \frac{2k(k+1)}{n-k-1} \quad (12.25a)$$

which differs from the standard AIC measure in the addition of the last term. Suppose that one has a set of m candidate models and computes the support for model i relative to the best fitting of all m models,

$$\Delta_i = AIC_{c,i} - \min(AIC_c) \quad (12.25b)$$

The resulting Akaike weights for each of the candidate models are given by

$$w_i = \frac{e^{-(\Delta_i/2)}}{\sum_{j=1}^m e^{-(\Delta_j/2)}} \quad (12.25c)$$

By construction, these weights sum to one, with each giving the relative support for model i , given the collection of proposed models.

Note that Equation 12.25c gives each model equal prior weight (for m models, a prior weight of $1/m$ on each cancels in the denominator and numerator of Equation 12.25c). More

generally, if one has prior weights π_i for each model,

$$w_i = \frac{\pi_i e^{-(\Delta_i/2)}}{\sum_{j=1}^m \pi_j e^{-(\Delta_j/2)}} \quad (12.25d)$$

For example, one might, a priori, assume that 60% of the traits are under drift, 30% are under stabilizing selection, and the rest are under directional selection. This would yield different Akaike weights than when our prior belief is equal for all three cases.

POPULATION STRUCTURE BASED-TESTS: Q_{ST} VERSUS F_{ST}

Species are often distributed in space as a series of populations isolated by semipermeable migration barriers. In such settings, the variation at a neutral locus represents a balance between input of new variation by mutation and migration, countered by its removal by drift (Chapter 2). One measure of the resulting genetic population structure is Wright's (1951) F_{ST} statistic, reviewed by Holsinger and Weir (2009). As discussed in Chapter 2, F_{ST} partitions the total genetic variance of the entire metapopulation (measured as heterozygosity under the assumption of panmixia) into the fractions within ($1 - F_{ST}$) and among (F_{ST}) populations (Cockerham 1973; Nei 1987; Weir 1996). As developed in Chapter 9, one signature of selection at a candidate locus is whether it shows too much or too little population structure with respect to the F_{ST} value estimated from a set of (presumably) neutral markers (the Lewontin-Krakauer test). An excessive F_{ST} value at the candidate locus suggests too much divergence relative to the drift-migration expectation, consistent with directional selection varying over populations. Too little divergence (F_{ST} is too small) is consistent with stabilizing selection over populations regarding the divergent effects of drift. Although there are a number of problems with such tests (Chapter 9), they still have wide appeal, as the required data are reasonably straightforward to collect.

The trait-based analog of this test is based on comparing Q_{ST} to F_{ST} . Q_{ST} (developed below) is a measure of the population structure of the genetic variance underlying a quantitative trait, which is then compared with a neutral-marker based estimate of F_{ST} for the same population. While the candidate-gene tests in Chapter 9 compare candidate-locus F_{ST} values with the neutral standard, the trait-based test compares Q_{ST} for the candidate trait against this standard. This is a rather active area of research, and reviews can be found in Merilä and Crnokrak (2001), McKay and Latta (2002), Whitlock (2008), and Leinonen et al. (2008, 2013). Standard Q_{ST} analysis assumes only a single level of structure, but extensions to more hierarchically structured populations were proposed by Whitlock and Gilbert (2012). Likewise, multivariate extensions (properly accounting for the genetic correlations among a series of measured traits) were developed by Chenoweth and Blows (2008), Martin et al. (2008), Chapuis et al. (2008), Ovaskainen et al. (2011), and Karhunen et al. (2013, 2014).

Q_{ST} : Partitioning Additive Variance Over Populations

Consider a quantitative trait in a diploid with a purely additive-genetic basis, and denote its genetic variance over the entire metapopulation by σ_G^2 . From Table 11.3 (setting $f = Q_{ST}$), the within- and among-population components of variance can be represented as $\sigma_{GW}^2 = (1 - Q_{ST})\sigma_G^2$ and $\sigma_{GB}^2 = 2Q_{ST}\sigma_G^2$, respectively, for a total variance in a structured population of $(1 + Q_{ST})\sigma_G^2$. Rearranging yields

$$Q_{ST} = \frac{\sigma_{GB}^2}{\sigma_{GB}^2 + 2\sigma_{GW}^2} \quad (12.26a)$$

While the term Q_{ST} was introduced by Spitze (1993), this metric was proposed earlier by Prout and Barker (1989, 1993) and Lande (1992), and strongly hinted at by Rogers and

Table 12.2 Interpretation of Q_{ST} versus F_{ST} comparisons.

Observation	Interpretation
$Q_{ST} > F_{ST}$	Divergent selection: spatial variation in trait values in excess of neutral expectation.
$Q_{ST} = F_{ST}$	Consistent with divergence expected under drift. Does not rule out selection, but does not support it either.
$Q_{ST} < F_{ST}$	Convergent selection: spatial variation in trait values less than neutral expectation. Similar trait values are favored over populations.

Harpending (1983). Equation 12.26a is a very general result, applicable to a wide range of population structures and migration patterns provided the character does indeed have an entirely additive genetic basis (Whitlock 1999). When dealing with haploid populations (Whitlock 2008) or collections of entirely selfed lines (Bonnin et al. 1996; Le Corre 2005; Rhoné et al. 2010), σ_{GW}^2 in Equation 12.26a is weighted by one, rather than two. More generally, when f is the amount of inbreeding within each population, then following Bonnin et al. (1996),

$$Q_{ST} = \frac{(1+f)\sigma_{GB}^2}{(1+f)\sigma_{GB}^2 + 2\sigma_{GW}^2} \quad (12.26b)$$

Equations 12.26a and 12.26b provide a potential approach for testing the hypothesis of neutral divergence among population means. Provided that a sufficient number of families from multiple populations can be grown in a common environment, appropriate statistical methods can be used to estimate σ_{GW}^2 and σ_{GB}^2 (e.g., by ANOVA; Lynch and Walsh 1998). The resultant estimate of Q_{ST} can then be compared to a parallel measure of subdivision (F_{ST}) derived from putatively neutral molecular markers. Under the assumption of neutrality, Q_{ST} should not be significantly different from F_{ST} . On the other hand, $Q_{ST} > F_{ST}$ is expected if population differentiation has been primarily driven by adaptive divergence, whereas the opposite relationship is expected if the mean phenotypes of all or most populations are kept relatively uniform by stabilizing selection for the same optima (Table 12.2). It is important to stress that any comparison of this sort *must* be performed using the *same set of populations* to obtain both Q_{ST} and F_{ST} . An analysis using an estimate of F_{ST} from one set of populations and Q_{ST} from another is not trustworthy.

The first (of many) caveats with respect to this strategy is that, even under neutrality, the expected value of Q_{ST} will not necessarily equal F_{ST} if the trait of interest is influenced by nonadditive genetic effects. As outlined in Chapter 11, with nonadditive gene action, the within- and among-population components of genetic variation for neutral characters under short-term divergence are no longer equal to $\sigma_{GW}^2 = (1-f)\sigma_G^2$ and $\sigma_{GB}^2 = 2f\sigma_G^2$ (where f is the parameter estimated by F_{ST}), but instead are influenced by a number of higher-order terms (see Table 11.3). In general, because the within-population genetic variance declines less rapidly with inbreeding under nonadditivity (and sometimes even increases; Chapter 11), Q_{ST} , as defined by Equation 12.26b, will tend to be smaller than F_{ST} under neutrality. In particular, Whitlock (1999) showed that additive \times additive variance always results in $Q_{ST} < F_{ST}$ under neutrality. Dominance also causes Q_{ST} and F_{ST} to deviate under neutrality, with the direction of the inequality depending on the details of the population structure. There is disagreement as to the practical importance of these departures, especially given the large variances associated with Q_{ST} estimates (López-Fanjul et al. 2003, 2006, 2007; Goudet and Büchi 2006; Goudet and Martin 2007; Whitlock 2008; Santure and Wang 2009). However, because these violations of assumptions often (but not always) result in $Q_{ST} < F_{ST}$, this general behavior makes conclusions regarding adaptive divergence based on elevated Q_{ST} conservative, while rendering observations of $Q_{ST} < F_{ST}$ ambiguous. Violations of the assumption of additivity may not be a serious issue for most morphological traits, but given that life-history traits often show considerable

nonadditive variance (Chapter 6), these may be more vulnerable to false impressions under a comparison of Q_{ST} and F_{ST} .

A second caveat is that the choice of markers used to estimate F_{ST} can introduce bias. The strong assumption is that the markers chosen are neutral, such that any structure associated with the markers reflects the neutral population structure. Historically, allozyme markers were commonly used to estimate F_{ST} , and because these represent variant protein products, some may not be neutral. Another problematic (but widely used) marker class is microsatellites. For F_{ST} to serve as a neutral proxy for the behavior of alleles underlying a focal trait, the mutational structure of the markers and QTLs must be compatible. Microsatellite alleles can easily back-mutate, resulting in underestimation of F_{ST} (Hendry 2002; Kronholm et al. 2010). While microsatellite-specific distance metrics (such as R_{ST} ; Slatkin 1995a; Goodman 1997) have been proposed, these should *not* be used in place of F_{ST} for comparison with Q_{ST} . These modified metrics adjust for high rates of back-mutations, something not expected at QTL alleles, potentially resulting in different adjusted measures of allelic divergence at the markers versus QTLs. These issues are of special concern given that many early studies used microsatellites (Edelaar and Björklund 2011; Edelaar et al. 2011). The ever-increasing use of SNPs to estimate F_{ST} avoids these concerns.

P_{ST} : Approximating Q_{ST} with Phenotypic Data

Because of the requirement for assays in a common-garden arena, true joint studies of Q_{ST} and F_{ST} are not common. Pujol et al. (2008) noted that roughly half of the wild population studies they reviewed were not based on estimated additive variances. Instead, a phenotypic-based proxy for Q_{ST} was used, where within- and/or among-population *phenotypic* variances replace the more challenging estimates of additive variation. The former can easily be obtained via a standard ANOVA (e.g., Holand et al. 2011), while the latter require a series of parent-offspring or sib rearings in a common environment. A modification of this purely phenotypic approach is to use

$$\hat{\sigma}_{GB}^2 = c \hat{\sigma}_{PB}^2, \quad \hat{\sigma}_{GW}^2 = h^2 \hat{\sigma}_{PW}^2 \quad (12.27a)$$

where c reflects the fact that only part of an observed phenotypic difference in means may be genetic (Merilä 1997; Leinonen et al. 2006; Sæther et al. 2007; Brommer 2011). Substitution into Equation 12.26 yields the P_{ST} statistic of Leinonen et al. (2006),

$$\hat{P}_{ST,L} = \frac{\hat{\sigma}_{PB}^2}{2(h^2/c) \hat{\sigma}_{PW}^2 + \hat{\sigma}_{PB}^2} \quad (12.27b)$$

When $c = h^2$, this reduces to Equation 12.26a, with phenotypic variances replacing their genetic counterparts. Holand et al. (2011) suggested doing a sensitivity analysis by varying the value of c (for a fixed h^2 value), and using simulations to find critical upper and lower c values for which Q_{ST} is significantly above and significantly below F_{ST} . While enticing because of their simplicity and relative ease of application (only phenotypic data are required), strong caution is advised when replacing Q_{ST} by a phenotypic surrogate (Pujol et al. 2008; Brommer 2011). At a minimum, such estimates should *always* be denoted as P_{ST} whenever *any* variance component is based on a purely phenotypic measure. Although the biology or ecology of a species might be such that only P_{ST} estimates are possible, in such cases the investigator needs to seriously consider if such a resulting study can give truly worthwhile results.

Even when genetic data (information from crosses) are used, bias can still be introduced into Q_{ST} estimates. Ideally, additive variances should be estimated from the covariance among paternal half-sibs. When covariance among full sibs is used, additive variance estimates can be inflated by the presence of dominance or maternal effects. Likewise, if among-group differences are not measured in a common garden, shared environmental effects can inflate this estimate. Conversely, a common garden may obscure any evolved plastic response that is part of the adaptive response to specific environments. See Whitlock (2008) for further discussion of such sources of bias.

A slightly optimistic note was struck by Pujol et al. (2008), who noted that the onerous requirement of a common garden may be circumvented through the use of BLUP-based genetic-group mixed models (e.g., Westell et al. 1988; Quaas 1988), which allow for the estimation of both within- and among-group additive variance (a variant of this approach was used by Roberge et al. 2007). BLUP uses the genetic relationships among all measured individuals to separate genetic from environmental contributions (Chapters 19 and 20). This requires good estimates of these genetic relationships, which (in the absence of pedigree data) requires a rather dense set of markers (a very large number of SNPs) for the accuracy needed, given the expected rather distant connections among groups.

Testing Q_{ST} Versus F_{ST}

The construction of rigorous statistical tests for comparing Q_{ST} with F_{ST} is problematic on several levels. First, both are ratios of variances, so that estimates obtained by directly substituting variance estimates into Equation 12.26 are biased, as the expectation of a ratio is not the same as a ratio of expectations (LW Equation A1.19a). Second, the sampling distribution of Q_{ST} is complex, as one must use a crossing design to estimate the variance components. Hence, the correct construction of dispersion intervals (such as standard errors in a frequentist setting or credible intervals in a Bayesian setting) is not trivial. Finally, there is the issue of formally comparing a somewhat noisy estimate (F_{ST}) with a very noisy estimate (Q_{ST}), which were obtained using very different designs. Some of these issues were addressed by O'Hara and Merilä (2005), Whitlock (2008), and Whitlock and Guillaume (2009). As noted by O'Hara and Merilä, one significant problem is simply power. The among-group variance is a function of the number of groups, with at least 20 needed for any substantial power. Unfortunately, the typical group number is around 7 for the studies reviewed by Merilä and Crnokrak (2001).

An important advance was the observation by Whitlock (2008) that the distribution of realized Q_{ST} values (ignoring, for now, the additional error introduced by using the sample estimate, \hat{Q}_{ST} , for the true value of the realization for a particular trait) can often be approximated using the Lewontin-Krakauer distribution for F_{ST} values (Equation 9.10a). Simulations by Whitlock confirmed the suggestion by Rogers and Harpending (1983) that, provided F_{ST} is small, the amount of information on population structure derived from the variance components of a quantitative trait is equivalent to that from a single-marker F_{ST} . Provided that the average F_{ST} is small, then under the null that $Q_{ST} = F_{ST}$, to a very good approximation, we have

$$\frac{n_d - 1}{\bar{F}_{ST}} Q_{ST} \sim \chi^2_{n_d - 1}, \quad \text{implying} \quad Q_{ST} \sim \frac{\bar{F}_{ST}}{n_d - 1} \chi^2_{n_d - 1} \quad (12.28a)$$

where \bar{F}_{ST} is the average F_{ST} over the scored molecular marker loci, and n_d is the number of demes. This expression assumes that Q_{ST} is estimated without error, a point addressed shortly.

The requirement that \bar{F}_{ST} is small arises (in part) from χ^2 being defined over $(0, \infty)$, while Q_{ST} is restricted to $(0, 1)$. Hence, the approximation given by Equation 12.28a assumes that there is essentially no probability in the upper tail of a χ^2 above a critical value,

$$\Pr \left(\frac{\bar{F}_{ST}}{n_d - 1} \chi^2_{n_d - 1} > 1 \right) = \Pr \left(\chi^2_{n_d - 1} > \frac{n_d - 1}{\bar{F}_{ST}} \right) \simeq 0 \quad (12.28b)$$

To achieve this condition, Whitlock (2008) recommended an upper limit of $\bar{F}_{ST} < 0.1$. For example, with $n_d = 2, 5$, and 10 , the probabilities in Equation 12.28b (with $\bar{F}_{ST} = 0.1$) become $0.002, 4 \cdot 10^{-8}$, and $2 \cdot 10^{-15}$, respectively.

Insight into power is obtained by asking, under the null, how often the ratio Q_{ST}/F_{ST} exceeds some value, δ . Rearranging Equation 12.28a yields

$$\Pr \left(\frac{Q_{ST}}{\bar{F}_{ST}} > \delta \right) = \Pr \left(\frac{(n_d - 1)Q_{ST}}{\bar{F}_{ST}} > \delta(n_d - 1) \right) = \Pr \left(\chi^2_{n_d - 1} > \delta(n_d - 1) \right) \quad (12.28c)$$

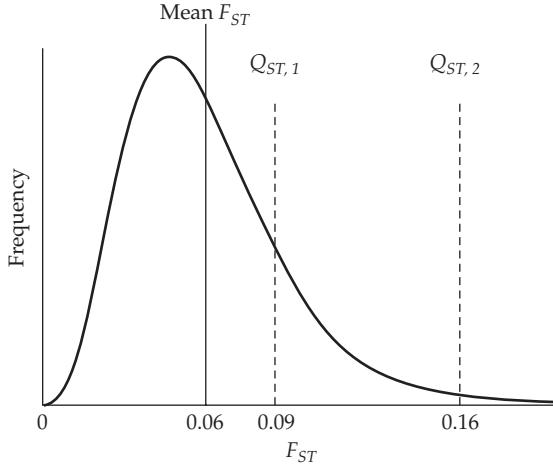

Figure 12.8 When \bar{F}_{ST} is small, the Q_{ST} distribution for a neutral, completely additive trait should approximately follow the Lewontin-Krakauer distribution (Equations 9.10a and 12.28a). In this example, two traits, one with $Q_{ST} = 0.09$, and a second with $Q_{ST} = 0.16$ are both larger than $\bar{F}_{ST} = 0.06$, but only trait 2 is significant. (After Whitlock 2008.)

Consider $n_d = 2$, as occurs when comparing two populations. How much larger must the true value of Q_{ST} be than the true value F_{ST} for this difference to be significant at the $\alpha = 0.05$ level? Because tests involving Q_{ST} are two-sided (either too large or too small being of interest), and $\Pr(\chi_1^2 > 5.02) = 0.025$, Equation 12.28c gives the critical value as $\delta = 5.02$. Hence, Q_{ST} must be in excess of 5 times \bar{F}_{ST} to be significant at the 5% level. For $n = 10$, $\Pr(\chi_9^2 > 19.03) = 0.025$, or $\delta = 19.03/3 = 2.1$, and hence only a two-fold difference is required for significance. The same logic can be used to obtain the critical value when $Q_{ST} < \bar{F}_{ST}$. For example, because $\Pr(\chi_9^2 < 2.7) = 0.025$, a value of Q_{ST} less than one third of \bar{F}_{ST} ($2.7/9 = 0.3$) is significant at the 5% level when $n_d = 10$.

Figure 12.8 shows the basic structure of tests based on this simple approach: compute Q_{ST} and compare this value with the distribution of realized values for single-locus F_{ST} , where the mean of this latter distribution as taken is \bar{F}_{ST} , the mean F_{ST} value over all loci in the sample. This approach assumes that just a *single* trait is of interest and that Q_{ST} is measured without error (again, we return to this below). In the typical study setting, however, one has k Q_{ST} values (one for each of the k traits in the study), but uses the same set of markers (and hence the same \bar{F}_{ST} value) for all traits. This is now a multiple-comparisons setting (Appendix 4). One approach to accommodate this concern is to use the first k order statistics from the Lewontin-Krakauer distribution (Equation 12.28a), which can be obtained as follows. A large number of samples are generated by randomly drawing k χ^2 random variables and scaling each using Equation 12.28a to generate an empirical distribution of the k order statistics (i.e., the values of the k realizations, ranked from largest—the first order statistic—to smallest; Chapter 14). The largest Q_{ST} value is assessed by comparing it against critical values for the empirical distribution of the largest value from each of the simulated samples. If this Q_{ST} value is significant (for example, only 2% of the simulated samples of k draws each have a greater value for their largest order statistic), one can then turn to the second largest Q_{ST} value and compare it with the simulated distribution of the second largest order statistic, and so on until a Q_{ST} value is no longer significant relative to its corresponding order statistic.

The major flaw with using Equation 12.28a is that it ignores the very important sampling variances of both our estimates, \hat{Q}_{ST} and \bar{F}_{ST} . Whitlock and Guillaume (2009), building

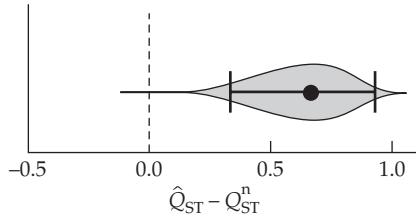

Figure 12.9 A violin plot for the distribution of the difference $(\hat{Q}_{ST} - Q_{ST}^n)$ for body length in the sea-run brown trout (*Salmo trutta*), using the resampling scheme suggested by Whitlock and Guillaume (2009), and detailed in Example 12.9. The width of the “violin” indicates the probability mass in that interval, the dot denotes the highest posterior probability, and the error bars the 95% credibility interval. Here this interval is completely above zero, demonstrating that \hat{Q}_{ST} is significantly in excess of its predicted neutral value given \bar{F}_{ST} . (After Rogell et al. 2012.)

on Equation 12.28a, showed how to incorporate such uncertainty to construct the distribution (which they denoted by Q_{ST}^n) of the estimated \hat{Q}_{ST} values under the assumption of an additive and neutral trait, which is also specific for the design used to estimate variance components (Example 12.6). A plot of the resulting distribution of the difference $(\hat{Q}_{ST} - Q_{ST}^n)$ provides a formal statistical test of whether the observed value, \hat{Q}_{ST} , is excessively large (the 95% credible interval is entirely above zero) or small (the 95% credible interval exclusively below zero). Figure 12.9 shows how **violin plots** provide a useful way to display these results.

Example 12.6. To generate draws from the distribution Q_{ST}^n accounting for the sampling of an estimated \hat{Q}_{ST} value, Whitlock and Guillaume (2009) started with the clever observation that because $Q_{ST} = F_{ST}$ for a neutral additive trait, Equation 12.26a can be rearranged to yield

$$\sigma_{GB}^2 = \frac{2 F_{ST} \sigma_{GW}^2}{1 - F_{ST}} \quad (12.29)$$

This trick allowed them to generate a random value for σ_{GB}^2 , given values of σ_{GW}^2 and F_{ST} . Their scheme to generate the i th sample of Q_{ST}^n was as follows:

- 1) Draw a bootstrap sample of the n markers by sampling with replacement. Compute the mean F_{ST} value for this (the i th sample, $\bar{F}_{ST,i}$).
- 2) Draw a sample value of $\sigma_{GW,i}^2$ as follows:
 - a) If σ_{GW}^2 is computed by a standard ANOVA, recall that $(MS/df) \sim \chi_{df}^2$, where MS is the observed mean sum of squares and df its degrees of freedom (LW Chapter 18). Generate X_i , a draw from a χ_{df}^2 and take the sample i value for MS as $MS/df \cdot X_i$, using this value to compute the variance estimates (O’Hara and Merilä 2005; Whitlock and Guillaume 2009). When σ_{GW}^2 is estimated as a function of several different sums of squares, compute each in the fashion above, and then use these realizations to compute $\sigma_{GW,i}^2$.
 - b) If σ_{GW}^2 is estimated by Bayesian methods, then $\sigma_{GW,i}^2$ is a sample drawn from the resulting posterior (i.e., Rogell et al. 2012).
- 3) Use the sample values of $\bar{F}_{ST,i}$ and $\sigma_{GW,i}^2$ with Equation 12.29 to generate a draw of the among-group variance, $\sigma_{GB,i}^2 = 2\bar{F}_{ST,i} \sigma_{GW,i}^2 / (1 - \bar{F}_{ST,i})$.
- 4) Take $Q_{ST,i}^n = \sigma_{GB,i}^2 / (\sigma_{GB,i}^2 + 2\sigma_{GW,i}^2)$.
- 5) Repeat steps (1) through (4) until a sufficient number of draws (say m) have been computed to generate a sufficiently dense empirical distribution under the null. Figure 12.9 was com-

puted using the m values ($\hat{Q}_{ST} - Q_{ST}^n$) obtained by subtracting the estimated Q_{ST} from each sample drawn from the underlying null distribution Q_{ST}^n .

Empirical Data

Results from the large number of Q_{ST} vs. F_{ST} comparisons from natural populations were summarized by Merilä and Crnokrak (2001), McKay and Latta (2002), and Leinonen et al. (2008, 2013). Values of Q_{ST} and F_{ST} are positively correlated, with $r = 0.24$ (Leinonen et al. 2013). Thus, there is a modest tendency for the structure of quantitative-trait variation to parallel the population structure for neutral alleles. The striking finding is that $Q_{ST} > F_{ST}$ for $\sim 70\%$ of all traits, which, taken at face value, suggested that diversifying selection was very widespread (Figure 12.10). Conversely, values of $Q_{ST} < F_{ST}$ are rare, despite the bias in this direction for neutral traits under a variety of conditions (discussed above), suggesting that persistent stabilizing or uniform selection is far less common.

One potential explanation for this trend of $Q_{ST} > F_{ST}$ was offered by Miller et al. (2008). They found that the variance of Q_{ST} is significantly larger than that for F_{ST} and noted a strong positive correlation in the data between Q_{ST} and the difference ($Q_{ST} - F_{ST}$). Hence, populations with larger Q_{ST} values tend to also have greater departures from F_{ST} . In particular, they noted that if more variable traits are overrepresented in the sampling process, this generates outliers of Q_{ST} , given the latter's larger variance, which in turn generates excessive ($Q_{ST} - F_{ST}$) values, even under neutrality. Whitlock (2008) further stressed this concern:

It will always be possible to choose a set of traits that have higher than average Q_{ST} values. Traits chosen in this way cannot reliably be used to infer the extent of spatially heterogeneous selection. Examination of the traits chosen for many Q_{ST} studies makes one wonder whether traits are in fact always chosen with previous knowledge of the likely results.

A second source of bias in comparisons of Q_{ST} and F_{ST} was noted by Edelaar and Björklund (2011) and Edelaar et al. (2011). Markers with high mutation rates underestimate F_{ST} , and the most widely used markers in early Q_{ST}/F_{ST} studies, microsatellites, have high mutation rates. As shown in Figure 12.11, there is a strong positive relationship between the polymorphism level of a marker (with highly polymorphic markers having higher mutation rates) and the excess values of Q_{ST} over F_{ST} . Note that most of this trend is driven by studies employing microsatellites, with allozyme studies showing an excess of Q_{ST} largely independent of their polymorphism level.

Thus, the striking trend of $Q_{ST} > F_{ST}$ is certainly inflated by ascertainment bias, and somewhat inflated by the use of highly polymorphic markers (which is a more recent trend), making it difficult to make any general statement about how commonly diversifying selection structures quantitative traits in subdivided populations. As noted by Whitlock (2008), “While useful, Q_{ST} is a crude measure of the genetic differentiation of a trait caused by local adaptation.”

One check of theory is to compare Q_{ST} and F_{ST} values between control and artificially selected groups. Morgan et al. (2005) examined the results of a 14-generation replicated selection experiment for increased wheel-running activity in mice. A base population was split into a control and a selected group, each with four replicate lines. The average selection intensity per generation was close to one ($\bar{\tau} \approx 1$: Chapter 14), and significant response was seen in both the target trait, and (as a correlated response) in body mass. Theory predicts that Q_{ST} contrasting the control versus selected group should exceed F_{ST} , and this was observed for both the directly selected (wheel running) and correlated (body mass) traits. Q_{ST} and F_{ST} should be similar *among* the replicate lines of the selected group, and this was indeed seen among the wheel-running treatments, where Q_{ST} was actually below F_{ST} for body mass, but not significantly so.

Support for Q_{ST} as a method for detecting selection was also offered by Rhoné et al.

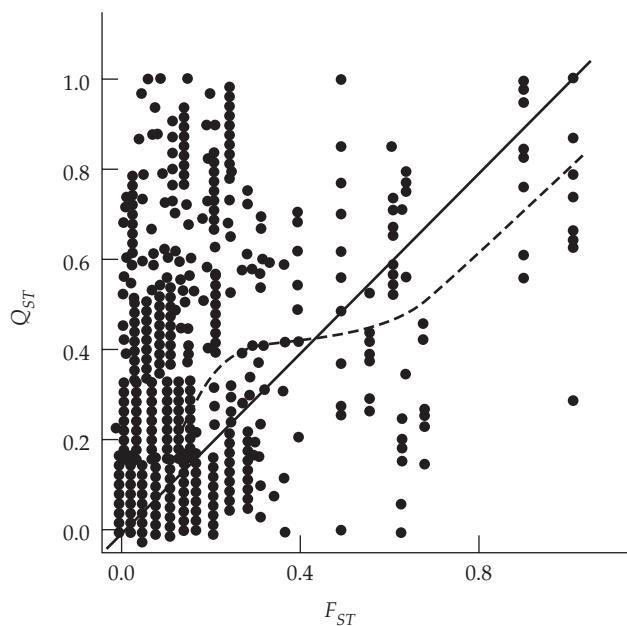

Figure 12.10 The joint distribution of Q_{ST} vs. F_{ST} seen in the meta-analysis of Leinonen et al. (2008). The solid line represents the neutral expectation, $Q_{ST} = F_{ST}$, while the dashed line is their smoothed nonlinear regression. There is a very strong tendency for $Q_{ST} > F_{ST}$. While consistent with widespread diversifying selection, as discussed in the text, such a pattern can also arise from ascertainment bias or the use of highly polymorphic markers (which underestimate F_{ST}).

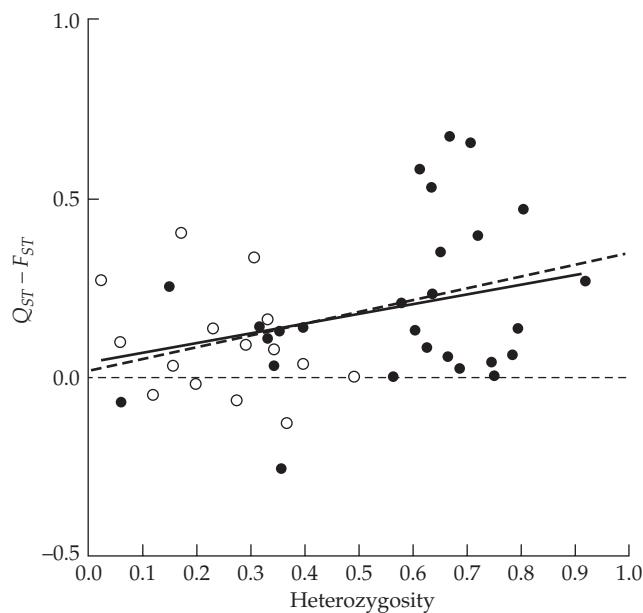

Figure 12.11 Correlation between the difference ($Q_{ST} - F_{ST}$) and heterozygosity at the marker loci, with each point representing one trait comparison. Filled circles involve microsatellites, and open circles denote allozyme markers. The solid line is the regression slope of ($Q_{ST} - F_{ST}$) on heterozygosity; the dashed line is the same regression, but correcting the previously discussed decline in F_{ST} with heterozygosity. (After Edelaar et al. 2011.)

(2010). They examined the response to 12 generations of natural selection on flowering times in a synthetic population of wheat grown in three locations in France (which experienced rather different environmental conditions). For generation 2 remnant seed assessed in a common garden, Q_{ST} and F_{ST} were not significantly different. However, individuals from generations 7 and 12 had Q_{ST} significantly larger than F_{ST} . Finally, agreement with theory was mixed in Porcher et al. (2004, 2006), who examined eight generations of selection in a series of structured *Arabidopsis* populations (migration was artificially controlled over a set of demes). Larger Q_{ST} values were seen under imposed heterogeneous selection among the experimental demes, consistent with theory, but F_{ST} increased as well.

Closing Comments: Q_{ST} , F_{STQ} , and Linkage Disequilibrium

Tests comparing F_{ST} values at candidate loci against the distribution of F_{ST} values at putatively neutral markers were discussed at length in Chapter 9. Comparisons of Q_{ST} to F_{ST} are a step removed, in that, ideally, we would like to contrast the F_{STQ} value (the average F_{ST} value for loci underlying our focal trait) against the genome-wide F_{ST} neutral standard. Given the near impossibility of locating all such causative loci, we have instead been using Q_{ST} , as with an additive trait, this should track the F_{STQ} values at the underlying causative loci. However, as is detailed in Chapters 16 and 24, allele-frequency changes are not the only route through which genetic variances (and hence the components of Q_{ST}) can change. Selection-generated gametic-phase disequilibrium (LD)—*even among unlinked loci*—can have a dramatic effect, even in situations where little allele-frequency change occurs. This impact of LD on Q_{ST} was stressed first by Latta (1998, 2005), and later by Le Corre and Kremer (2003, 2012; Kremer and Le Corre 2012). Because Q_{ST} is based on variance components, it can be influenced by linkage disequilibrium, which generates covariances between alleles at different loci, either inflating or deflating the resulting variances. When this happens, the values of Q_{ST} and F_{STQ} can become decoupled, and (as we will see) Q_{ST} can have more power to detect selection than F_{STQ} (even presuming we could locate all the underlying loci).

Thus, while a significant departure of Q_{ST} from the background value of F_{ST} is usually taken as indicating a shift in the F_{STQ} values at the underlying trait loci, this is only strictly correct when linkage disequilibrium is absent. Even in cases where selection induces little allele-frequency change (and hence little shift in F_{STQ} relative to the background F_{ST}), selection-induced disequilibrium (i.e., shifts in gamete, as opposed to allele, frequencies) can still generate a significant Q_{ST} signal. In particular, under the infinitesimal model, there is essentially no shift in the allele frequencies at underlying loci ($F_{STQ} \simeq F_{ST}$), but there can be a substantial change in the genetic variances due to selection-induced LD (Chapters 16 and 24), and hence a perturbation of Q_{ST} away from F_{STQ} . In such a setting, a direct comparison of F_{STQ} to the genome-wide F_{ST} standard would not reveal any evidence of selection, *but* a comparison of Q_{ST} (with its LD-shifted variance components) against F_{ST} might. Hence, under polygenic sweep conditions (Chapter 8), an appropriately performed Q_{ST} test might detect selection signatures missed by allele-frequency based tests.

To expand on this point, we need to consider how the within- and among-population LD (Ohta 1982) impact Q_{ST} . Letting the subscript x denote either within- or among-population values ($x = w$ and $x = a$, respectively), we can express the variances comprising Q_{ST} as

$$\sigma_x^2 = \sigma_{x,0}^2 + d_x = (1 + \phi_x)\sigma_{x,0}^2, \quad \text{where } \phi_x = \frac{d_x}{\sigma_{x,0}^2} \quad (12.30a)$$

where $\sigma_{x,0}^2$ is the linkage equilibrium value, d_x is the disequilibrium contribution generated by covariance among alleles at different loci (Equations 16.1 and 16.2), and ϕ_x is the ratio of the disequilibrium contribution to the linkage-equilibrium (i.e., genic) variance (note that ϕ_x is negative when d_x is negative). As discussed in Chapter 16, stabilizing or directional selection within a population generates negative d , so we often expect negative within-population LD (negative values of d_w and ϕ_w).

Turning to the among-population LD, Latta (1998) noted that if each population is under stabilizing selection for a different optimum value (θ), then for an additive trait where the

population means have reached their optimal values,

$$d_a = \sigma_\theta^2 - 2F_{STQ} \sigma_A^2 \quad (12.30b)$$

where σ_θ^2 is the variance in the optimum value over populations, and σ_A^2 is the expected additive genetic variation if the populations were to be randomly mated to form a single, panmictic, population (in linkage equilibrium). With nearly uniform selection (the variance in θ values over demes is small) and reduced migration (so that F_{STQ} is large), Equation 12.30b gives a negative covariance ($d_a, \phi_a < 0$) between trait-increasing alleles at different loci across demes, reducing the among-group variance σ_{GB}^2 below its linkage-equilibrium value. Conversely, if diversifying selection is strong (σ_θ^2 is large) and gene flow is high (F_{STQ} is small), a positive covariance is expected ($d_a, \phi_a > 0$), and σ_{GB}^2 is inflated relative to its value in the absence of LD. Thus, Q_{ST} often magnifies the effect of selection over what is expected from changes in F_{STQ} alone, with significant changes in Q_{ST} (relative to F_{ST}) possible even when little differentiation has occurred at the underlying QTLs ($F_{STQ} \simeq F_{ST}$).

For a completely additive trait, Le Corre and Kremer (2003) quantified the influence of LD on Q_{ST} by noting that the relationship between Q_{ST} (based on variance components) and F_{STQ} (based on the underlying loci) is given by

$$Q_{ST} = \frac{(1 + \phi_a)F_{STQ}}{(\phi_a - \phi_w)F_{STQ} + 1 + \phi_w} \quad (12.30c)$$

where ϕ_x is given by Equation 12.30a. Note that Q_{ST} equals F_{STQ} only when the among- and within-population LD values are equal ($\phi_a = \phi_w$). Using Equation 12.30c, Kremer and Le Corre (2012) showed that $Q_{ST} > F_{STQ}$ when $\phi_a > \phi_w$. Given that stabilizing selection within populations generates negative values of ϕ_w , while diversifying selection (variation in the optimum over populations) generates positive values of ϕ_a (Equation 12.30b), this combination amplifies the signal in Q_{ST} over that generated from F_{STQ} . As $Q_{ST} > F_{ST}$ is the signal for divergent selection (Table 12.2), while our last result implies that $Q_{ST} > F_{STQ} > F_{ST}$, the impact of LD is to *magnify* the impact of divergent selection over that expected from allele-frequency change alone (F_{STQ}). Again, the salient point is that even if the difference between F_{STQ} and F_{ST} is small, the difference between Q_{ST} and F_{ST} can still be large.

Hence, while Q_{ST} -based tests are fraught with complications, if properly performed (which is no small feat), they may actually be more powerful than a scan for F_{ST} outliers at known candidate genes for the trait of interest (Chapter 9). While F_{ST} -based scans are trait independent, knowledge of the potential target trait or traits allows Q_{ST} , and thus further information from LD, to be exploited. We return to this point below when considering certain trait-augmented marker-based tests.

Example 12.7. Using candidate genes in the photoperiod pathway (detected in *Arabidopsis thaliana*), Ma et al. (2010) explored whether variation in these loci is involved in growth cessation in populations of European aspen (*Populus tremula*) across a latitudinal gradient in Sweden. Their population sample consisted of 10 trees from each of 12 sites (spanning roughly ten degrees of latitude), scoring 113 SNPs from 23 photoperiod genes and 93 SNPs from 21 random control genes. Six of the photoperiod SNPs showed significant associations with growth cessation (with no evidence of epistatic interactions between these detected loci). While four of the photoperiod SNPs showed a significant correlation with latitude, the F_{ST} values for the photoperiod and control groups of SNPs were not significantly different (0.018 vs. 0.016, corresponding to F_{STQ} and F_{ST} , respectively), although photoperiod SNPs showed a significantly greater variance in F_{ST} values relative to the control SNPs. None of the individual SNPs showed significant F_{ST} departures from the control loci, so that even when using candidate genes in a known pathway that is likely to be under selection, no signature of selection was observed in individual F_{STQ}

values. However, as a group, the photoperiod SNPs showed a significant excess of pairs of alleles from different loci correlated with each other (i.e., showed LD), while no such pattern was seen with the control SNPs. Further, the highest five of the allelic pairs correlated between loci also involved either one (or both) alleles (SNPs) that showed significant clines with latitude. Thus, while selection in this study did not seem to generate a significant departure between F_{STQ} and F_{ST} , it did generate among-population covariances.

TRAIT-AUGMENTED MARKER-BASED APPROACHES: TESTS USING QTL INFORMATION

Our last class of tests for neutral trait evolution exploit marker information from either a QTL mapping experiment or a GWAS study. We refer to these as trait-augmented marker-based approaches, as tests are not based on a set of *random* markers (as was the case for genome scans; Chapter 9), but rather on a very *specific* set of markers, namely those chosen because they are associated with a target trait (as either markers linked to QTLs or GWAS hits). We first examine approaches using QTLs, which focus fixed sites, and then consider GWAS information, which focuses on segregating sites (i.e., changes in allele frequencies).

Leveraging QTL Studies

In theory, one could take localized QTL regions detected from such a cross (LW Chapters 14–16) as candidate regions for tests of selection using the machinery in Chapters 9 and 10. Here we examine a different class of tests, based not on a signature from a *single* QTL, but rather on the signature from an *entire collection* of QTLs for a given trait. We assume that the lines have been fixed (or nearly so) for alternative alleles at the underlying causative QTLs, and the pattern of fixation (i.e., which alleles were fixed in which line) provides information on whether this pattern was neutral.

The basic idea traces back to three papers, all coincidentally examining crosses for male secondary traits involving *Drosophila simulans* (Coyne 1996; Laurie et al. 1997; True et al. 1997). Under the neutral hypothesis, the relative abundances of “plus” and “minus” QTL alleles (associated with larger versus smaller trait values, respectively), are expected to be randomly distributed over lines and thus should not differ over the crossed lines. Intuitively, this might suggest a simple **sign test**: is there an excessive number of plus alleles in one line? If so, this is not consistent with neutral drift (which is agnostic with respect to the direction and effect sizes of QTLs being fixed). This general strategy will be biased if the parental lines are intentionally chosen (ascertained) to have extreme phenotypes, as the high line would naturally be expected to be enriched with “plus” alleles. Orr (1998a) suggested several approaches to correct for any such bias.

Orr’s QTLST and QTLST-EE Sign Tests

Assume that n detected QTL differences (alternative fixed alleles at n loci) are found via a standard QTL mapping experiment involving a cross between two lines (LW Chapter 15). Under neutrality, there should be no systematic directionality as to whether a line is fixed for increasing (plus) alleles over decreasing (minus) alleles at any particular QTL. This simple idea forms the basis of sign tests, but it requires modifications to account for the actual biology. For example, when the line means differ, the high (larger trait value) line is expected to contain more plus alleles (assuming equal effects; with a distribution of allelic effects, this need not be the case, as is discussed below). Orr noted that by choosing the larger line, we have introduced an ascertainment bias, as this line is *expected* to contain an excess of plus alleles. To proceed, we need some appropriate conditioning on this fact to obtain an unbiased statistic representing the value that constitutes an excess of plus alleles. The simplest approach is Orr’s **equal-effects model**, where all n QTLs have close to equal

effects. Here, the large line must contain at least $[n/2]$ high (plus) QTLs, where

$$[n/2] = \begin{cases} (n/2) + 1 & \text{for } n \text{ even} \\ (n+1)/2 & \text{for } n \text{ odd} \end{cases}$$

In other words, the high line must contain *at least* one more high allele than the low line (because all have equal effects). Determining whether an observed number, n_{high} , of plus alleles in the high line constitutes an excess now becomes a simple combinatorial problem. The probability of k high alleles in one line (under neutrality) follows from the binomial, where there is an equal chance that a random line gets a plus or a minus allele at any particular QTL, yielding

$$\Pr(n_+ = k) = \binom{n}{k} (1/2)^k (1/2)^{n-k} = \binom{n}{k} (1/2)^n$$

Note that all values of k contain a $(1/2)^n$ term. We now condition this probability of k alleles in the high line on the fact that this line *must* contain at least $[n/2]$ plus alleles, yielding

$$\Pr(n_+ \geq n_{high} | n_+ \geq [n/2]) = \frac{\Pr(n_+ \geq n_{high})}{\Pr(n_+ \geq [n/2])} = \sum_{i \geq n_{high}}^n \binom{n}{i} / \sum_{j \geq [n/2]}^n \binom{n}{j} \quad (12.31a)$$

where the common term of $(1/2)^n$ in both the numerator and denominator cancels. This is Orr's **QTL sign test for equal effects**, or *QTLST-EE*. Orr noted that a *minimum* of $n = 6$ detected QTLs is required for this test to be applied. To see this, note for $n = 6$ that $[n/2] = 4$, and the most extreme value, $n_{high} = 6$, gives a p value of $1/22 \sim 0.05$, while for $n = n_{high} = 5$, the smallest p is $1/16 \sim 0.0625$. For large values of n , Orr noted that Equation 12.31a can be approximated by a normal, with

$$\Pr\left(n_+ \geq n_{high} | n_+ \geq [n/2]\right) \simeq 2 \left[1 - \Phi\left(\frac{n_{high} - [n/2]}{\sqrt{n/4}}\right) \right] \quad (12.31b)$$

where $\Phi(x) = \Pr(U \leq x)$ for $U \sim N(0, 1)$.

Example 12.8. True et al. (1997) found that none of the eight detected QTLs for the posterior lobe in the male genitalia in a *Drosophila* cross were **antagonistic**, i.e., with effects in the opposite direction of the line value, such as low (minus) alleles in the high line or high (plus) alleles in the low line. Orr suggested that the equal-effects model may be reasonable for this trait. Assuming that this model holds, we have $n = 8$, $[n/2] = 5$, $n_{high} = 8$, and Equation 12.31a yields the probability of having all eight detected QTLs from the high line being plus alleles as

$$\sum_{i=8}^8 \binom{8}{i} / \sum_{j \geq 5}^8 \binom{8}{j} = \frac{\binom{8}{8}}{\binom{8}{5} + \binom{8}{6} + \binom{8}{7} + \binom{8}{8}} = \frac{1}{56 + 28 + 8 + 1} = 0.011$$

showing that this is a highly significant excess. Orr's normal approximation (Equation 12.31b) yields

$$p \simeq 2 \left[1 - \Phi\left(\frac{8 - 5}{\sqrt{8/4}}\right) \right] = 2 [1 - \Phi(2.1213)] = 0.034$$

The latter approximation is rather conservative, but not surprising, as this is a large-sample approximation and the number of detected QTLs here is very modest.

Under this strong assumption of equal effects, *QTLST-EE* is a nonparametric test, making no other assumptions, and not using any information on the actual difference between the high and low lines. Anderson and Slatkin (2003) noted that this test can be highly biased by trait choice (whereby the investigator, often unconsciously, chooses traits showing excessive divergence). While Orr's approach corrects for ascertainment bias *within* any specific trait comparison, it assumes that the traits were chosen at random. To examine the impact from nonrandom trait sampling (which, as previously discussed, also biases Q_{ST} tests), Anderson and Slatkin simulated T identical and independently distributed traits, each with 10 QTLs of equal effects, and then chose the most divergent single trait from this set for the subject of a *QTLST-EE* test. They found that this process of trait ascertainment introduces a significant bias. For $n = 10$ QTLs, Equation 12.31a gives the probability of 9 or more plus alleles in the high line as 0.0285. However, when the trait was not randomly chosen, but rather the high line from the *most divergent* trait in a set of 25 traits was used, then over 50% of the time it contained at least 9 high alleles. This lack of robustness with respect to the trait ascertainment scheme means that significant *QTLST-EE* results must be interpreted with caution.

A second class of tests proposed by Orr avoids this problem, and indeed, simulations show that it is conservative (Anderson and Slatkin 2003; Rice and Townsend 2012). For these tests, let D be the difference between the high and low lines. This may be either the actual observed difference, or the difference based on summing the effects over all detected QTLs. With a distribution of QTL effects in hand, one can then condition on the number of plus alleles, *given* the observed difference, D . This is Orr's **QTL sign test (QTLST)**. The seemingly problematic issue of the distribution of QTL effects can be easily handled via a bootstrap approach in one of two ways. First, one could use the observed distribution of absolute QTL effects ($|a|$), and then fit this using some standard distribution. Orr used the gamma distribution (Equation A2.25a; Figure A2.2) because of its flexibility and the fact that the exponential, a commonly assumed distribution of effect sizes (Chapter 27), is a special case. Note that estimating the distribution parameters that give the best fit is done using a truncated distribution, as QTL effects below a critical absolute size would not be detected. One can then generate the p value for the observed number of plus alleles through parametric bootstrapping. To do so, we generate n draws from this distribution, randomly assign each a sign, and only keep those samples for which the total (G) of signed QTL effects equals or exceeds D . The resulting distribution of plus alleles in the high line is now conditioned on neutrality (signs drawn at random), the assumed distribution of QTL effects, and the actual divergence D , yielding

$$p = \Pr(n_+ \geq n_{high} | G \geq D) = \sum_{i \geq n_{high}}^n \Pr(n_+ = i | G \geq D) \quad (12.32)$$

where $\Pr(n_+ = i | G \geq D)$ is simply the fraction of times that exactly i plus alleles were found in the retained bootstrap samples (i.e., those showing a divergence of at least D). Alternatively, instead of sampling from the fitted distribution, one could use standard bootstrapping and directly sample (with replacement, and with draws randomized with respect to sign) from the observed distribution of QTL effects (e.g., Rice and Townsend 2012).

While the *QTLST* adjusts for ascertainment bias, it does so the expense of power. As noted by Rice and Townsend (2012), the difference (D) provides some information on the amount of any previous selection, and by conditioning on its value, we are removing this evidence. Consider the extreme case where a line fixes plus alleles at all ten QTLs, and all have equal effect. In order to obtain the observed value of D , we must condition on only those cases where all ten are fixed, giving this test zero power (Griswold and Whitlock [2003] also noted the low power of this test). Rice and Townsend found that both the power and the false-positive rate increase with the variance of QTL effects.

Orr's tests have a simple appeal, but (as we have shown) there are a number a caveats

Table 12.3 Summary of the analysis of Rieseberg et al. (2002) on the signs of QTLs in traits from wild species, analyzed by trait categories. Within a category, number of antagonistic (opposite sign) and total QTLs are given, along with their QTL ratio (the fraction of antagonistic QTLs). Under the equal-effects assumption, this ratio should be close to 0.5. As indicated by **, all ratios are significant at $p < 0.001$ (using *QTLST-EE*, with p values adjusted using a sequential Bonferroni correction; Appendix 4), except for *, which denotes $p < 0.01$. A clearer comparison of the category effects is offered by the LS means estimate of the QTL ratio, which uses a linear model to estimate the direct effect of a category. For example, 0.139 is the average fraction of antagonistic QTLs for life history traits, after removing effects of taxon type, species comparison, and mating system. For the LS mean column, † denotes a mean in excess of two standard deviations from zero. Note that the presence of either a smaller QTL ratio or a smaller LS mean implies a stronger effect (a smaller fraction antagonistic QTLs, and hence greater departure from the neutral expectation of close to 0.5).

Trait Category	Antagonistic QTLs	Total QTLs	QTL ratio	LS Means
Animals	73	312	0.234**	$0.185 \pm 0.039^\dagger$
Plants	128	439	0.292**	$0.202 \pm 0.025^\dagger$
Interspecific	47	245	0.192**	0.137 ± 0.154
Intraspecific	154	506	0.304**	0.250 ± 0.243
Outcross	98	425	0.231**	0.170 ± 0.174
Self	103	326	0.316**	0.217 ± 0.262
Life history	111	540	0.206**	0.139 ± 0.175
Morphology	138	508	0.272**	0.266 ± 0.255
Physiology	8	40	0.200*	0.176 ± 0.125
Phenology	37	124	0.298**	0.236 ± 0.219
Total	201	751	0.268	

concerning their application. Another restriction is that no significant epistasis is allowed, as both tests sum over single-locus effects. There are additional biological reasons for Orr's tests to be conservative. A trait with a smaller fraction of antagonistic QTLs could imply either stronger past selection or more temporally consistent selection. If the sign of directional selection changes on a trait over evolutionary time, then different bouts of selection may fix alleles of opposite signs, lowering the observed excess. If the trait is under stabilizing selection and at its optimal value, random fixations of small-effect alleles are equally likely to be positive or negative. Likewise, if a trait fixes a major allele that causes it to overshoot an optimal value, subsequent fixations of smaller effects in the corrective direction will also reduce any signature from this test. Despite these concerns, Orr's tests can still be useful, even if one treats them as nothing more than an exploratory device, rather than as a formal test (which was our suggestion for most of the locus-specific tests of selection discussed in Chapters 9 and 10).

Applications of QTL Sign Tests

Using *QTLST-EE*, Rieseberg et al. (2002) performed a meta-analysis of over 2600 QTL effects from 572 traits in 86 studies. Their summary statistic was the QTL ratio: the fraction of antagonistic QTLs for the comparison of interest (Table 12.3). Roughly half of the studies involve wild \times domesticated crosses, where strong directional selection is suspected for domestication traits. Upon restricting analysis to those examples with six or more QTLs per trait (Orr's condition for such tests to have any power), 35 of the 54 qualifying traits (65%) believed to be involved in domestication showed significant departures from neutrality (i.e., too few antagonistic QTLs). By contrast, only 14 of 84 nondomestication traits (15.6%) in crosses involving domesticated species showed significant departures. Treating this latter class of traits as a control demonstrates that *QTLST-EE* behaved in the direction predicted for these crosses (revealing signatures for domestication traits and a lack of signatures for nondomestication traits).

Given that most studies in this survey involved just four or five QTLs per trait, the restriction of *QTLST-EE* to traits with six or more QTLs discards much potential information. To utilize these additional data, Rieseberg et al. amalgamated traits into a series of categories to accrue a sufficient number of QTLs for the *QTLST-EE* test to be applicable. As shown in Table 12.3, two different analyses were performed on these amalgamated data. First, the table simply reports the unadjusted QTL ratio (the fraction of antagonistic QTLs) for each category. Given that the same study can appear in multiple categories, the unadjusted QTL ratio is potentially influenced by these other categories. The second analysis in Table 12.3 (LS means) uses a linear model to estimate the impact from each category on the fraction of antagonistic QTLs, once the effects of other categories have been removed. This latter analysis more accurately reflects the category contribution.

As shown in the table, all (unadjusted) categories showed significant departures from neutrality, while only two of the adjusted categories (the LS means) did. Rieseberg et al. noted that interspecific crosses had a smaller fraction of antagonistic QTLs than did within-species (intraspecific) crosses (LS mean ratios of 0.137 versus 0.250), which they interpreted as a stronger role for directional selection in generating among-species differences. They also noted that life-history traits (LS ratio 0.139) were (by this criterion) more strongly selected than morphological traits (LS 0.266). While all of these differences are suggestive, it needs to be stressed that none are significant. Further, this pattern of more strongly selected life-history traits is at odds with meta-analyses based on the strength of selection as directly measured in the field (Figure 30.10). Rieseberg noted that the widespread departures from neutrality over all traits could result from an ascertainment bias due to investigators focusing on divergent traits in their crosses.

Ironically, a contrary example to Rieseberg's pattern of life-history and physiological traits tending to have fewer antagonistic QTLs than morphological traits comes from Rieseberg's own group (Lexer et al. 2005). A cross of two wild sunflowers (*Helianthus annuus* and *H. petiolaris*) revealed QTL ratios for life-history, physiological, and morphological traits of 0.345, 0.388, and 0.287, respectively. However, the reduction in the fraction of antagonistic QTLs for morphological traits appears to be due entirely to flower morphology (QTL ratio of 0.214; significant under *QTLST*), with the other measured morphological features (root/shoot and leaf traits) having (nonsignificant) QTL ratios (0.333 and 0.322, respectively) similar to those for life-history and physiological traits.

A second QTL meta-analysis worth mentioning is that of Louthan and Kay (2011), who focused on traits that were expected to be under biotic rather than abiotic selection. While larger QTL effects were more common for biotically selected traits, the fraction of antagonistic QTLs did not differ between the two groups. Both trait groups showed significant departures from neutrality using *QTLST-EE*.

We conclude by briefly highlighting the utility of two applications of sign tests to specific biological problems (as compared to the broad generalizations explored above). Albertson et al. (2003) examined traits in the massive species radiation occurring among cichlid fishes in the East African rift lakes. One striking feature of this radiation is extensive convergent evolution across lakes in feeding morphology, suggesting parallel directional selection. The authors used *QTLST* (with effect sizes drawn from a gamma distribution) to examine the genetic basis of feeding morphology through crossing two wild species from Lake Malawi. Because most individual traits had less than six QTLs, they grouped the traits, finding that only 4 of the 46 QTLs were antagonistic for jaw and teeth features. The highly significant *p* value supports directional selection on these feeding traits. Muir et al. (2014) examined QTLs in tomatoes (*Lycopersicon*) to explore leaf-related traits in wild species thought to be associated with adaptation to precipitation. They found no significant departure from neutrality for two leaf and two trichome (leaf hair) traits, but a significant departure from neutrality for two stomatal traits. They computed *p* values using both *QTLST* and *QTLST-EE*, and they found (in agreement with Anderson and Slatkin 2003) that *QTLST* was more conservative, yielding *p* values about twice as large as those obtained from *QTLST-EE*.

TRAIT-AUGMENTED MARKER-BASED APPROACHES: TESTS USING GWAS INFORMATION

While QTL data usually involves fixed differences that are revealed by crossing two divergent lines, genome-wide association studies (GWAS) provide information on currently segregating alleles within a target population (or set of populations). As such, GWAS data potentially offer inroads into the vexing problem of detecting a polygenic sweep (Chapter 8). In this setting, allele-frequency shifts at the underlying loci are expected to be small, and hence missed by most standard tests that look for single-locus signatures of selection (Chapter 9). The power of trait-augmented marker tests is that one chooses a set of markers given a trait, and then pools information across all of these markers, potentially generating a much stronger signal than could be found by considering any single marker in isolation.

Approaches Based on Combining Signals

The basic idea of combining signals over a set of GWAS markers has been exploited in several different ways. The initial suggestion was **gene set enrichment analysis (GSEA)** from genomics (Subramanian et al. 2005), wherein one considers clusters of genes on the basis of membership in some functional group (i.e., the same gene ontology, GO, class). This tactic was used by Daub et al. (2013), who computed the average F_{ST} value over a set of pathway-connected genes and contrasted this with the average F_{ST} value over a same-sized set of putatively neutral markers. Using this approach, they found evidence for selection on several human pathways, many connected with pathogen response. They also noted that long-distance LD was detected, which they attributed to epistatic interactions. While this could be correct, a confounding factor is that selection is also expected to generate such long-distance (i.e., between loosely-linked sites) LD with strictly additive genes (Chapters 16 and 24).

In the Daub et al. analysis, the “trait” was a specific pathway, while other analyses have considered more classical human traits, in particular, height. A simple, but robust, approach was used by Turchin et al. (2012). They examined allele frequency differences for 139 GWAS markers for height between Northern- and Southern-European populations. Under neutrality, allele-frequency increases in plus alleles should be randomly distributed between two populations (i.e., the sign test introduced above). Instead, what they found was that 85 of the 139 markers (sign test $p = 0.01$) showed an increase for high alleles in the Northern-European population. Note that one advantage of GWAS data is that typically a reasonable number of hits (marker-trait associations) are found, while QTL-based studies often fail to have more than five detected QTLs for a focal trait (and hence Orr’s test is not applicable).

Tests Based on *tSDS* Scores

Recall Field et al.’s (2016) singleton density score, *SDS* (Equation 9.42), for detecting very recent selection on a given single site. In that paper, they also showed how to extend this approach to search for polygenic selection on a given candidate trait, given a set of associated GWAS marker scores. This requires that both the *SDS* values and GWAS test statistics (such as a z value under a normality test) for a set of markers were generated using the same population. The *SDS* score for a given marker is first translated into a ***tSDS* (trait-*SDS*)** score, where the sign of the *SDS* score is changed so that trait-increasing markers receive positive scores. Their simplest approach was to combine the *tSDS* scores associated with all the significant GWAS markers for a target trait, using this mean as the test statistic.

Field et al. noted that most of the trait variance is usually explained by markers whose GWAS test statistics do not pass the genome-wide significance threshold (Chapter 24), and hence are not included in the test set. To incorporate information from these nonsignificant (but potentially biologically important) markers, they used a regression-based approach. Data points for the regression were generated by first binning SNPs with very similar GWAS scores, taking the bin average GWAS score as the predictor variable and bin average *tSDS* score as the associated response variable. A significant regression (or correlation) is expected

under selection, but not under drift. Both the average *tSDS* score and regression approaches detected clear signals of selection for increased height in Britain over the past 2000 to 3000 years. Several other traits (infant head size, body mass index [BMI], and female hip size, to name a few) also showed evidence of recent polygenic selection.

The Berg and Coop Q_x Test

The final approach leveraging GWAS-estimated marker effects for a target trait is due to Berg and Coop (2014), building on previous work by them (Coop et al. 2010; Günther and Coop 2013) as well as by Ovaskainen et al. (2011). Let $\mathbf{p}_i^T = (p_{i,1}, p_{i,2}, \dots, p_{i,m})$ denote the vector of allele frequencies for the i th marker over m subpopulations, where $p_{i,j}$ denotes the allele frequency in population j . Example 9.5 showed that the expected distribution of \mathbf{p}_i under neutrality is approximately given by

$$\mathbf{p}_i \sim \text{MVN}_m [p_{i,0}\mathbf{1}, p_{i,0}(1-p_{i,0})\boldsymbol{\Omega}] \quad (12.33a)$$

where $\boldsymbol{\Omega}$ is a (marker-estimated) matrix of expected covariances in allele frequencies over the subpopulations and $p_{i,0}$ is the allele frequency in the ancestral population. As detailed in Chapter 9, this formed the basis of Coop's *Bayenv* test for excessive divergence at a *specific locus*. Berg and Coop (2014) extended this result to a *trait-based* test as follows. Suppose n GWAS hits are discovered for the focal trait, where the trait-increasing allele for the i th marker changes the trait by a value of g_i , with $p_{i,j}$ denoting the frequency of this allele in population j . The GWAS-predicted mean genetic value for the trait in population j thus becomes

$$a_j = 2 \sum_{i=1}^m g_i p_{i,j} \quad (12.33b)$$

Letting $\mathbf{a}^T = (a_1, a_2, \dots, a_m)$ be the vector of mean trait genetic values over the m populations, then combining Equations 12.33b and 12.33a gives the expected distribution of trait means under drift as

$$\mathbf{a} \sim \text{MVN}_m [\mu\mathbf{1}, 2V_A\boldsymbol{\Omega}] \quad (13.33c)$$

where

$$\mu = \frac{2}{m} \sum_{i=1}^n g_i p_{i,0} \quad \text{and} \quad V_A = 2 \sum_{i=1}^n g_i^2 p_{i,0}(1-p_{i,0}) \quad (13.33d)$$

represent the expected genetic value and additive variance in the ancestral population.

To proceed, Berg and Coop expressed all of the a_j values as deviations from the grand mean, yielding $a_j^* = a_j - \bar{a}$. This uses one degree of freedom, and returns the vector $(\mathbf{a}^*)^T = (a_1^*, a_2^*, \dots, a_{m-1}^*)$, where one population is dropped. As Berg and Coop note, information from the dropped population is fully retained by the vector \mathbf{a}^* , so that the choice of which population to drop has no impact on the resulting analysis. The resulting vector is now distributed as

$$(\mathbf{a}^*)^T \sim \text{MVN}_{m-1} [\mathbf{0}, 2V_A\boldsymbol{\Omega}] \quad (13.33e)$$

As discussed in Appendix 5, a standard trick with a vector of correlated variables is to use a transformation to return a vector of uncorrelated variables of unit variance. Berg and Coop did this by using the Cholesky decomposition (Appendix 5) of $\boldsymbol{\Omega} = \mathbf{C}\mathbf{C}^T$, using the transformation

$$\mathbf{x} = \frac{1}{\sqrt{2V_A}} \mathbf{C}^{-1} \mathbf{a}^* \quad (13.33f)$$

which returns

$$\mathbf{x} \sim \text{MVN}_{m-1} (\mathbf{0}, \mathbf{I}) \quad (13.33g)$$

This is the basis for the **Berg-Coop Q_x test**, whose statistic is given by

$$Q_x = \mathbf{x}^T \mathbf{x} = \frac{(\mathbf{a}^*)^T \boldsymbol{\Omega}^{-1} \mathbf{a}^*}{2V_A} \quad (12.33h)$$

Under neutrality, $Q_x \sim \chi^2_{m-1}$, as $\mathbf{x}^T \mathbf{x}$ is the sum of $(m - 1)$ squared unit-normal random variables. Note by comparing this result to Equation 9.13c, that the Q_x test is very similar in form to the Günther-Coop (2013) $\mathbf{X}^T \mathbf{X}$ test for selection on a single site, but with estimated trait genetic values replacing allele frequencies.

Robinson et al. (2015) applied this test to height and BMI based on ~9400 individuals from 14 European countries, finding evidence that selection favored increased height and reduced BMI. Mathieson et al. (2015) also applied this test to Europeans, but used ancient DNA from 230 individuals (who lived between 6400 to 300BC), and reported evidence for two independent episodes of selection for height.

DIVERGENCE IN GENE EXPRESSION

The power of quantitative genetics is that its machinery can be applied to *any* character of interest, including omics traits (e.g., amounts of specific transcripts, proteins, and metabolites). Application of quantitative-genetic machinery to such omics traits has been coined **genetical genomics** by Jansen and Nap (2001), and it traces back to Damerval et al. (1994), who mapped QTLs controlling the spot volume of anonymous maize proteins detected by two-dimensional gel electrophoresis (LW Figure 15.10).

Level of Gene Expression as a Quantitative Trait

Much of the current work in genetical genomics has focused on the transcriptome, treating the level of expression of a specific gene as a quantitative trait and then attempting to map **eQTLs** (expression QTLs) or **eSNPs** (in GWAS studies) that influence this trait. Modern transcriptomic tools (initially using **microarray analyses**, and more recently, **RNA-Seq**) allow one to measure the level of expression for essentially the full repertoire of an individual's genes (Schena et al. 1995; Brown and Botstein 1999; Duggan et al. 1999; Wang et al. 2009). The amount of mRNA present (either measured by the intensity of hybridization against probes for a gene or from the amount present in massive sequencing of an RNA pool) is a typical quantitative trait, showing both genetic and environmental sources of variation, and further confounded by measurement error. This transcriptomics approach yields thousands of traits, as expression levels of each gene are separate, although potentially highly correlated, characters.

Our treatment of the evolutionary analysis of gene expression glosses over a number of very important concerns in the actual generation and processing of the raw data. Gene expression is both highly environmentally dependent and tissue specific, and formally, it should be viewed as a function-valued trait (Volume 3)—a character whose value is indexed by time and potentially other features (such as tissue type or developmental stage). In the following discussion, we simply refer to “the” expression level of a gene, but this is highly context-specific, with many transcripts showing considerable variation within an individual (over both time and tissues). There is also **technical variation** due to sampling and hybridization/amplification, so that an otherwise identical sample might still show considerable variation. Much of the early work used whole organisms (and hence all tissues at the sampled developmental stage), and it often pooled multiple individuals. RNA-seq relaxes many of these restrictions, as it requires much smaller amounts of material. Whichever method is used to assess expression levels, significant care is required to ensure that traits being compared are indeed the same character (i.e., expression levels at the same development time in the same set of tissues). As highlighted by Lynch and Walsh (1998), accurate quantitative-genetic studies, especially with noisy traits, require very significant replication, something lacking in many published studies of expression variation. All of these concerns highlight the fact that careful experimental design is absolutely critical in expression studies (Kerr and Churchill 2001a, 2001b; Churchill 2002; Yang and Speed 2002; Kerr 2003; Rosa et al. 2005).

While microbes have historically had only a relatively minor role in classical quantitative genetics (largely due to their limited number of easily scored traits), they have

flourished in the genetical genomics era, in part because they allow many of these design issues to be addressed. Starting with Brem and Kruglyak (Brem et al. 2002, 2005; Brem and Kruglyak 2005), yeast was quickly adapted as a model system for the quantitative genetics of gene expression, allowing investigators to examine the heritability of expression and map eQTLs for thousands of transcripts. This work was closely followed by similar analyses in mice, humans, and maize (Schadt et al. 2003), and has subsequently been extended to an ever-growing number of species. Such genome-wide transcription studies offer very high phenotypic throughput, allowing thousands of traits to be scored in a single experiment. While there is some modest bias against weakly expressed genes, the sample of expression levels over thousands of loci offers a largely unbiased view of the quantitative genetics of this class of traits. This is an extremely active area, with the early work reviewed by (among others) Stamatoyannopoulos (2004), de Koning and Haley (2005), Gibson and Weir (2005), Ranz and Machado (2006), Rockman and Kruglyak (2006), Whitehead and Crawford (2006), Fay and Wittkopp (2007), Gilad et al. (2008), Skelly et al. (2009), Emerson and Li (2010), Romero et al. (2012), and Albert and Kruglyak (2015). The conclusion from this early work is that the control of gene expression often has considerable heritability, involves both *cis* and *trans* factors, and can be very polygenic.

In order to understand the nature of evolutionary forces shaping the complex webs of gene regulation, appropriate null models are needed. That our initial impression of the origins of a given network structure can be highly misleading was stressed in Kauffman's (1969) classic paper. He showed that randomly constructed gene networks appear to be highly coordinated and hence give the appearance of being highly evolved (i.e., highly structured by natural selection). Thus, tests of whether certain features of gene regulation (or any omics data) are largely neutral are critical to understanding which evolutionary forces might shape these features. Much of the machinery developed in this chapter for detecting departures from neutral drift has been applied to the amount of divergence in gene expression.

Finally, before proceeding, a subtle, but important, clarification is in order. Our focus here is on detecting selection on particular *traits*, while Chapters 9 and 10 discuss machinery for detecting selection on particular *genes* (or, more correctly, specific *sequences*). Selection on the *expression level* at a specific gene is different from selection acting on the *sequence* of that gene. To see this, suppose only *trans*-acting factors influenced the expression levels at our target gene. In this case, *trans*-factor alleles at the eQTLs for that transcript would be under selection, *not* the alleles at the target gene itself. A test of a sequence-specific signature of selection would not pick up the target gene, but might detect genes coding for these *trans*-acting factors (subject to all the caveats discussed in Chapters 9 and 10). Likewise, a genome-wide association study would highlight sequence variation in *trans*-acting genes, *not* sequence variation in the gene whose expression is under selection. This distinction becomes murky when a gene also has *cis*-acting sites, as, while the expression level is the target, sequence variation near the gene (*cis*-acting sites), as well as at more distant (often unlinked) sites, would be the genetic targets of selection. An example of such a *cis*-acting site is in the *tb1* gene, which is involved in the domestication of maize (Chapter 9). This site is roughly 60 kilobases upstream of the *tb1* gene itself, and it is influenced by the insertion of a *Hopscotch* retrotransposon that increases the amount of *tb1* transcripts (Studer et al. 2011).

Rate-based Tests for Neutrality in Divergence of Gene Expression

Early attempts to detect departures of gene expression evolution from neutral trait predictions used rate-based approaches, based on Lande's F_{MDE} test (Equation 12.20a). While the standard version of this test uses the ratio of the observed among-group variance, V_B , to the expected among-group variance (expressed as $2t\sigma_m^2$, where t is the separation time in generations), a modified version uses an estimate of V_A (the additive-genetic variance of expression in the reference population or species) in place of $2t\sigma_m^2$. An important caveat is that these early studies were based on the phenotypic variance, such as the among-line variance, as a surrogate in place of the additive-genetic variance (Hsieh et al. 2003; Rifkin

et al. 2003; and Nuzhdin et al. 2004). This approach raises some of the issues discussed previously when using P_{ST} as a surrogate of Q_{ST} ; see Example 12.9.

With this concern in mind, the version of Lande's test used by these investigators starts by noting that $E[V_A] = 2N_e\sigma_m^2$ for an additive trait at mutation-drift equilibrium (Equation 11.20c). Assuming expression values are drawn from a normal distribution under the null model, then when L lineages are used to estimate the among-group variance and k individuals per line were used to estimate V_A , Equation 12.5a shows that both estimators approximately follow χ^2 distributions, with

$$V_B \sim (2t\sigma_m^2) \cdot \chi_{L-1}^2 / (L-1) \quad \text{and} \quad V_A \sim (2N_e\sigma_m^2) \cdot \chi_{k-1}^2 / (k-1) \quad (12.34a)$$

where t is the time of divergence since the common ancestor. These expressions suggest a modified version of Lande's F_{MDE} test statistic,

$$F_{MDE}^* = \frac{V_B/(2t\sigma_m^2)}{V_A/(2N_e\sigma_m^2)} = \frac{V_B}{V_A} \cdot \left(\frac{N_e}{t} \right) \sim \frac{\chi_{L-1}^2 / (L-1)}{\chi_{k-1}^2 / (k-1)} \quad (12.34b)$$

where this statistic follows an F distribution, with $F_{MDE}^* \sim F_{L-1,k-1}$ (as it is the ratio of two χ^2 random variables, scaled by their degrees of freedom; see LW Appendix 5). A scaled ratio less than a critical value of $F_{\alpha/2}$ is suggestive (at level α) of too little divergence, and hence suggestive of stabilizing selection, while a scaled ratio in excess of $F_{1-\alpha/2}$ implies too much divergence, suggestive of directional selection. These critical values are given by

$$\frac{V_B}{V_A} \leq F_{\alpha/2,L-1,k-1} \left(\frac{t}{N_e} \right) \quad \text{and} \quad \frac{V_B}{V_A} \geq F_{1-\alpha/2,L-1,k-1} \left(\frac{t}{N_e} \right) \quad (12.34c)$$

where $F_{\alpha,M,N}$ denotes critical values for an F distribution and satisfies

$$\Pr(F_{M,N} \leq F_{\alpha,M,N}) = \alpha$$

In the case where just two populations ($L = 2$) are compared by using their squared difference, d^2 , then recalling that $V_B = d^2/2$ (Equation 12.8c), the conditions given by Equation 12.34c become

$$\frac{d^2}{V_A} \leq F_{\alpha/2,1,k-1} \left(\frac{2t}{N_e} \right) \quad \text{or} \quad \frac{d^2}{V_A} \geq F_{1-\alpha/2,1,k-1} \left(\frac{2t}{N_e} \right) \quad (12.34d)$$

Example 12.9. Rifkin et al. (2003) examined variation in gene expression at the start of metamorphosis in six inbred lines of *Drosophila*: four *melanogaster*, one *simulans*, and one *yakuba*. Of the roughly 12,900 genes whose transcripts were examined, 52% (~6700 genes) showed expression changes in at least one lineage (either between species or within the *melanogaster* lines). For ~4500 of these genes, the authors could not reject the hypothesis that all six lineage-specific samples came from the same distribution, and these were deemed to be evolutionarily stable and potentially under stabilizing selection. Of the remainder, ~1700 genes showed no significant variation across the sampled *melanogaster* lines, but a significant difference between *melanogaster* and one of the other species. These were deemed to be under lineage-specific selection.

The evolutionary forces acting on the remaining 527 genes were examined using Equation 12.34b. Divergence was scored separately between *melanogaster* and each of the other two species ($L = 2$) using d^2 , with V_A estimated from the among-group variance in four fully inbred *D. melanogaster* lines ($k = 4$). Because d^2 is used, critical values are given by Equation 12.34d, with one correction. The expected among-group variance (for an additive trait) between a set of fully inbred lines is twice the additive variance (from Table 11.3, with $2f = 2$), so that $2N_e$ replaces N_e in the critical values. The resulting upper and lower 2.5% critical values follow

first by noting that $\Pr(F_{1,3} \geq 17.4) = 0.025$ and $\Pr(F_{1,3} \leq 0.001) = 0.025$. These authors used an estimated effective population size for *D. melanogaster* of $N_e = 3 \cdot 10^6$, while the total divergence times (twice the separation time, in generations) were estimated as $2t = 4.6 \cdot 10^7$ (*melanogaster-simulans*) and $2t = 10.2 \cdot 10^7$ (*melanogaster-yakuba*). Hence, the critical values for excessive divergence were

$$F_{c,mel-sim} = 17.4 \cdot \frac{4.6 \cdot 10^7}{6 \cdot 10^6} = 133.4 \quad \text{and} \quad F_{c,mel-yak} = 17.4 \cdot \frac{10.2 \cdot 10^7}{6 \cdot 10^6} = 195.8$$

Transcripts whose ratio of d^2/V_A exceeded these values are unusually divergent. Using this criterion (as well as the lower threshold for too little divergence), of these remaining 527 genes, 464 were consistent with drift, while 63 were consistent with excessive divergence between at least one species pair.

One caveat with using half the among-group variance over a set of fully inbred lines as an estimate of σ_A^2 is that, when dominance is present, the among-line genetic variance becomes $2\sigma_A^2 + 2\sigma_{AD}^2 + \sigma_{DI}^2$ (Equation 11.6a). Depending on the sign in the middle covariance and the magnitude of the last two terms, this can be considerably larger, or smaller, than $2\sigma_A^2$, and hence can bias the results.

While straightforward to apply, a concern with Equation 12.34b is the estimation of t and N_e . One approach is that, under neutrality, the ratio of the expected divergence D_s at silent sites divided by their expected polymorphism (P_s) is $D_s/P_s \simeq t/(2N_e)$ (Equation 10.1b). While this marker-based estimate could be substituted into Equation 12.34b, this is an ad hoc approach, as the sampling error of this estimator of t/N_e is ignored. The idea of combining silent-site information with the within- and between-population expression variances was also considered by Warnefors and Eyre-Walker (2012), who proposed a MacDonald-Kreitman-type approach (Chapter 10); see their paper for details. Again, these are useful metrics, but not formal statistical tests.

The rate-based test given by Equation 12.34b was scaled to be independent of σ_m^2 , at the cost of assuming or estimating an effective population size. Conversely, Equation 12.20d can be used to compare the rate divergence to that of candidate values of σ_m^2 (or h_m^2), which circumvents the potentially problematic issue of estimating N_e , although (as with Equation 12.34b) one must still estimate t . This was the approach taken by Lemos et al. (2005). Using a diverse series of lineage comparisons (within mice strains, populations of *Drosophila*, and between species in primates and flies), and assuming h_m^2 is in the range of 10^{-4} to 10^{-2} , they found that the majority of gene-expression differences were consistent with stabilizing selection (an average of 85% of all transcripts), with drift comprising the next largest category (an average 11.5%), and directional selection comprising the smallest (an average of <4%).

These approaches either ignore σ_m^2 or estimate its required value under drift given the observed divergence. A more arduous approach is to directly estimate σ_m^2 from a mutation-accumulation experiment (LW Chapter 12). This estimate is then used to predict either the within-population variation ($2N_e\sigma_m^2$) or the among-population divergence ($2t\sigma_m^2$) and to assess if these are consistent or too extreme. The general conclusion from such studies is that stabilizing selection plays a prominent role in reducing the amount of variation in gene expression below the neutral expectation—both within and among species, levels of variation are much lower than expected based on the estimated mutational variance. For example, using lines of the nematode *C. elegans* from a long-term (280 generation) mutation-accumulation experiment, Denver et al. (2005) estimated values of σ_m^2 for several thousand genes. By comparing levels of variation among a global collection of natural isolates, they found that the gene-specific ratios of the standing level of genetic variance to the estimated σ_m^2 value were generally no greater than a few hundred. Given that this ratio provides an estimate of $4N_e$ under the assumption of neutrality in a selfing organism (as opposed to $2N_e$ in an outcrosser, as σ_A^2 is inflated by $2f = 2$ with complete inbreeding), these observations

provide a firm rejection of the hypothesis that gene-expression levels evolve in a neutral fashion. Rifkin et al. (2005) were able to estimate mutational heritabilities for expression in mutation-accumulation lines of *D. melanogaster* by factoring out the variance at the level of the individual fly to obtain an estimate of σ_e^2 . They found a median of $h_m^2 \simeq 2.4 \cdot 10^{-5}$ across all genes, and they showed that although interspecific variance in the expression of a gene was correlated with its mutational variance (in qualitative accordance with the neutral theory), the absolute level of divergence was too low to be compatible with neutrality, consistent with the results of Denver et al. (2015).

An especially interesting analysis of expression levels was offered by Hodgins-Davis et al. (2015), who used the machinery developed in Chapter 28 on the expected level of variation under a balance between mutation and stabilizing selection. Using data sets for yeast and *Drosophila*, they found that the model of mutation-selection balance that best explains the observed pattern of variation is one of large mutational effects and weak stabilizing selection (details are given in Example 28.3).

Largely Neutral Evolution of Expression Levels in Primates?

While these results strongly suggest a leading role for stabilizing selection, there has been considerable discussion regarding the evolution of gene expression among the great apes. One key focus has been the expected pattern of divergence under pure drift. However, as with many of the early applications of rate-based tests to expression data, much of the analysis is largely phenotypic in nature, and therefore does not utilize the much stronger comparisons based on estimates of the additive variances of these traits.

Under a Brownian motion model, the expected divergence (measured by the among-group variance) scales linearly with divergence time, t (Equation 12.10, under the infinite-alleles assumption). In contrast, under an Ornstein-Uhlenbeck (OU) process (drift countered by stabilizing selection), the total divergence approaches an asymptotic value (Equation 12.22c). Bedford and Hartl (2009) used an OU process to fit the pattern of expression divergence within a clade of seven species of *Drosophila*. In accordance with the OU model (and consistent with stabilizing selection), they found that the divergence variance does not increase linearly with time but, rather, quickly approaches an asymptotic value.

In contrast, Khaitovich et al. (2004, 2005) argued that gene expression can evolve in a mostly neutral fashion, based in large part on an observed linear increase in the divergence of among-species expression with time within the clade of great apes. They also noted the observation of Rifkin et al. (2005), namely, a positive correlation between levels of within- and among-species variation for the expression of different genes. Such a pattern is expected under neutrality, as both divergence and standing variation are functions of σ_m^2 . However, this is not strong support for neutrality, as a number of other features can create such a correlation. For example, genes whose expression is strongly influenced by the environment may naturally exhibit higher levels of variation, both within and among samples. Likewise, linearity in divergence, by itself, is suggestive, but not sufficient. Unless the actual rate of divergence is consistent with the rate of polygenic mutation, linear patterns of evolutionary diversification need not imply neutrality.

An important complication is that Khaitovich et al. (2004, 2005) used human probes to measure differences in expression among species. Because sequence divergence between the probes and target sites accumulates over time, generating reduced levels of hybridization, this technique will result in an artifactual increase in apparent expression divergence over time. Broadley et al. (2008) reported a similar linear divergence of expression variance with time in a series of 14 taxa in the Brassicaceae but, again, the probes were based on a single species (*Arabidopsis*). In evaluating primates more broadly (human, chimpanzee, orangutan, and rhesus macaque), Gilad et al. (2006) found that the between-species variance in expression of most genes did not increase with divergence time, contrary to the neutral expectation. This study was well designed in that it employed only probes for which the sequences were identical across all four species, thereby removing any species-specific bias in hybridization. Thus, the conclusion that primate gene expression is evolving in a neutral

fashion is questionable, and it has, in fact, been essentially retracted in a more recent analysis (Chaix et al. 2008), which suggested a rate elevation specific to the human lineage.

Conversely, drift was suggested by an analysis by Perry et al. (2012), who used RNA-seq data (very high-coverage sequencing of an RNA pool) to examine liver transcript levels for roughly 5700 genes over humans and 11 other primates. Expression levels were modeled by a Brownian motion model over the entire phylogeny. The base model assumed a constant rate of change (per unit time), and this was contrasted with a model in which the rate of change was allowed to vary over the phylogeny. The latter model provided a significantly better fit for slightly less than 10% of the genes, with specific branches showing accelerated rates of evolution (and hence being candidates for directional selection). Taken as a whole, this analysis suggested that most of the expression changes over this large phylogeny were at least partly consistent with neutral drift. This conclusion, however, is somewhat tempered, as the contrast between two different Brownian motion models is not nearly as conclusive as a contrast between a Brownian and an Ornstein-Uhlenbeck model to compare drift versus stabilizing selection. Further, there were no quantitative genetics involved in this analysis—the more powerful comparison of the expected rate of change (given an estimated additive variance) with the observed rate is lacking.

Transcriptional Q_{ST} , tQ_{ST}

Gibson and Weir (2005) suggested that comparisons of Q_{ST} and F_{ST} can be applied to gene expression data, and proposed the term tQ_{ST} for such a transcriptome scan. By scoring a very large number of traits at once, the vexing issue of ascertainment bias (wherein researchers are naturally drawn to the most variable traits) that plagues Q_{ST} tests can be largely avoided. However, other problems with this approach persist. One involves obtaining the estimated genetic variances of within- and among-population components, as opposed to their phenotypic proxies (P_{ST}). The second problem is low power, especially when only two populations are compared. Perhaps because of these concerns, this approach has not been widely applied to expression data. A Q_{ST} approach was hinted at by Whitehead and Crawford (2006), but these authors ultimately resorted to rate-based tests for comparing transcripts.

A formal application of this approach was performed by Roberge et al. (2007) to study a very recent population divergence, which was created by the installation of a fish ladder in 1981 on the Sainte-Marguerite River in Quebec. Upstream and downstream populations of Atlantic salmon (*Salmo salar*) showed an F_{ST} divergence of just over 0.03 after roughly six generations of presumed differential natural selection. The authors used a mixed-model framework (Chapters 19 and 20) to estimate the among-group genetic variance for transcripts from these two populations, and then searched for transcripts showing up as Q_{ST} outliers. They found 16 such transcripts, with an average Q_{ST} roughly three times the F_{ST} value between these two populations, leading them to suggest that the expression levels for these genes were under extensive directional selection following the population subdivision. However, Equation 12.28c shows that Q_{ST} must be roughly five times as large as F_{ST} for significance when $L = 2$. Thus, while there are hints of selection, low power prevents a definitive conclusion.

Cis Versus *Trans*, Local Versus Distant, and Allele-Specific Expression (ASE)

Finally, before discussing applications of sign-based tests to gene-expression data, we need to review a few additional features of transcriptional regulation. Historically, the term *cis* refers to a control element that only acts on a gene residing on the same DNA molecule. *Cis*-acting control elements are thought to be binding sites for diffusible factors (e.g., transcription factors, small RNAs, etc.), target sequences for gene-processing features (intron splice sites, poly-A sites, etc.), or sites that exert some local control over chromatin structure. By contrast, *trans*-acting factors are diffusible and exert their influence throughout the genome, presumably by coding for proteins or RNAs that interact with specific *cis* sites to control regulation. Formally, the terms *cis* and *trans* refer to this difference in functional-

ity. However, the early eQTL mappers co-opted them to refer (respectively) to sites that closely mapped to the gene coding for the target transcript (whose expression is being followed) and those that mapped further away (often on different chromosomes). Rockman and Kruglyak (2006) suggested that the terms **local** and **distant** are more appropriate for describing eQTL location. Given that the uncertainty region for a typical QTL spans tens of centimorgans (and hence tens of megabases), what is called a *cis* eQTL could actually be several genes away and thus could act in *trans*.

There are formal genetic procedures for determining whether a region truly does act in *cis*, and these are exploited by a few of the sign-based tests. These employ a more nuanced view of the expression from a single gene in an individual, as not simply its total amount of mRNA, but rather at the levels of expression from different *alleles* at that gene—**allele-specific expression** (ASE; Wright and Moyer 1966; Knight 2004). When the gene products from the different alleles at a locus can be distinguished (either by hybridization or sequencing), then the expression of each product can be followed (e.g., Yan et al. 2002). Cowles et al. (2002) and Wittkopp et al. (2004) both proposed that the use of hybrids (crosses of different, often inbred, lines) can distinguish *cis* from *trans* control of expression. If allele-specific differences seen in the parental lines persist in an F₁ hybrid, these are (at least in part) due to *cis*-acting factors, as the two alternative alleles in the hybrid both experience the same environment, and hence the same set of *trans*-acting factors. Wittkopp et al. (2008) defined the amount, C , of *cis*-acting differences by the ratio of expression of the two alleles in the hybrid ($C = \text{allele 1}/\text{allele 2}$), while $P = \text{strain 1}/\text{strain 2}$ is the ratio of expression in the parental homozygous lines. The amount of *trans*-acting differences is estimated by the difference between these two sets of ratios, $T = P - C$, although this approach can be complicated by *cis* × *trans* interactions. Because parent-of-origin (i.e., imprinting) effects can also create ASE, reciprocal crosses are used to rule out such effects. Emerson et al. (2010) offered an alternative approach for determining the amount of *cis* and *trans* effects.

Applications of Sign-based Tests to Expression Data

While Orr's tests were framed in the increasingly dated technology of QTL mapping, their central underlying idea (effects are randomly distributed among lines under neutrality) fits very nicely with genomics-era data. We already mentioned a GWAS application of sign-based tests, and there is an increasing use of sign-based approaches to explore the nature of selection on gene expression. The standard QTL-based tests discussed above are not directly applicable, as most genes have very few detected eQTLs, and thus do not qualify for testing based on Orr's requirement of at least six QTLs per trait. However, as reviewed by Fraser (2011), two rather different approaches have been used to circumvent this limitation.

The first approach is simply to shift focus from the expression levels at *single genes* to the pattern of expression over a *set of genes*, pooling these to create a setting with more than six eQTLs for the trait. Bullard et al. (2010) used this approach in a cross of two closely related yeast species, *Saccharomyces cerevisiae* and *S. bayanus*. One key requirement in the statistical analysis is that each eQTL is independent, as a single eQTL that simultaneously influences k genes should be weighted as one change, not k changes, in the same direction. The use of *cis*-regulatory alleles ensures independence over a set of loosely linked genes. Bullard et al. accomplished this by only considering alleles showing ASE. An excessive number of up-regulated ASEs over a specific gene set from one species indicates the presence of lineage-specific selection, and a number of pathways were detected showing this feature. Fraser et al. (2011) used a similar approach in a cross of two subspecies of the mouse (*Mus musculus*). They chose gene sets defined by shared GO (Gene Ontology Consortium) membership, and found over 100 genes with evidence of lineage-specific selection. These studies are important, as (at least for these two crosses) they suggest that adaptation via gene-expression changes may be widespread, highly polygenic, and involves *cis*-regulatory sites.

As noted by Fraser (2011; Fraser et al. 2011), a significant result (an excess in one direction) is not necessarily indicative of directional selection, as regulatory mutations are

biased toward down-regulation. A pattern that is seen could simply be a relaxation of purifying selection in one lineage, resulting in a series of neutral, but down-regulated, substitutions, given this inherent mutational bias. In essence, this is the same limitation seen in the McDonald-Kreitman test (Chapter 10). Fraser et al. (2011) noted that a simple solution to this problem is to examine expression levels in an outgroup and assess whether a directional change was due to up-regulation (relative to the outgroup) in one lineage, which is likely due to selection, or down-regulation, which could simply be due to relaxed selection. However, selection for reduced expression in a pathway cannot formally be ruled out in the latter case, nor can overexpression be interpreted with certainty as being adaptive.

A second modification of a sign-based test for expression data, which was offered by Fraser et al. (2010), applies to genes whose expression levels are influenced by both *cis* and *trans* eQTLs. The central premise of sign-based tests is that *directionality is random under the null*, so that in a cross of lines A × B, if an eQTL from A is a *cis* up-regulator, this should provide no information as to whether a *trans*-acting factor from A (acting on the expression level at the same target gene) is an up- or down-regulatory allele. *Cis*- and *trans*-acting alleles whose influence is in the same direction (up and up, down and down) are called **reinforcing**, and those acting in opposite directions are called **opposing**. With a collection of genes whose expression is influenced by both *cis* and *trans* eQTLs, a simple 2 × 2 contingency table can be constructed and tested for departures from randomness. If a significant departure is seen, it is a straightforward process to estimate the amount of excess in a particular class (e.g., Example 10.1). Fraser et al. applied this approach in a cross of two yeast (*Saccharomyces cerevisiae*) strains that diverged roughly 10⁷ generations ago and found an excess of roughly 242 genes showing reinforcing levels of *cis* and *trans*. While this approach suggests significant regulatory evolution over the genome, it does not indicate *which* specific transcripts are involved. This result is reminiscent of some of the approaches for detecting genome-wide signatures of selection examined in Chapter 10: evidence of a genome-wide pattern is seen, but no particular gene can be singled out with confidence as being a target of the selection process generating the observed pattern.

Artieri and Fraser (2014) used this statistical machinery to examine the nature of selection on the *translational* profiles of mRNA, using **ribosome profiling**—extracting mRNA bound to ribosomes to create a sample of the mRNA pool actually undergoing translation. Using this enriched pool, Artieri and Fraser examined the translation rates of specific transcripts within and between two species of yeast, and found both *cis*- and *trans*-acting regulatory divergence. They reported that the majority of translational divergence appears to buffer the amounts of mRNA, consistent with stabilizing selection on expression levels acting at both the transcriptional and translational stages of gene regulation.

Example 12.10. Using *cis* and *trans* expression data, Emerson et al. (2010) suggested a test for neutral expression evolution that is related in spirit to sign-based tests. They combined their polymorphism data with divergence data from Tirosh et al. (2009) to examine the within- and among-species expression control in the yeasts *Saccharomyces cerevisiae* and *S. paradoxus*. They used a MacDonald-Kreitman approach (Chapter 10) by examining the fraction of *cis*- and *trans*-controlled transcripts measured within and between species. Their resulting contingency table,

	Polymerism	Divergence
<i>Cis</i>	396	1270
<i>Trans</i>	412	541

was highly significant, with *trans* polymorphisms being slightly more common than *cis*, but over twice as many *cis* regions were fixed. Such a pattern could arise from either an excessive number of *cis* fixations between species, an excessive amount of *trans* polymorphism within a species, or a combination of both. Analogous to arguments with interpretations of MacDonald-

Kreitman data discussed in Chapter 10, an excessive amount of polymorphism could arise from a high mutation rate for slightly deleterious alleles. This generates an excess amount of within-species polymorphism that does not transfer to among-species differences (as they are not fixed). Wittkopp et al. (2008), working with *Drosophila*, also noted an excess of *cis* regions being fixed over *trans* regions and suggested that the fixation of some *cis* mutations by directional selection, coupled with a larger number of slightly deleterious *trans* alleles, likely underlies this pattern.

Example 12.11. Fraser (2013) suggested yet another approach for detecting selection on the expression level of specific sets of transcripts. First, the genes comprising a specific functional set are chosen (e.g., UV protection), and then an expression score for a population is calculated from the mean frequency of all eSNPs that up-regulate members of this set. This was done over a series of roughly 60 human populations that have lived and evolved under different environmental conditions (such as summer UV flux), computing the correlation between the environment variable and expression score. The significance of this correlation was tested using a randomization approach, wherein the correlation between expression score and environmental variable is computed using a random set of genes. This was repeated $\sim 10^6$ times to generate a distribution for each gene-environment correlation under the null. This approach is very similar to methods examined in Chapter 9 to search for individual SNP frequency–environmental associations (Hancock et al. 2010a, 2010b, 2011; Fumagalli et al. 2011). However, the latter is performed on a SNP-by-SNP basis, whereas the focus here is on the *entire set* of regulatory actors in some network. Using Fraser’s approach, significant signals were detected for transcript sets involved in UV response, immune cell proliferation, and diabetes. Further, using a catalogue of putative locally adaptive human SNPs, Hancock et al. (2011) found a roughly ten-fold enrichment of eSNPs and SNPs in *cis*-regulatory regions over amino-acid replacement SNPs in the same genes. This suggests a more important role in local adaptation for regulatory, as opposed to structural, changes.

Evolution of Expression Levels: Drift, Directional, or Stabilizing Selection?

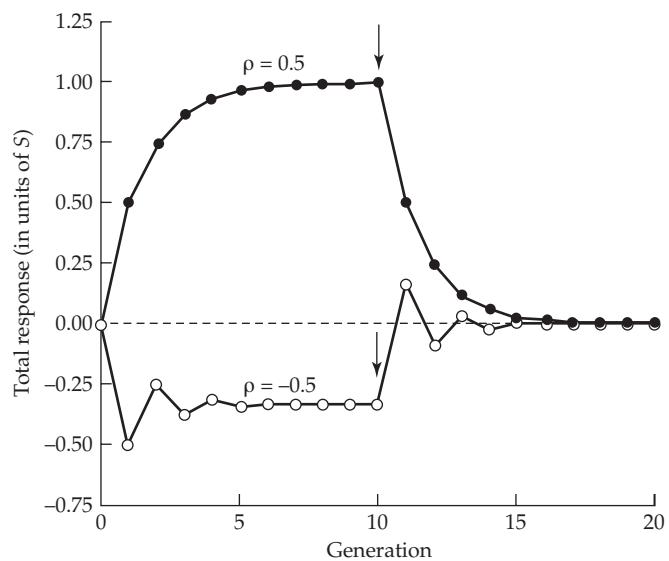

The study of gene regulatory evolution is still in a rather embryonic state. Historically, the field has moved from an early era of speculation that regulatory changes may be at least as, if not more, important than structural changes (Britten and Davidson 1969, 1971; King and Wilson 1975), to a broader acceptance favoring regulatory evolution, at least in some groups or traits (Carroll 2005, 2008; Wray 2007); but see Hoekstra and Coyne (2007) for a counterperspective. As our previous discussion suggests, the initial view provided from transcriptome-wide studies is that stabilizing selection is important, but that some drift in expression level can occur, which is more constrained as phylogenetic distance increases. There is also evidence that directional selection on some *cis*-acting sites has occurred between closely related species.

Taken together, these results (along with those described above for more general traits) suggest, perhaps not surprisingly, that at both the phenotypic and gene-regulatory levels, evolution is primarily characterized by periods of stabilizing selection, although episodes of directional selection certainly occur. However, it must also be emphasized that the interpretation of conservative rates of evolution is far from clear-cut. In principle, evolutionary divergence rates that are below the expectation of the infinite-alleles model of mutation may be a consequence of the general opposition of selection to all allelic changes associated with the trait. Alternatively, they might reflect a situation in which a fraction of mutations is truly neutral, with the rest having negative pleiotropic effects on fitness (Chapter 28). In that case, an observed level of divergence could actually be entirely based on neutral mutations, but with the appropriate measure of mutational variance being lower (and likely *much* lower) than the actual value observed in mutation-accumulation experiments (where

even highly deleterious mutations can accumulate). In addition, if the house-of-cards is a more appropriate model for mutation effect sizes, then one would expect cumulative levels of divergence to plateau in time rather than to increase indefinitely, not because of direct selective constraints, but rather due to the limited availability of alternative allelic states.

IV

Short-Term Response on a Single Character

13

Short-term Changes in the Mean:

1. The Breeder's Equation

Prediction is very difficult, especially if it's about the future. Niels Bohr

The topic of selection on quantitative traits, and its consequences, comprises the remainder of this book. We start by discussing the simplest situation—the expected change in the mean of a single character following a single generation of selection from an unselected base population. This response is reasonably predictable in a wide variety of settings, using a regression framework and the appropriate covariances between relatives. By contrast, the response after a number of generations is much less predictable, as allele- and gamete-frequency change alter genetic variances (and hence the resemblance between relatives) from their initial values. Provided that each locus has only a small effect on the trait, only small allele-frequency changes are expected over the first several generations. In the extreme under the infinitesimal model (the limit of a very large number of loci, each with a vanishingly small effect), the additive *genic* variance (that part of the additive genetic variance that is independent of any disequilibrium effects) remains essentially unchanged during selection. **Short-term** response refers to these early generations, where allele-frequency change has a negligible effect on the initial additive variance. As discussed in Chapters 16 and 24, gametic-phase disequilibrium is generated by even a single generation of selection, changing gametic frequencies (and hence genetic variances) even in the absence of allele-frequency change. As detailed in Chapter 16, such short-term changes in the additive variance from disequilibrium are easily computed under the infinitesimal model. Over longer time scales, allele-frequency evolution results in substantial changes in the variance that are extremely difficult to predict; this is the setting for **long-term response** (Chapters 25–28).

Selection can occur in a myriad of ways. Our focus in this chapter is **individual** (or **mass**) **selection** under random mating, wherein individuals are chosen solely on the basis of their phenotypic value (i.e., information from relatives and other such factor are ignored). **Family selection**, whereby individuals are chosen based on their family mean and/or ranking within a family, is discussed in Chapter 21. Chapter 22 discusses the setting in which individuals interact in groups (**kin selection** if they are related) and selection may operate at the individual and/or group level (**group selection**), while Chapter 23 examines response in inbred populations. Using additional information, such as the trait value in relatives and/or the values of other traits in the focal individual, can improve the accuracy in predicting an individual's breeding value and hence increase the expected selection response relative to individual selection. One way to accomplish this is by **index selection**, which generalizes to BLUP-based selection (Chapters 19, 20, and 22; LW Chapter 26), both of which, along with a number of other important selection schemes (such as multivariate selection, marker-assisted and genomic selection, selection for outcross performance, pure-line selection, and selection in age-structured populations) are largely deferred until Volume 3.

There is a huge literature on breeding schemes that exploit specific features of the reproductive biology of a target organism (such as artificial insemination in animals and complex crossing schemes in selfing plants). See Lush (1945), Turner and Young (1969), Pirchner (1983), Ollivier (1988), Weller (1994), Cameron (1997), Simm (1998), and Kinghorn et al. (2000) for applications in animal breeding, and Namkoong (1979), Wricke and Weber (1986), Mayo (1987), Stoskopf et al. (1993), Bos and Caligari (1995), Gallais (2003), Hallauer et al. (2010), and Bernardo (2010) for applications in plant breeding.

SINGLE-GENERATION RESPONSE: THE BREEDER'S EQUATION

The Breeder's Equation: A General Approximation for Response

Previous chapters developed explicit expressions for a single generation of response in the mean of a trait, based on either specific population-genetic models (Equations 5.23c and 5.27b) or completely general covariance-based expressions using Price's theorem (Equations 6.12, 6.39, and 6.40). These results show that either a large number of underlying loci of small effect and/or a linear parent-offspring regression generally will recover the simple **breeder's equation**

$$R = h^2 S \quad (13.1)$$

plus correction terms that are often small. This approximation is perhaps the most well-known expression in quantitative genetics, and its myriad of extensions form the backbone of the quantitative-genetic theory of short-term response. Although the actual origin of the breeder's equation is somewhat unclear, elements of it (in multivariate form) appear in the early writings of Pearson (1903), and it was popularized by Lush (1937). Indeed, Ollivier (2008) made the quite reasonable suggestion that it be called the **Lush equation**. Its simplicity is compelling, as it relates the change in mean *across* a generation (the **response**, R) to the product of the *within*-generation change (the **selection differential**, S) and a measure of how the character value is passed across generations (the heritability, h^2).

As discussed in Chapter 6, a necessary (but not sufficient) condition to recover the breeder's equation is a linear parent-offspring regression, with the phenotypic value, z_o , of an offspring whose parents have the mean phenotypic value, z_{mp} , given by

$$z_o = \mu + b_{o|mp}(z_{mp} - \mu) + e$$

where $b_{o|mp}$ is the slope of the midparent-offspring regression, which in this chapter is usually assumed to be equivalent to the narrow-sense heritability, h^2 (but is generalized later). If we take the average over all selected parents, then $E_s[z_{mp} - \mu] = S$, while the difference between the expected value of the offspring from such parents and the overall mean is the selection response, R , which yields

$$E_s[z_o - \mu] = R = b_{o|mp} E_s[z_{mp} - \mu] = b_{o|mp} S = h^2 S$$

Recall (Equation 6.12) that two other technical restrictions are also required to formally obtain $R = b_{o|mp} S$. First, it is assumed that the residuals of the linear parent-offspring and fitness-phenotype regressions are uncorrelated with each other. Second, it is assumed that the mean does not change in the absence of selection. As will be discussed below, cases do exist in which the mean and/or variance can change under random mating as disequilibrium induced by prior selection decays (Chapters 15 and 16). In our treatment we either assume that these potential complications introduce only very small errors, or we explicitly model their effects (e.g., Chapters 15, 20, 22, and 23).

The Importance of Linearity

A variety of factors, such as a major gene with dominance, can result in a nonlinear parent-offspring regression (Chapter 6; LW Chapter 17). In such cases, the mean of the selected parents (and hence the selection differential, S) is *not* sufficient to predict the offspring mean. As Figure 13.1 shows, two selected parental populations with the same mean, but different variances, can have different expected responses when this regression is nonlinear. Even if phenotypes are normally distributed and the character is completely determined by additive loci (no dominance or epistasis), if the underlying distribution of genotypic values is skewed, selection on the variance (e.g., selection for, or against, extreme phenotypes) also results in a change in the mean (see Equation 5.27b). In this case, S is again not sufficient to describe the expected response to selection. While

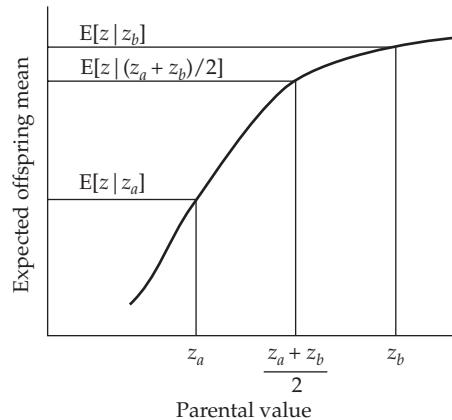

Figure 13.1 The importance of linearity in the parent-offspring regression. If this regression is nonlinear, different subsets of the population with the same mean can have different offspring means. Suppose equal numbers of parents with values z_a and z_b are chosen. If we denote the expected value of offspring from parents with value z_x by $E[z|z_x]$, the offspring mean in this case is given by $(E[z|z_a] + E[z|z_b])/2$. In contrast, choosing parents all with value $(z_a + z_b)/2$ gives the same parental mean as in the case of mixed parents, and hence the same S , but the expected offspring mean is now $E[z|(z_a + z_b)/2]$, which, as shown above, can deviate considerably from $(E[z|z_a] + E[z|z_b])/2$ when nonlinearity is significant.

a sufficient condition for linearity is that the joint distribution of breeding and phenotypic values be bivariate normal (LW Chapter 8), selection generally causes the distribution of genotypic values to depart from normality (Chapters 16 and 24), creating at least slight departures from linear parent-offspring regressions. The selection response under strongly nonnormal distributions can be very complicated, depending on summary statistics of the underlying genetic architecture, which do not easily translate into standard (and measurable) variance components (Chapter 24).

Response is the Change in Mean Breeding Value

Under the infinitesimal model and a linear parent-offspring regression, a key concept is that the *response equals the mean breeding value of the selected parents*. Recall that (non-inbred, sexually reproducing) parents pass along only a fraction of their total genotypic value, namely, their breeding value, A , to their offspring. Under the infinitesimal model, the expected offspring value is simply the average breeding values of its parents (LW Chapter 4).

Trait improvement by artificial selection is achieved by choosing parents with the most favorable breeding values. The problem is that we cannot completely predict the breeding value of an individual from its phenotype alone (unless $h^2 = 1$). Because the phenotype of an individual is an imperfect indicator of its breeding value, the offspring of phenotypically exceptional parents are generally not themselves as exceptional. From standard regression theory (LW Chapter 3), the predicted breeding value, \hat{A} , for an individual with a phenotypic value of z (given no other information) is

$$\hat{A} - \mu_A = \frac{\sigma(A, z)}{\sigma_z^2}(z - \mu_z) \quad \text{or} \quad \hat{A} = h^2(z - \mu_z)$$

where μ_z and μ_A are the mean phenotype and breeding value, respectively, and $\sigma(A, z)$ is the covariance between the breeding value and the phenotype. This expression follows because the regression $y = a + bx$ can be expressed as $y - \mu_y = b(x - \mu_x)$, where $b = \sigma(x, y)/\sigma_x^2$.

For the regression of A on z , the means are $\mu_A = 0$ and μ_z , respectively, while the slope is $\sigma(z, A)/\sigma_z^2 = \sigma_A^2/\sigma_z^2 = h^2$, which follows because

$$\sigma(z, A) = \sigma(G + E, A) = \sigma(A + D + E, A) = \sigma(A, A) = \sigma_A^2$$

The expected breeding value for a set of selected parents thus becomes

$$E_s[\hat{A}] = E_s[h^2(z - \mu_z)] = h^2 E_s[z - \mu_z] = h^2 S$$

The change in the mean value of their offspring (relative to the base population) is simply the mean breeding value of the selected parents, because (by definition) $\mu_A = 0$ in the base population. Thus, the response equals $h^2 S$, and we recover the breeder's equation. A key assumption is $E_s[h^2] = h^2$, namely, that the regression using the selected parents is the same as (or extremely close to) the regression in the absence of selection, an assumption discussed at length in Chapter 6.

Response Under Sex-Dependent Parent-Offspring Regressions

It is not uncommon for a trait to show different variances between the sexes or to have a less than perfect correlation across the sexes. In such cases, the coefficients for parent-offspring regressions can vary with the sex of both the parents and of the offspring. We denote the phenotypic values of the *father* and *mother* by z_{fa} and z_{mo} and an offspring by z_o (if its sex is unimportant) or by z_{so} and z_{da} for *sons* and *daughters* (respectively) if sex is important. Let $E[z_o | z_{fa}, z_{mo}]$ be the expected phenotypic value of an offspring whose parents have phenotypic values z_{mo} and z_{fa} . The importance of this conditional expectation (the **biparental regression**) is that the expected character value in the next generation (assuming there are no fertility differences) is the average of this expectation over all selected parents. Taking expectations is straightforward when the biparental regression is linear, i.e.,

$$E[z_o | z_{fa}, z_{mo}] = \mu_o + b_{o,fa} (z_{fa} - \mu_{fa}) + b_{o,mo} (z_{mo} - \mu_{mo}) \quad (13.2)$$

where μ_{fa} and μ_{mo} are the mean character values of males and females before selection, and μ_o is the mean for the offspring sex being considered. Taking the expectation over all selected parents, the expected offspring mean after selection is

$$\begin{aligned} E_s[E(z_o | z_{fa}, z_{mo})] &= \mu_o + b_{o,fa} E_s[(z_{fa} - \mu_{fa})] + b_{o,mo} E_s[(z_{mo} - \mu_{mo})] \\ &= \mu_o + b_{o,fa} S_{fa} + b_{o,mo} S_{mo} \end{aligned} \quad (13.3)$$

where S_{fa} and S_{mo} are the directional selection differentials for fathers and mothers.

Given that Equations 13.2 and 13.3 acknowledge the presence of differences between sexes in regression coefficients, separate equations for sons and daughters are required (e.g., Example 13.1). For example, the expected change in the mean character value of daughters, R_{da} , equals the expected mean of daughters of selected parents minus the mean of females before selection. Applying Equation 13.3,

$$E_s[E(z_{da} | z_{fa}, z_{mo})] = \mu_{mo} + b_{da,fa} S_{fa} + b_{da,mo} S_{mo}$$

implying

$$R_{da} = b_{da,fa} S_{fa} + b_{da,mo} S_{mo} \quad (13.4a)$$

where $b_{da,fa}$ is the regression coefficient of daughters on fathers and $b_{da,mo}$ is the mother-daughter regression coefficient. Likewise, for sons

$$R_{so} = b_{so,fa} S_{fa} + b_{so,mo} S_{mo} \quad (13.4b)$$

Equations 13.4a and 13.4b require that the biparental regression be linear, in which case $b_{o,fa}$ and $b_{o,mo}$ are partial regression coefficients and can be obtained from the sex-specific

covariances between relatives. Again, linearity is ensured if the joint distribution of breeding values in both parents and their offspring is multivariate normal. If there is no correlation between the phenotypes of the parents (which is guaranteed under random mating), the partial regression coefficients are standard univariate regression coefficients (LW Chapter 8) and applying LW Equation 3.14b yields

$$b_{o,fa} = \frac{\sigma(z_o, z_{fa})}{\sigma^2(z_{fa})} \quad \text{and} \quad b_{o,mo} = \frac{\sigma(z_o, z_{mo})}{\sigma^2(z_{mo})}$$

If mating is random, and genotype \times environmental interactions, shared environmental effects, epistasis, and sex-specific effects (i.e., the need for separate regression coefficients) can all be neglected, the regression slope (for each parent-offspring combination) is $b_{o,p} = h^2/2$ (LW Chapters 7 and 17). If we define the total selection differential as the average of both parental values, $S = (S_{fa} + S_{mo})/2$, we again will recover the breeder's equation

$$R = \frac{h^2}{2} S_{fa} + \frac{h^2}{2} S_{mo} = h^2 S \quad (13.5)$$

Equation 13.5 shows how differential selection on parents is incorporated into the breeder's equation. For example, consider selection on dioecious plants. If plants that form the next generation are chosen *after* pollination, fathers (pollen donors) are chosen at random with respect to the character under selection ($S_{fa} = 0$), yielding $R = (h^2/2)S_{mo}$. If parents are selected before pollination with equal amounts of selection (S) on both sexes, $R = h^2S$. Chapter 21 examines family-based breeding schemes that ensure equal selection on both pollen and seed parents.

Example 13.1. Coyne and Beecham (1987) estimated the following parent-offspring regression coefficients for abdominal bristle number in laboratory populations of *Drosophila melanogaster*:

Mother-son	$b_{so,mo} = 0.39 \pm 0.08$
Mother-daughter	$b_{da,mo} = 0.32 \pm 0.08$
Father-son	$b_{so,fa} = 0.13 \pm 0.10$
Father-daughter	$b_{da,fa} = 0.40 \pm 0.08$

Note that the father-son regression has a significantly smaller slope than the three other parent-offspring sex combinations. Other *Drosophila* examples where the regressions differ significantly between sons and daughters were given by Gimelfarb and Willis (1994).

Suppose that different amounts of selection are applied to fathers and mothers, with selected fathers showing an increase of two bristles, while selected mothers show a decrease of one bristle. What is the expected change in mean bristle number in the male and female offspring using these estimated regression coefficients, assuming all parent-offspring regressions are linear? Here $S_{mo} = -1$ and $S_{fa} = 2$, and from Equation 13.4a, the expected change in bristle number in females becomes

$$R_{da} = b_{da,fa} S_{fa} + b_{da,mo} S_{mo} = 0.40(2) + 0.32(-1) = 0.48$$

Likewise, from Equation 13.4b, the expected change in males is

$$R_{so} = b_{so,fa} S_{fa} + b_{so,mo} S_{mo} = 0.13(2) + 0.39(-1) = -0.13$$

This expected response of a decrease in males and an increase in females is the exact opposite of the pattern of selection on the sexes.

The Selection Intensity, \bar{i}

While the selection differential (S) is a convenient and simple measure of selection on the mean, it does not tell us the actual *strength* of selection. Consider selection acting on the same character in two different populations. In one, the largest 5% of measured individuals are allowed to reproduce, while in the second, the largest 25% reproduce. Clearly, selection is more intense in the first population. However, under truncation selection on a normally distributed trait, the selection differentials for these two populations are $S_1 = 2.06 \sigma_1$ and $S_2 = 1.27 \sigma_2$, respectively, where σ_k^2 is the phenotypic variance in population k (Equation 14.3a). Thus, if the second population is more variable than the first, it may have the larger selection differential even though it clearly experiences less intense selection.

For this reason, in many applications, a more informative measure of the strength of selection is the **selection intensity** (or **standardized selection differential**), which is the selection differential expressed in phenotypic standard deviations

$$\bar{i} = S/\sigma_z \quad (13.6a)$$

and also denoted by i or ι in the literature (we will use \bar{i} throughout to avoid any confusion with i as an index variable). The selection intensity accounts for differences in the phenotypic variances, in the same way that a correlation coefficient is a better measure of the strength of association than a covariance (LW Chapter 3). Substituting $\bar{i}\sigma_z$ for S gives the **selection-intensity version** of the breeder's equation

$$R = h^2 \bar{i} \sigma_z = \bar{i} h \sigma_A = \sigma_A^2 \bar{i} / \sigma_z \quad (13.6b)$$

which follows from

$$h^2 \sigma_z = \frac{\sigma_A^2}{\sigma_z^2} \sigma_z = \frac{\sigma_A}{\sigma_z} \sigma_A = h \sigma_A$$

The various forms of Equation 13.6b will prove to be useful starting points for generalizations (developed below) of the breeder's equation to accommodate more general types of selection. A second reason why breeders and experimentalists generally work with \bar{i} is that specifying the fraction (p) of adults saved to form the next generation determines the expected value of \bar{i} , and hence $S = \bar{i}\sigma_z$, in some future selection experiment.

The Robertson-Price Identity, $S = \sigma(w, z)$

As introduced in Chapter 6, the selection differential can be written as the covariance between relative fitness and trait value

$$S = \sigma(w, z) \quad (13.7a)$$

This is the Robertson-Price identity (Equation 6.10), which was first noted by Robertson (1966a) and later elaborated on by Price (1970, 1972a). Chapter 6 showed how this expression directly follows from Price's theorem. For an alternative derivation, let z_i , p_i , and w_i be the trait value, frequency before selection, and relative fitness, respectively, of class i . The selection differential is simply the mean after selection minus the mean before

$$S = \mu_s - \mu = \sum z_i w_i p_i - \sum z_i p_i = E[z w] - E[z]$$

Because $E[w] = 1$ by definition, we can write this as

$$S = E[z w] - E[z] E[w] = \sigma(w, z)$$

thus recovering the Robertson-Price identity. The last step follows from the standard definition of a covariance (LW Equation 3.8).

If, instead of considering the phenotypic value (z) of a trait, we consider its breeding value, A_z , then from the Robertson-Price identity, the expected change in breeding value following selection is

$$\Delta\mu_{A_z} = R_{A_z} = \sigma(A_z, w) \quad (13.7b)$$

Under the conditions of the breeder's equation, this change in the breeding value in the selected parents equals the change in the offspring mean (Chapter 6), thereby equating this covariance with the response (R) in the phenotypic mean of the trait. Equation 13.7b is the 1966 version of Robertson's secondary theorem of natural selection (Equation 6.25a). The more restricted 1968 version, $R = \sigma(A_z, A_w)$, based on the *breeding value* of relative fitness (A_w versus w , Equation 6.24a), appears in the literature as well (Chapters 6 and 20). These covariance-based identities for S and R play important roles in evolutionary quantitative genetics. Chapter 20 examines applications of Equation 13.7b in predicting the selection response in natural populations, while Equation 13.7a routinely appears in selection theory (Chapters 15, 20–23, 29, and 30).

An important application of the Robertson-Price identity follows if we consider the slope of the least-squares linear regression of relative fitness (w) on phenotypic value, z

$$w = a + \beta z + e \quad (13.8a)$$

The interpretation of the slope is that a unit change in z results in a change in relative fitness of β (Chapter 29 examines this regression in detail). From the theory of least-squares regression (LW Chapter 3)

$$\beta = \frac{\sigma(z, w)}{\sigma_z^2} = \frac{S}{\sigma_z^2} \quad (13.8b)$$

Substituting $S = \sigma_z^2 \beta$ into Equation 13.1 yields

$$R = \sigma_A^2 \beta \quad (13.8c)$$

which relates the strength of association, β , between trait value and fitness with the response. This is the univariate version of the multivariate Lande equation ($\mathbf{R} = \mathbf{G}\beta$), to be introduced shortly (Equation 13.26a).

Correcting for Reproductive Differences: Effective Selection Differentials

In artificial selection experiments, S is usually estimated as the difference between the mean of the selected adults and the sample mean of the population before selection. However, selection need not stop at this stage. For example, strong artificial selection to increase a character might be countered by natural selection associated with a decrease in the fertility of individuals with extreme trait values. This is the simplest example of a partitioning of **episodes of selection** (multiple rounds of selection within the same generation), in this case a single episode of viability selection followed by fertility selection, which will be explored more broadly in Chapter 29.

Biases introduced by such differential fertility in experimental or breeding settings can be removed by randomly choosing the same number of offspring from each selected parent, thus ensuring equal fertility. Alternatively, differential fertility can be accounted for by using the **effective** (or **realized**) **selection differential**, S_e ,

$$S_e = \frac{1}{n_p} \sum_{i=1}^{n_p} \left(\frac{n_i}{\bar{n}} \right) (z_i - \mu_z) \quad (13.9)$$

where z_i and n_i are the phenotypic value and total number of offspring of the i th parent, n_p is the number of parents selected to reproduce, \bar{n} is the average number of offspring from the selected parents, and μ_z is the mean before selection. If all selected parents have the same number of offspring ($n_i = \bar{n}$ for all i), then S_e reduces to S . If there is variation in the number of offspring among selected parents, S_e can be considerably different from S .

The derivation of Equation 13.9 follows directly from the Robertson-Price identity. If we examine a total of N individuals, n_p of which are selected as parents, then

$$S = \sigma(z, w) = E[wz] - E[z]E[w] = \frac{1}{N} \sum_{i=1}^N \left(\frac{W_i}{\bar{W}} \right) z_i - \mu_z \cdot 1$$

where the fitness of individual i is $W_i = n_i$ (with $n_i = 0$ for individuals not chosen as parents). The mean fitness becomes

$$\bar{W} = \frac{1}{N} \sum_{i=1}^N n_i = \frac{\bar{n} n_p}{N} \quad \text{where} \quad \bar{n} = \sum_{i=1}^N n_i / n_p$$

and therefore \bar{n} is the mean number of offspring left by the adults that were selected to reproduce. Hence

$$w_i = \frac{W_i}{\bar{W}} = \frac{n_i N}{\bar{n} n_p}, \quad \text{yielding} \quad \sigma(z, w) = \frac{1}{n_p} \sum_{i=1}^n z_i \frac{n_i}{\bar{n}} - \mu_z$$

Rearranging recovers Equation 13.9.

Example 13.2. Consider a trait with heritability 0.3 and a before-selection mean of 30. Suppose five parents are selected, with the following trait values and offspring numbers:

Parent	Phenotypic value	Number of offspring
1	45	1
2	40	2
3	35	3
4	33	5
5	32	5

The unweighted phenotypic mean of the selected parents is 37, yielding $S = 37 - 30 = 7$ and an expected response of $R = 0.3 \cdot 7 = 2.1$. Is the predicted response altered when differential fertility is taken into account? Computing the effective selective differential by weighting the selected parents by the number of offspring they leave yields

i	z_i	n_i	n_i / \bar{n}
1	45	1	0.313
2	40	2	0.625
3	35	3	0.938
4	33	5	1.563
5	32	5	1.563

$$\frac{1}{n_p} \sum_{i=1}^{n_p} \left(\frac{n_i}{\bar{n}} \right) z_i = 34.70$$

Hence, $S_e = 4.70$, yielding an expected response of $R = 0.3 \cdot 4.70 = 1.41$. In this case, not using the effective differential results in a 50% overestimation of the expected response.

EXPANDING THE BASIC BREEDER'S EQUATION

The basic breeder's equation predicts the mean breeding value of the set of parents chosen to form the next generation because of their exceptional phenotypic values. However,

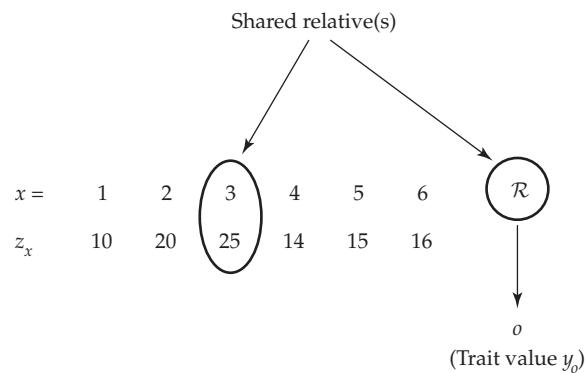

Figure 13.2 The general selection problem: The ultimate goal is to predict the selection response in some response trait (whose values are denoted by y), based on the values of a potentially different—but genetically correlated—selected trait (whose values are denoted by z). The values of the selected trait are measured on one set of individuals (indexed by x_i). For example, the value (z_x) of the selected trait in individual x may be an index that weights x 's value for the response trait, as well as the values of the response trait in several of x 's relatives. In the figure, x_3 has the highest value of the selected trait, but instead of using x_3 as a parent for the next generation (which would correspond to individual selection), we instead use a relative, \mathcal{R} , of x_3 , with o denoting an offspring from \mathcal{R} . The covariance required for predicting the mean change in the response trait is $\sigma(z_x, y_o)$, namely, the covariance between the selection trait value (z_x) in individual x and the response trait value (y_o) in the offspring of parent \mathcal{R} . Under our infinitesimal assumption that the expected value of an offspring is the average of the two parental breeding values, this covariance is also $\sigma[z_x, A_y(\mathcal{R})/2]$, half the covariance between the phenotypic value of the selection trait in x and the breeding value for the response trait in x 's relative, \mathcal{R} .

breeders, experimentalists, and natural selection all may use additional information in determining the fitness of individuals. For example, one may measure traits in one set of individuals and then use this information to predict the mean breeding value for a second set of related individuals that will be the actual parents of the next generation. One such setting is family selection, wherein one measures the values of a number of family members (for example, by growing seed from a family over a number of environments) and, based on their means, selects the exceptional families. Remnant seeds from these families (i.e., seeds whose phenotypes are not scored) are then used to form the next generation. The prediction of the selection response now involves predicting the breeding value of a family member given the mean of other family members. The breeder's equation is easily extended to these more complex settings, as we now demonstrate. The structure of the general selection problem is given by Figure 13.2.

Accuracy

Suppose our goal is increased milk production. The top females are easy to score, but with no selection on males (who do not display the trait), Equation 13.5 gives the selection response as $h^2(S/2)$. Selection on males is made possible, however, by choosing brothers of the top-scoring females as the sires for the next generation, as breeding values are correlated between relatives. Predicting selection response in this case depends upon the genetic covariance between the phenotypic value (z_x) of individual x and the phenotypic value (z_o) in a relative (o) of x . Here, z_x is milk-yield in female x , whose relative, \mathcal{R} (her brother), is then used as a parent for the next generation and whose resulting offspring are denoted by o (Figure 13.2).

Figure 13.2 shows the most general setting, where selection is based on one trait (the selected trait), while our interest is the resulting response in another, genetically correlated, trait (the response trait). Let z_x and y_o denote, respectively, the value of the selected trait (z) in a measured individual x (upon which selection decisions are based), and the value of

the response trait (y) in the offspring, o . Assuming that the regression of y_o on z_x is linear (i.e., the same assumption as for the breeder's equation), standard regression theory (LW Chapter 3) yields

$$E[y_o - \mu_y | z_x] = \frac{\sigma(z_x, y_o)}{\sigma^2(z)} (z_x - \mu_z) \quad (13.10a)$$

where μ_y and μ_z are the preselection means of the selected and response traits, respectively. Taking expectations over the selected parents gives the expected change in y from selection on x as

$$R_y = \mu_y^{**} - \mu_y = \frac{\sigma(z_x, y_o)}{\sigma^2(z)} (\mu_z^* - \mu_z) = \frac{\sigma(z_x, y_o)}{\sigma^2(z)} S_z = \frac{\sigma(z_x, y_o)}{\sigma(z)} \bar{t}_z \quad (13.10b)$$

where μ^* denotes the within-generation change in the mean following selection (but before reproduction), μ^{**} denotes the offspring mean, and \bar{t}_z is the selection intensity used when choosing parents. The latter is a function of the fraction, p , of measured individuals chosen to have a relative as a parent of the next generation. For example, if brothers from only the top 5% of females are used, then $p = 0.05$, yielding $\bar{t}_z \simeq 2.06$ (Example 14.1).

The selection-intensity version of Equation 13.10b can alternatively be expressed as

$$R_y = \frac{\sigma(z_x, y_o)}{\sigma(z)} \bar{t}_z = \frac{\sigma(z_x, y_o)}{\sigma(z) \sigma(y)} \bar{t}_z \sigma(y) = \bar{t}_z \rho(z_x, y_o) \sigma(y) \quad (13.11a)$$

where $\rho(z_x, y_o)$ is the correlation between z_x and y_o . This correlation is referred to as the **accuracy** in predicting the value of the response trait measured in o (y_o) from the selected trait measured in x (z_x). One immediately sees that by improving the accuracy of our selection scheme, we improve the response. Expressing Equation 13.11a in terms of the **relative response**, the change in y in phenotypic standard deviations, gives the expected change in the response trait when using the selected trait measure in a relative as

$$\frac{R_y}{\sigma(y)} = \bar{t}_z \rho(z_x, y_o) \quad (13.11b)$$

A more powerful way of viewing Equation 13.11a is in terms of the *breeding values*, A_y , for the trait of interest. Under the assumption (used throughout this chapter) that the expected mean of the offspring equals the average breeding values of its parents (Chapter 6 examined this assumption in detail), the mean of the response trait in the offspring is simply the mean breeding value of this trait in the parents. Hence, $R_y = R_{A_y}$, namely, the difference between the mean breeding value for the response trait in the selected parents versus that for the overall population. By taking the response trait to be the breeding value, A_y , of the trait of interest, Equation 13.11a becomes

$$R_{A_y} = \bar{t}_z \rho(z_x, A_y) \sigma(A_y) \quad (13.11c)$$

Hence, the breeder's equation can be considered as a special case of the more general expression

$$\text{Response} = (\text{Intensity}) \cdot (\text{Accuracy in predicting breeding value using } z_x) \cdot (\text{Usable variation}) \quad (13.11d)$$

An accuracy of special interest that arises during individual selection is the correlation between an individual's phenotype (z) and breeding value (A), where

$$\rho(z, A) = \sigma(z_x, A_x)/(\sigma_z \sigma_A) = \sigma_A^2/(\sigma_z \sigma_A) = \sigma_A/\sigma_z = h \quad (13.11e)$$

This accuracy corresponds to individual selection (x is the parent, $x = \mathcal{R}$; and the selected and response traits are the same, $y = z$). When substituted into Equation 13.11c, this recovers Equation 13.6b. As illustrated in Example 13.4, this is a key result, as whether some proposed

selection scheme is more efficient than individual selection depends on the correlation between the breeding value of a chosen parent and the selection variable used for that scheme (e.g., z_x could be x 's family mean of the response trait). If this correlation exceeds h , then from Equation 13.11c (because \bar{t} and $\sigma^2[A]$ are the same), the response is larger. Equations 13.11a through 13.11c form the foundation for most of Chapter 21, which deals with various selection schemes using family information (e.g., family means and within-family deviations).

The greatest selection response occurs if we take the selection variable (z_x) with the largest correlation with the breeding value for the response trait (assuming \bar{t} and σ_A are the same over all comparisons). This idea forms the foundation of **index selection**, whereby individuals are chosen based on some index, $z_x = \sum a_i z_i$, a linear combination of trait values in the relatives and/or correlated traits in the focal individual (Volume 3).

Example 13.3. Consider selection on clones or other pure lines, where parents pass on their entire genome to their offspring. The phenotypic value (z_o) of an offspring from a parent with a genotypic value G_p can be written as $z_o = G_p + E_o$, so that the parent-offspring covariance (in the absence of any genotype \times environment covariance and/or interactions) equals

$$\sigma(z_o, z_p) = \sigma(G_p + E_o, G_p + E_p) = \sigma(G_p, G_p) = \sigma(G, G)$$

namely, the total genetic variance, σ_G^2 . The resulting parent-offspring regression has a slope $b_{op} = \sigma_G^2 / \sigma_z^2 = H^2$, the broad-sense heritability (LW Chapter 20), yielding

$$R = H^2 S$$

Because $H^2 \geq h^2$ (as $\sigma_G^2 \geq \sigma_A^2$), the single-generation response to selection is at least as large for clones as for a sexual population with the same variance components. However, when selection continues for several generations, using clones is expected to be far less effective, as selection among clones very rapidly removes any genetic variation from the population without any mechanism (other than mutation) to regenerate it. Likewise, the assumption of a normal distribution of genotypic values quickly breaks down as only a few genotypes remain. By contrast, with selection among sexually reproducing individuals, segregation and recombination will generate an almost endless supply of new variation if a large number of segregating loci underlie the trait. Special issues with regard to the selection and development of pure lines are examined in Volume 3.

Example 13.4. **Progeny testing** uses the mean of an individual's offspring (here, all are assumed to be half-sibs) to predict its breeding value. In order to predict the selection response using this scheme, we first need the correlation between the mean (\bar{z}_o) of n half-sib offspring and the breeding value (A) of the common parent. This is given by

$$\rho(\bar{z}_o, A) = \frac{\sigma(\bar{z}_o, A)}{\sigma_A \cdot \sigma(\bar{z}_o)}$$

To obtain this, first note that the covariance between the parent and its offspring is $\sigma_A^2/2$

$$\sigma(\bar{z}_o, A) = \frac{1}{n} \sum_{i=1}^n \sigma(z_i, A) = \frac{1}{n} n \sigma(z_i, A) = \sigma_A^2 / 2$$

The expression for $\sigma^2(\bar{z}_o)$ requires a bit more bookkeeping, as sibs are correlated. Assuming half-sibs and that there are no shared environmental effects, $\sigma(z_i, z_j) = \sigma_A^2/4$ (for $i \neq j$), yielding

$$\begin{aligned} \sigma^2(\bar{z}_o) &= \sigma \left(\frac{1}{n} \sum_{i=1}^n z_i, \frac{1}{n} \sum_{j=1}^n z_j \right) = \frac{1}{n^2} n \sigma(z_i, z_i) + \frac{n(n-1)}{n^2} \sigma(z_i, z_j) \\ &= \frac{\sigma_z^2}{n} + \left(1 - \frac{1}{n} \right) \frac{\sigma_A^2}{4} = \frac{\sigma_z^2}{4n} [4 + (n-1)h^2] \end{aligned}$$

Combining these results yields

$$\rho(\bar{z}_o, A) = \frac{\sigma_A^2/2}{\sigma_A \sigma_z \sqrt{\frac{4+(n-1)h^2}{4n}}} = \frac{\sigma_A}{\sigma_z} \sqrt{\frac{4n/4}{4 + (n-1)h^2}} = \sqrt{\frac{h^2 n}{4 + (n-1)h^2}} = \sqrt{\frac{n}{n + \gamma}}$$

where $\gamma = (4 - h^2)/h^2$. For large n , note that the accuracy approaches one. Substituting this result into Equation 13.11c, the response to selection becomes

$$R = \bar{\iota} \rho(\bar{z}_o, A) \sigma_A = \bar{\iota} \sigma_A \sqrt{\frac{n}{n + \gamma}} = \bar{\iota} \sigma_A \sqrt{\frac{h^2 n}{4 + h^2(n-1)}}$$

Recalling Equation 13.6b, the ratio of response for progeny testing (R_{pt}) to mass selection (R_{ms}) becomes

$$\begin{aligned} \frac{R_{pt}}{R_{ms}} &= \frac{\bar{\iota}_{pt} \rho(\bar{z}_o, A) \sigma_A}{\bar{\iota}_{ms} \rho(z, A) \sigma_A} = \left(\frac{\bar{\iota}_{pt}}{\bar{\iota}_{ms}} \right) \frac{1}{h} \sqrt{\frac{h^2 n}{4 + h^2(n-1)}} \\ &= \left(\frac{\bar{\iota}_{pt}}{\bar{\iota}_{ms}} \right) \sqrt{\frac{n}{4 + h^2(n-1)}} \end{aligned}$$

The selection intensity under progeny testing is likely to be lower, as it is easier (and cheaper) to score a phenotype than to progeny test. When the intensities are equal, the ratio of responses approaches $1/h$ for large n . Assuming $\bar{\iota}_{pt} = \bar{\iota}_{ms}$, progeny testing gives a larger response when $\rho(\bar{z}_o, A) > \rho(z, A)$, or when

$$\sqrt{\frac{n}{4 + h^2(n-1)}} > 1 \quad \text{or} \quad n > \frac{4 - h^2}{1 - h^2}$$

In particular, $n > 4, 5$, and 7 is required for $h^2 = 0.1, 0.25$, and 0.5 , respectively, for progeny testing to give a larger response. Hence, when the heritability of a trait is high, more offspring must be scored for the accuracy of progeny selection to exceed that of mass selection. A high heritability implies that an individual's phenotype is a good predictor of its breeding value, which requires increasingly more observations of an indirect measure (offspring values) to obtain higher accuracy than the simple direct measure of the individual phenotype.

Example 13.5. Suppose a character of interest is extremely hard to measure in live individuals. For example, one cannot directly select on individuals that have to be killed to measure a trait such as meat quality. Similarly, consider traits expressed in only one sex, such as milk production. How can we select on males if they do not express the trait themselves? One solution to both of these problems is **sib selection** (Chapter 21), or using sibs of exceptional individuals as the parents for the next generation (e.g., choosing males based on the milk production of their sisters).

Under sib selection, the selection unit (x) is the trait value in sib s_1 , with the correlation between its phenotypic value (z_{s_1}) and the breeding value (A_{s_2}) of sib s_2 being (LW Table 7.3)

$$\sigma(z_{s_1}, A_{s_2}) = \begin{cases} \sigma_A^2/2 & \text{for full sibs} \\ \sigma_A^2/4 & \text{for half-sibs} \end{cases} \quad \text{yielding} \quad \rho(z_{s_1}, A_{s_2}) = \begin{cases} h/2 & \text{for full sibs} \\ h/4 & \text{for half-sibs} \end{cases}$$

For example, when s_1 and s_2 denote full sibs

$$\rho(z_{s_1}, A_{s_2}) = \frac{\sigma(z_{s_1}, A_{s_2})}{\sigma(z_{s_1}) \cdot \sigma(A_{s_2})} = \frac{\sigma_A^2/2}{\sigma_z \sigma_A} = \frac{\sigma_A}{2\sigma_z} = \frac{h}{2}$$

with the correlation between half-sibs obtained similarly. Applying Equation 13.11c, the resulting response to selection (assuming equal selection intensity on both sexes) based on the performance of a sib is

$$R = \begin{cases} \bar{\tau}(h/2)\sigma_A & \text{for full sibs} \\ \bar{\tau}(h/4)\sigma_A & \text{for half-sibs} \end{cases}$$

where the selection intensity, $\bar{\tau}$, is a function of the fraction of measured sibs chosen in order to have a relative as a parent of the next generation. For example, if only 5% of the measured sibs are chosen to have a sib as a parent in the next generation, then $\bar{\tau} \approx 2.06$ (Example 14.1). Comparison with Equation 13.6b shows that using a single full sib (in place of the measured individual) gives a response that is half that of mass selection, while using a single half-sib gives only a quarter of the response.

One can also have a mixture of direct and sib selection, as can occur when selection is based on milk production. Here, there is direct selection on females (based on their trait value) and sib selection on males (based on the trait value of a sister). Summing the separate responses from selection on females and males, the expected response becomes

$$R = (1/2)\bar{\tau}h\sigma_A + (1/2)\bar{\tau}(h/2)\sigma_A = (3/4)\bar{\tau}h\sigma_A$$

where the first term is the response from using superior females (Equation 13.11a with selection on only one sex, giving $\bar{\tau}/2$), and the second term is the response using a brother of a superior sister (full sib selection, or this term divided by two for half-sib selection). Here, we have assumed the same intensity, $\bar{\tau}$, in both sexes, while with different amounts of selection

$$R = (1/2)\bar{\tau}_d h\sigma_A + (1/2)\bar{\tau}_s(h/2)\sigma_A = [(2\bar{\tau}_d + \bar{\tau}_s)/4]h\sigma_A$$

While one could develop additional extensions (for example, by using progeny testing for males), in practice, information from all relatives is handled using BLUP selection, a robust and general approach for predicting response under very diverse schemes of selection that will be introduced shortly.

Reducing Environmental Noise: Stratified Mass Selection

Accuracy (and hence response) can also be increased by using designs that reduce environmental noise. One approach is Gardner's (1961) method of **stratified mass selection**: a population is stratified into a number of blocks (potentially representing different microenvironments) and selection occurs *within* each block. The motivation behind Gardner's method was to improve individual selection for yield in maize. At the time of his paper, selection based solely on the observed yield of individual plants resulted in a very poor response, largely because environmental effects overwhelm genetic differences, resulting in very small h^2 values. Simply by selecting for plants within blocks of presumably similar environments, Gardner was able to use mass selection to obtain fairly significant gains (about 4% per year). Stratified mass selection is an important component in Burton's (1974, 1982) method of **recurrent restricted phenotypic selection (RRPS)** for turf grass breeding.

To obtain the expected response under stratified mass selection, we need to compute the accuracy, which first requires the covariance between within-block deviations and an individual's breeding value. Suppose n individuals are measured within each block, and selection occurs on the deviation from the block mean, e.g., on $z_{ij} - \bar{z}_i$ where z_{ij} is the j th individual from block i and \bar{z}_i is the block mean. An individual's phenotypic value can be expressed as its genotypic value, G_{ij} (indicating the j th individual from block i), plus an environmental value consisting of a block effect, B_i , and the residual environmental value, e_{ij} ,

$$z_{ij} = \mu + G_{ij} + B_i + e_{ij} \quad (13.12a)$$

The total environmental variance equals the variance among blocks, σ_B^2 , plus the within-block variance, σ_e^2 (the variance of the residuals e_{ij}), resulting in a total variance of

$$\sigma_z^2 = \sigma_G^2 + \sigma_E^2 = \sigma_G^2 + \sigma_B^2 + \sigma_e^2 \quad (13.12b)$$

For the j th individual in block i , the covariance between individual breeding value and within-block deviation is

$$\sigma(z_{ij} - \bar{z}_i, A_{ij}) = \sigma(z_{ij}, A_{ij}) - \frac{1}{n} \sum_{k=1}^n \sigma(z_{ik}, A_{ij}) = \sigma_A^2 \left(1 - \frac{1}{n}\right) \quad (13.13)$$

as the assumption is that individuals within blocks are unrelated. The variance of deviations within a block is $\sigma_G^2 + \sigma_e^2$, making the accuracy

$$\rho(z_{ij} - \bar{z}_i, A_{ij}) = \frac{\sigma_A^2(1 - 1/n)}{\sigma_A \sqrt{\sigma_G^2 + \sigma_e^2}} = \frac{\sigma_A(1 - 1/n)}{\sqrt{\sigma_G^2 + \sigma_e^2}} \quad (13.14a)$$

Applying Equation 13.11c yields the resulting response of

$$R = \bar{\iota} \rho(z_{ij} - \bar{z}_i, A_{ij}) \sigma_A = \frac{\bar{\iota} \sigma_A^2(1 - 1/n)}{\sqrt{\sigma_G^2 + \sigma_e^2}} \simeq \frac{\bar{\iota} \sigma_A^2}{\sqrt{\sigma_G^2 + \sigma_e^2}} \quad (13.14b)$$

where $\bar{\iota}$ is the selection intensity *within blocks*, and the final approximation assumes a large n .

In contrast, if the effects of blocks are ignored and individuals are simply selected from the entire population, the between-block variance is incorporated into the variance of z , and from Equation 13.6b the response becomes

$$R = \frac{\bar{\iota} \sigma_A^2}{\sqrt{\sigma_G^2 + \sigma_B^2 + \sigma_e^2}} \quad (13.14c)$$

The relative advantage of stratification (assuming the block size is modest to large, so that $1 - 1/n \simeq 1$) is

$$\sqrt{\frac{\sigma_G^2 + \sigma_B^2 + \sigma_e^2}{\sigma_G^2 + \sigma_e^2}} = \sqrt{1 + \frac{\sigma_B^2}{\sigma_G^2 + \sigma_e^2}} \quad (13.15)$$

Thus, within-block selection can significantly improve the selection response when the among-block variance accounts for a significant fraction of the total variation. Schutz and Cockerham (1966) extend this idea of selecting within blocks to a number of other designs.

Reducing Environmental Noise: Repeated-Measures Selection

The **repeated-measures** design is a second example of increasing accuracy (and response) by providing some control over environmental noise. Here the character of interest is measured n different times on each individual, and selection occurs on \bar{z}_i , the mean value for individual i . For example, if we are considering the number of days to ripening, a better approach is to use a collection of fruit, rather than a single one, to assign a value to an individual tree. Repeated-measures selection is a common design in behavioral experiments, wherein a single measure (such as wheel-running speed) may vary greatly within an individual over time.

Our analysis depends on the **repeatability** (LW Chapter 6) of the trait. The character value for the j th measure of individual i is decomposed as

$$z_{ij} = G_i + E_i + e_{ij} \quad (13.16a)$$

where G_i and E_i are the genotypic and (permanent) environmental values common to all measures of i , and e_{ij} is the special environmental value restricted to the j th measure of i , with the repeatability, r , being defined as

$$r = \frac{\sigma_G^2 + \sigma_E^2}{\sigma_z^2} = 1 - \frac{\sigma_e^2}{\sigma_z^2} \quad (13.16b)$$

yielding

$$r\sigma_z^2 = \sigma_G^2 + \sigma_E^2 \quad \text{and} \quad (1 - r)\sigma_z^2 = \sigma_e^2 \quad (13.16c)$$

To obtain the accuracy in using \bar{z}_i to predict A_i , we need both the covariance between \bar{z}_i and A_i , and the variance of \bar{z}_i . The former is simply

$$\sigma(A_i, \bar{z}_i) = \sigma\left(A_i, \frac{1}{n} \sum_{j=1}^n z_{ij}\right) = \frac{1}{n} \sum_{j=1}^n \sigma(A_i, z_{ij}) = \frac{1}{n} n \sigma(A_i, A_i) = \sigma_A^2 \quad (13.17a)$$

To obtain the variance of \bar{z}_i , starting with

$$\bar{z}_i = \frac{1}{n} \sum_{j=1}^n z_{ij} = G_i + E_i + \frac{1}{n} \sum_{j=1}^n e_{ij} \quad (13.17b)$$

it immediately follows from Equation 13.16c that

$$\begin{aligned} \sigma^2(\bar{z}_i) &= \sigma_G^2 + \sigma_E^2 + \sigma_e^2/n \\ &= \sigma_z^2 r + \sigma_z^2 \frac{1-r}{n} = \sigma_z^2 \left(\frac{1+(n-1)r}{n} \right) \end{aligned} \quad (13.17c)$$

The resulting accuracy in using \bar{z}_i to predict A_i becomes

$$\rho(\bar{z}_i, A_i) = \frac{\sigma(A_i, \bar{z}_i)}{\sigma_A \sigma(\bar{z}_i)} = \frac{\sigma_A^2}{\sigma_A \sqrt{\sigma_z^2 \left(\frac{1+(n-1)r}{n} \right)}} = h \sqrt{\frac{n}{1+(n-1)r}} \quad (13.18a)$$

giving the response as

$$R = \bar{i} \rho(\bar{z}_i, A_i) \sigma_A = \bar{i} h \sqrt{\frac{n}{1+(n-1)r}} \sigma_A \quad (13.18b)$$

The ratio of accuracies under repeated-measures versus (single-measure) mass selection becomes

$$\frac{\rho(\bar{z}_i, A_i)}{\rho(z_i, A_i)} = \sqrt{\frac{n}{1+(n-1)r}} \quad (13.19a)$$

which approaches $1/\sqrt{r}$ for large values of n . Hence, when repeatability is low ($\sigma_e^2 \gg \sigma_G^2 + \sigma_E^2$), repeated-measures selection can result in a considerable improvement in response.

This comparison assumes the same selection intensity under single- versus repeated-measures selection, but one might imagine that they could differ. For example, if one has the time and resources to only score 500 individuals, and (for breeding reasons) must keep (at least) 50 parents, then the fraction to be saved can be as small as $50/500 = 10\%$ under single-measure selection. However, with five replicate measures per individual, we can only score 100 individuals, if we are to save a fraction no smaller than $50/100 = 50\%$. Applying Equation 14.4c, these translate into selection intensities of $\bar{i}_{\bar{z}_i} = 0.79$ for repeated-measures selection and $\bar{i}_{z_i} = 1.75$ for single-measures selection, respectively. Such differences in the potential selection intensity are easily incorporated into comparisons of different selection strategies, with the comparison now being

$$\frac{R_{\bar{z}_i}}{R_{z_i}} = \frac{\bar{i}_{\bar{z}_i}}{\bar{i}_{z_i}} \sqrt{\frac{n}{1+(n-1)r}} \quad (13.19b)$$

Finally, we note that our analysis of repeated-measures selection assumes that the additive-genetic correlation across individual measurements is 1.0, which is expected for many traits. However, if measures are sufficiently separated in time that age effects are

important, or if they represent significantly distinct events (such as litter size at different **parities**, i.e., distinct litters), these correlations can be less than one. In other words, the traits measured at different ages may not be the same genetically. In such cases, one should treat these measurements as a set of correlated traits and use index-selection theory (Volume 3). With measurements at arbitrary time points that may differ over individuals, the method of random regression (Volume 3) is used.

Example 13.6. As an example of the consequences of basing selection decisions on single versus multiple measurements, consider the following data set, which was simulated by assuming a character with $h^2 = 0.1$, $\sigma_z^2 = 100$, $\mu = 50$, and $r = 0.2$. The simulated values for 20 individuals for either a single measurement, $z(1)$, or the average of five measurements, $\bar{z}(5)$, are

j	$z_j(1)$	$\bar{z}_j(5)$	j	$z_j(1)$	$\bar{z}_j(5)$
1	54.97	56.80	11	49.81	48.76
2	64.01	54.51	12	51.92	46.76
3	42.64	52.61	13	43.56	51.79
4	42.70	38.69	14	41.60	47.23
5	61.62	56.42	15	51.80	48.90
6	39.86	47.70	16	52.88	47.21
7	56.54	48.63	17	63.86	54.03
8	35.88	47.26	18	39.76	49.62
9	54.32	53.93	19	36.45	47.78
10	57.85	45.10	20	59.07	51.16

where j indexes the individuals. Suppose the uppermost 25% (top 5 of the 20) are chosen for selection. Based on single measures, individuals 2, 5, 10, 17, and 20 would be chosen, while based on five measures, individuals 1, 2, 5, 9, and 17 would be selected. Using the single (initial) measurement, the overall mean is 50.05, while the mean of selected individuals is 61.28, yielding an S of 11.23.

If we use repeated-measures selection, the overall mean of the five-sample averages for each individual is 49.74, while the mean of selected individuals is 55.14, resulting in an S of 5.39. The smaller value of S under repeated measures under the same selection intensity, \bar{t} , is a simple consequence of the reduced variance associated with using the mean (repeated measures) versus a single observation. To see this, note from Equation 13.6a that $S_{\bar{z}}/S_z = (\bar{t}\sigma_{\bar{z}})/(\bar{t}\sigma_z) < 1$, as $\sigma_{\bar{z}} < \sigma_z$ (Equation 13.17c). From the breeder's equation, the expected response based on single measures is

$$R = h^2 S = 0.1 \cdot 11.23 = 1.12$$

To express the response given by Equation 13.18b (the repeated-measures expression) in terms of S , note that here $\rho = \sigma_A^2/(\sigma_A \sigma_{\bar{z}}) = \sigma_A/\sigma_{\bar{z}}$, and hence $R = \bar{t}\rho\sigma_A = \bar{t}\sigma_A^2/\sigma_{\bar{z}} = (\bar{t}\sigma_{\bar{z}})\sigma_A^2/\sigma_{\bar{z}}^2 = S\sigma_A^2/\sigma_{\bar{z}}^2$, which, using Equation 13.17c, yields

$$R = h^2 \left(\frac{n}{1 + (n-1)r} \right) S = 0.1 \cdot 2.78 \cdot 5.39 = 1.50$$

Thus, the reduction in S under repeated measures (5.39 versus 11.23) is more than made up for by increased accuracy, yielding a larger expected response relative to mass selection (i.e., selection based on single measures). From Equation 13.19a, the expected ratio of the accuracies (and hence responses, assuming the same selection intensities) of the five-measure to single-measure schemes is 1.67, which approaches $1/\sqrt{r} \simeq 2.24$ for large values of n . The value of the response ratio for our simulated data ($1.50/1.12 = 1.34$) deviated from the expected value due to the small number (20) of randomly sampled individuals.

Adjustments for Overlapping Generations

Thus far, we have been assuming that we are examining nonoverlapping generations, with all parents reproducing in a discrete single generation. However, domesticated animals, perennial plants, and many species in nature can have offspring over multiple years and for varying life spans. In such cases, generations overlap and the selection response should be considered on an absolute time scale (typically years) rather than a per-generation scale. To express the breeder's equation in terms of a yearly rate of response, we first need to compute the **generation intervals**, L_x (the average age of parents when progeny are born), for both sexes.

Assuming that the variance components are independent of age and sex, the yearly rate of response, r_y , can be expressed as

$$r_y = \left(\frac{\bar{t}_s + \bar{t}_d}{L_s + L_d} \right) h^2 \sigma_z = \left(\frac{\bar{t}_s + \bar{t}_d}{L_s + L_d} \right) h \sigma_A \quad (13.20)$$

where \bar{t}_s and \bar{t}_d denote the selection intensities of the sire (father) and dam (mother). This result (in a slightly different form) is from Rendel and Robertson (1950), although the basic idea traces back to Dickerson and Hazel (1944). Thus, one way to increase the rate of response is to reduce the generation intervals, for example, by using younger parents. However, the problem here is that there is a tradeoff between generation interval and selection intensity. In species that are reproductively limited (with few offspring per dam), using younger dams means that a higher fraction of the dams must be kept to replace the population. As a consequence, the selection intensity on the parents is reduced. Equation 13.20 is an *asymptotic result*, as it takes time for the selection response to propagate through an age-structured population. Volume 3 examines the effects of age structure on selection response in greater detail.

Example 13.7. Compute the sire, L_s , and dam, L_d , generation intervals for the following age structure:

Parental Age at Birth of Progeny					
Sires Number	Year 2	Year 3	Year 4	Year 5	Total
	760	380	0	0	1140
Dams Number	Year 2	Year 3	Year 4	Year 5	Total
	400	600	100	40	1140

The resulting sire generation interval is the average age of sires when offspring are born. Here, $760/1140 = 2/3$ of the sires are age two, while $1/3$ are age three, yielding

$$L_s = 2 \cdot \frac{760}{1140} + 3 \cdot \frac{380}{1140} = \frac{2 \cdot 760 + 3 \cdot 380}{1140} = 2.33$$

Similarly, the dam generation interval is

$$L_d = \frac{2 \cdot 400 + 3 \cdot 600 + 4 \cdot 100 + 5 \cdot 40}{1140} = 2.81$$

Because each offspring has a single mother and father, the population-level average generation interval is just the average of the two parental intervals, or 2.57 years.

Maximizing Response Under the Breeder's Equation

We can combine both the selection accuracy (Equations 13.11c) and generation-interval (Equation 13.20) versions of the breeder's equation to give a more general expression, with the expected rate of response being

$$r_y = \left(\frac{\bar{t}_s + \bar{t}_d}{L_s + L_d} \right) \rho(A, x) \sigma_A \quad (13.21a)$$

where x is the measure used to choose the parents to form the next generation. Even more generally, if the accuracies vary over sex

$$r_y = \left(\frac{\bar{t}_s \rho_s(A, x) + \bar{t}_d \rho_d(A, x)}{L_s + L_d} \right) \sigma_A \quad (13.21b)$$

Beyond importing new genetic material, there is not much a breeder can do to increase σ_A^2 , which leaves three selection features that the breeder has some control over (Dickerson and Hazel 1944; Kinghorn et al. 2000):

- (i) selection intensity, \bar{t}
- (ii) generation interval, L
- (iii) selection accuracy, ρ

The response rate increases with ρ and \bar{t} , and it decreases with increasing values of L . We have already discussed tradeoffs between L and \bar{t} , and there are similar tradeoffs between L and ρ . Clearly, the longer we wait to allow a parent to reproduce, the more accurately we can predict its breeding value, as information from other relatives and from progeny testing accumulates over time. However, these increases in ρ also result in increases in L . An optimal selection program must balance all of these competing interests.

Equation 13.21 highlights the importance to animal breeding of advances in reproductive technologies such as **artificial insemination (AI)** and **multiple ovulation embryo transfer (MOET)** schemes (e.g., Wooliams 1989). The more offspring a parent can produce, the stronger is the selection intensity that can be applied while still keeping a fixed number of animals in a population. AI has resulted in the potential for far greater sire selection intensities (but as a side effect, far more inbreeding) than would be possible under natural insemination. Likewise, MOET schemes that increase the number of offspring from females allow for increases in the selection intensity on dams as well as decreases in the generation interval.

Equation 13.21a is also highly relevant to **genomic selection** (wherein high-density marker information is used to predict the values of offspring; Volume 3). The gain from genomic selection is generally *not* the result of an increased accuracy, ρ , when using marker information, but rather from much quicker and earlier scoring of phenotypes, which lowers L and increases \bar{t} .

Example 13.8. As an example of the tradeoff between accuracy and generation intervals, consider a trait with $h^2 = 0.25$ and selection only on sires (fathers). One scheme is to simply select on the sire's phenotype, which results in a sire generation interval of (say) 1.5 years. Alternatively, one might perform progeny testing to improve the accuracy of the selected sires, which results in an increase of the sire generation interval to (say) 2.5 years. Suppose that in both cases, the dam (mother) interval is constant at 1.5 years. Because the additive-genetic variation is the same in both schemes, the ratio of response under mass selection to response under progeny testing becomes

$$\frac{r_y(\text{sire phenotype})}{r_y(\text{progeny mean})} = \left(\frac{\bar{t}_{sp}}{\bar{t}_{pt}} \right) \frac{\rho(A, \text{sire phenotype}) / (L_s + L_d)}{\rho(A, \text{progeny mean}) / (L_s + L_d)}$$

where \bar{t}_{sp} and \bar{t}_{pt} are the selection intensities under individual selection (sire phenotype) and progeny testing, which can differ due to costs in scoring. From Equation 13.11e, $\rho(A, \text{sire phenotype}) = h = \sqrt{0.25} = 0.5$, while the generation interval becomes $L_s + L_d = 1.5 + 1.5 = 3$. With progeny testing, Example 13.4 yields

$$\rho(A, \text{progeny mean}) = \sqrt{\frac{n}{n + \gamma}} = \sqrt{\frac{n}{n + 15}}$$

as $\gamma = (4 - h^2)/h^2 = 15$, with a total generation interval of $L_s + L_d = 2.5 + 1.5 = 4$. Rearrangement of this expression yields

$$\frac{r_y(\text{sire phenotype})}{r_y(\text{progeny mean})} \left(\frac{\bar{t}_{pt}}{\bar{t}_{sp}} \right) = \frac{0.5/3}{(1/4)\sqrt{\frac{n}{n+15}}} = \frac{2}{3} \cdot \sqrt{\frac{n+15}{n}}$$

For $n = 2$ progeny tested per sire, this ratio is 1.95, resulting in a much larger rate of response under sire-only selection. For $n = 12$, the ratio is exactly one, while for a very large number of offspring tested per sire, the ratio approaches 2/3, or a 1.5-fold increase in the rate of response under progeny testing, despite the increase in the sire generation interval. Thus, taking into account the ratio of selection intensities, mass selection always gives a higher per-year rate of response (for the values of the other parameters assumed in this example) when $\bar{t}_{pt}/\bar{t}_{sp} < 3/2$. By contrast, from Example 13.4, when $n > 4$, progeny testing yielded a larger response (for $h^2 = 0.25$), but that example did not discount for the effect of the longer sire generation intervals required for progeny testing.

Maximizing the Economic Rate of Response

Example 13.8 hints at another important feature of the selection response, economics. Notice that by scoring more than 12 offspring, we can obtain a larger expected rate of response using progeny testing (assuming equal selection intensities). Why not simply score 30 progeny, giving a 122% rate of response relative to simple mass selection? The economic reality relates to the cost of raising and scoring a large number of progeny. Much of applied breeding is concerned with the *economic* rate of response—trying to maximize the rate of response per unit of capital, although this point is often underappreciated, even by some breeders. Along these same lines, much of current selection in animal breeding is for increased efficiency (conversion of resources into desirable traits), and hence greater economic gain per unit of input at the production level. Weller (1994) presented a nice development of how to incorporate economics into breeding.

Mean- Versus Variance-Standardized Response

As was the case with the selection differential, S , in order to assess the relative strength of response one needs some sort of standardization. One obvious approach is to express the response in units of phenotypic standard deviations (**variance-standardization**). From Equation 13.6b,

$$\frac{R}{\sigma_z} = h^2 \bar{t} \quad (13.22a)$$

implying that a (scaled) strength of selection of $\bar{t} = 1/h^2$ is required for a standard deviation of response. For example, with $h^2 = 0.25$, a total selection intensity of $\bar{t} = 4$ is required to achieve a total response of one phenotypic standard deviation. Example 14.1 shows that $\bar{t} = 2.06$ for truncation selection saving the upper 5%, so that only two generations of such selection are required for a one standard deviation change in the trait mean.

While scaling traits in units of phenotypic standard deviations is extremely common, it can potentially be rather misleading (Houle 1992; Houle et al. 2011). To see this, imagine two traits, both with a standard deviation of 2.0. Trait one has a mean of 10 and trait two

has a mean of 100. A response of one standard deviation increases trait one by 20%, but trait two by only 2%. From a variance-standardized viewpoint, the response is equal, but as a proportional response of the total mean, trait one has clearly experienced a stronger response.

Houle and colleagues (Houle 1992; Hansen et al. 2003; Hansen et al. 2011; Houle et al. 2011) argued that using **mean-standardization**, R/μ_z , namely the *proportional amount of response*, is often more appropriate. Again using Equation 13.6b,

$$\frac{R}{\mu_z} = \bar{z} h \frac{\sigma_A}{\mu_z} = \bar{z} h CV_A \quad (13.22b)$$

where $CV_A = \sigma_A/\mu_z$, the coefficient of additive genetic variation, is Houle's (1992) **evolvability** index, which he argued was a better measure of evolutionary potential than h^2 (Chapter 6). Houle (1992) and Hansen et al. (2011) found that h^2 is essentially uncorrelated with evolvability, so that a trait with a lower h^2 could still have high evolvability (i.e., potential for a significant proportional change in the mean), and vice versa.

BLUP SELECTION

LW Chapter 26 introduced the basic **mixed model** for estimating a vector, \mathbf{a} , of breeding values for a set of individuals given some vector, \mathbf{y} , of *records* (observations), a relationship matrix, \mathbf{A} , connecting individuals with records with individuals whose breeding values are of interest, and a set, β , of fixed effects to estimate

$$\mathbf{y} = \mathbf{X}\beta + \mathbf{Z}\mathbf{a} + \mathbf{e}, \quad \mathbf{a} \sim MVN(\mathbf{0}, \sigma_A^2 \cdot \mathbf{A}), \quad \mathbf{e} \sim MVN(\mathbf{0}, \sigma_e^2 \cdot \mathbf{I})$$

where (as detailed in Chapters 19 and 20) the matrices \mathbf{X} and \mathbf{Z} are given from the data (relating which observations contribute information to which fixed and random effects), and \mathbf{A} is obtained from the pedigree or from sufficiently dense genetic markers. Solving the model returns a vector, $\hat{\mathbf{a}}$, of BLUP (best linear unbiased prediction) breeding values.

Much of modern animal breeding (and a growing amount of plant breeding) is based on using BLUP estimates to select individuals with the highest breeding values for the trait to form the next generation. This is called **BLUP selection**. The expected response is simply given by the difference between the mean breeding value of selected parents and the population from which they were chosen. This is an *extremely* flexible methodology, with all of the examples in this chapter being special cases of this general approach. Indeed, provided relatives are measured, BLUP can be used to predict the breeding value of individuals with no phenotypic values (such as milk production in sires). Relatedness information for all measured individuals enters through \mathbf{A} , and multiple records (repeated measurements) from the same individual are easily incorporated, as are additional fixed (and random) factors such as plot, location, and herd effects. Further, the effects of age structure are fully accounted for by the relationship matrix \mathbf{A} . Chapters 19, 20, and 22 discuss features of BLUP estimation of breeding values, while more technical details (such as maximal avoidance of inbreeding) are deferred until Volume 3 (also see Henderson 1984; Simm 1998; Bernardo 2010; and Mrode 2014).

THE MULTIVARIATE BREEDER'S EQUATION

Expressing the heritability in terms of additive-genetic and phenotypic variances, the breeder's equation can be written as

$$R = \sigma_A^2 \sigma_z^{-2} S \quad (13.23a)$$

While this decomposition seems rather trivial, it suggests (as we formally show in Volume 3) that its multivariate version (under appropriate linearity assumptions) is given by

$$\mathbf{R} = \mathbf{G}\mathbf{P}^{-1}\mathbf{S} \quad (13.23b)$$

where \mathbf{R} and \mathbf{S} are the vectors of responses and selection differentials for each character, and \mathbf{G} and \mathbf{P} are the additive-genetic and phenotypic covariance matrices (LW Chapter 21), with

$$P_{ij} = \sigma(z_i, z_j) \quad \text{and} \quad G_{ij} = \sigma(A_i, A_j) \quad (13.23c)$$

Here, we briefly consider a few features of Equation 13.23b; we examine its full range of consequences and applications at length in Volume 3. As an aside, note that Equation 13.23b breaks the standard convention that vectors (here \mathbf{R} and \mathbf{S}) are usually written as lower case bold letters. This is to conform with the standard notation for these two vectors in the literature.

Response With Two Traits

One expects that selection is always acting on more than a single trait, as even with strong artificial selection on a single character, natural selection is likely operating on other traits as well. What risks do we run by ignoring this expectation and treating selection as a univariate problem? While this is examined much more fully in Volume 3, we can gain significant insight by considering the simple case of two traits, both of which are potentially under selection. Equation 13.23b gives the expected vector of responses as

$$\mathbf{R} = \begin{pmatrix} R_1 \\ R_2 \end{pmatrix} = \mathbf{GP}^{-1}\mathbf{S} = \begin{pmatrix} G_{11} & G_{12} \\ G_{12} & G_{22} \end{pmatrix} \begin{pmatrix} P_{11} & P_{12} \\ P_{12} & P_{22} \end{pmatrix}^{-1} \begin{pmatrix} S_1 \\ S_2 \end{pmatrix} \quad (13.24a)$$

Using LW Equation 8.11 to compute the inverse of \mathbf{P} , and, recalling for a covariance that $P_{12} = \rho_z \sqrt{P_{11}P_{22}}$, where ρ_z is the phenotypic correlation between the two traits, yields

$$\begin{aligned} \mathbf{P}^{-1}\mathbf{S} &= \frac{1}{P_{11}P_{22} - P_{12}^2} \begin{pmatrix} P_{22} & -P_{12} \\ -P_{12} & P_{11} \end{pmatrix} \begin{pmatrix} S_1 \\ S_2 \end{pmatrix} \\ &= \frac{1}{P_{11}P_{22}(1 - \rho_z^2)} \begin{pmatrix} S_1P_{22} - S_2P_{12} \\ -S_1P_{12} + S_2P_{11} \end{pmatrix} \end{aligned} \quad (13.24b)$$

Substituting into Equation 13.24a and recalling that $h_i^2 = G_{ii}/P_{ii}$, the response in trait one becomes

$$\begin{aligned} R_1 &= \frac{1}{P_{11}P_{22}(1 - \rho_z^2)} (G_{11} \quad G_{12}) \begin{pmatrix} S_1P_{22} - S_2P_{12} \\ -S_1P_{12} + S_2P_{11} \end{pmatrix} \\ &= \frac{G_{11}(S_1P_{22} - S_2P_{12}) + G_{12}(-S_1P_{12} + S_2P_{11})}{P_{11}P_{22}(1 - \rho_z^2)} \\ &= \frac{h_1^2}{(1 - \rho_z^2)} \left(S_1 - S_2 \frac{P_{12}}{P_{22}} \right) + \frac{G_{12}(-S_1P_{12} + S_2P_{11})}{P_{11}P_{22}(1 - \rho_z^2)} \end{aligned} \quad (13.24c)$$

with an analogous expression for R_2 . The breeder's equation is recovered only when trait one is phenotypically ($P_{12} = \rho_z = 0$) and genetically ($G_{12} = 0$) uncorrelated with trait two. As we now demonstrate, this complicated expression masks the rather different roles played by phenotypic and genetic correlations, impacting (respectively) the within- and between-generation changes. Volume 3 examines these points in some detail.

Accounting for Phenotypic Correlations: The Selection Gradient

Recall from Equation 13.8b that the univariate **directional selection gradient**, $\beta = S/\sigma_z^2$, is the slope of the linear regression of relative fitness, w , as a function of the phenotypic value, z , of the trait (Equation 13.8a). The multivariate extension is given by

$$\boldsymbol{\beta} = \mathbf{P}^{-1}\mathbf{S} \quad (13.25a)$$

where the vector $\boldsymbol{\beta} = (\beta_1, \dots, \beta_n)^T$ contains the coefficients for the multiple linear regression

$$w = a + \sum_i \beta_i z_i + e = a + \boldsymbol{\beta}^T \mathbf{z} + e \quad (13.25b)$$

of relative fitness, w , on the vector, \mathbf{z} , of trait values (LW Equation 8.10c). The interpretation of β_i is that it represents the change in relative fitness given a one unit change in trait i while holding all other trait values constant. In other words, β_i measures the amount of direct selection on trait i , removing any indirect effects from selection on phenotypically correlated traits *included in the analysis*, i.e., all traits in the vector \mathbf{z} (Chapter 30). Because $\boldsymbol{\beta} = \mathbf{P}^{-1}\mathbf{S}$, then $\mathbf{S} = \mathbf{P}\boldsymbol{\beta}$, resulting in an observed selection differential of

$$S_i = P_{ii}\beta_i + \sum_{j \neq i} P_{ij}\beta_j \quad (13.25c)$$

The *within-generation* change, S_i , in the mean of trait i following selection thus consists of an effect from direct selection on that trait ($P_{ii}\beta_i$) plus the effects of selection on all other phenotypically correlated traits ($P_{ij}\beta_j \neq 0$). Hence, the sign of S_i tells us nothing about the sign of β_i (the amount of direct selection on that trait), as **correlated selection** ($P_{ij}\beta_j$ terms) can easily overpower the direct effect. The selection gradient, $\boldsymbol{\beta}$, presents the correct picture of which traits are under selection, *provided* there are no additional traits under direct selection that are phenotypically correlated with our focal vector, \mathbf{z} , of traits (Chapter 30).

Accounting for Genetic Correlations: The Lande Equation

To see the effects of genetic correlations, substituting $\mathbf{P}^{-1}\mathbf{S} = \boldsymbol{\beta}$ into Equation 13.23b gives the **Lande equation** (Lande 1979a),

$$\mathbf{R} = \mathbf{G}\boldsymbol{\beta} \quad (13.26a)$$

which is the multivariate version of Equation 13.8c, $R = \sigma_A^2\boldsymbol{\beta}$. Considering two traits, using the Lande equation

$$\mathbf{R} = \begin{pmatrix} R_1 \\ R_2 \end{pmatrix} = \mathbf{G}\boldsymbol{\beta} = \begin{pmatrix} G_{11} & G_{12} \\ G_{12} & G_{22} \end{pmatrix} \begin{pmatrix} \beta_1 \\ \beta_2 \end{pmatrix} \quad (13.26b)$$

yields greatly simplified expressions (relative to Equation 13.24c) for the responses

$$\begin{aligned} R_1 &= G_{11}\beta_1 + G_{12}\beta_2 \\ R_2 &= G_{12}\beta_1 + G_{22}\beta_2 \end{aligned} \quad (13.26c)$$

The role of genetic correlations (G_{12}) is now obvious, in that direct selection on trait two ($\beta_2 \neq 0$) influences the response (between-generation change) in trait one *only* when the two traits have a nonzero genetic correlation ($G_{12} \neq 0$). The contribution, $G_{ii}\beta_i$, from direct selection is called the **direct response**, and the contribution to response on trait i from direct selection on other *genetically* correlated traits ($G_{ij}\beta_j \neq 0$) is called the **correlated response**. If two traits are genetically uncorrelated, selection on one has no impact on the *response* of the other, *even if they are phenotypically correlated*. More generally, with n potentially correlated traits

$$R_i = G_{ii}\beta_i + \sum_{j \neq i} G_{ij}\beta_j \quad (13.26d)$$

Comparison with Equation 13.25c shows that P_{ij} for the within-generation changes (S_i) are replaced by G_{ij} for the between-generation changes (R_i).

The Lande equation shows that when the multivariate breeder's equation holds, we can distinguish between **phenotypic selection**, which is the change in a phenotypic distribution *within* a generation (measured by \mathbf{S} , with the nature of selection, i.e., the direct effects, summarized by $\boldsymbol{\beta}$), and the **evolutionary response to selection**, which is the transmission of these within-generation changes to the next generation (given by \mathbf{R}). Lande and Arnold (1983) and Arnold and Wade (1984a, 1984b), following Fisher (1930, 1958) and Haldane (1954), have stressed the utility of this approach. Attempts to measure selection by comparing phenotypic distributions across generations are confounded by inheritance, as \mathbf{R} depends on $\boldsymbol{\beta}$ through \mathbf{G} . Chapters 29 and 30 examine in detail methods for estimating

the nature of phenotypic selection in natural populations. When the breeder's equation fails, this separation of selection from inheritance may no longer be possible, leading to the recent use of Robertson's secondary theorem, $\mathbf{R} = \sigma(w, \mathbf{A}_z)$, for examining response in natural populations (Chapter 20).

Selection Gradients and Mean Population Fitness

Under appropriate conditions, the selection gradient, β , demonstrates how a within-generation change in the vector of trait means maps into a change in the mean fitness of a population. If $W(z)$ denotes the expected fitness of an individual with a character value of z , then when phenotypes are normally distributed and fitness is frequency-independent (individual fitnesses are not a function of the means of the characters), the directional selection gradient satisfies $\beta = \partial \ln \bar{W} / \partial \mu$ (Lande 1976; Example A6.3 gives the full multivariate derivation). Hence we can express the breeder's equation as

$$R = \sigma_A^2 \left(\frac{\partial \ln \bar{W}}{\partial \mu} \right) \quad (13.27a)$$

The multivariate version of this partial derivative is the **gradient of mean fitness** with respect to the vector of character means, which is the vector of partials of the log of mean fitness with respect to each trait mean under consideration

$$\beta = \frac{\partial \ln \bar{W}}{\partial \mu} \quad (13.27b)$$

with $\beta_i = \partial \ln \bar{W} / \partial \mu_i$ (the change in log mean fitness from a change in the mean of trait i). The resulting gradient version of the Lande equation becomes

$$\mathbf{R} = \mathbf{G} \frac{\partial \ln \bar{W}}{\partial \mu} \quad (13.27c)$$

The vector β represents the direction for the joint change in the means that maximizes the local increase in mean fitness. In contrast, the *actual* response involves the product (or **projection**) of this vector with the genetic covariance matrix \mathbf{G} . The resulting response vector is generally not parallel to β , as the genetic covariance structure causes the character means to change in a direction that does not necessarily result in the optimal change in population fitness. We examine the implications of genetic constraints imposed by the structure of \mathbf{G} in detail in Volume 3.

We can connect the somewhat abstract notion of variance in fitness with a measurable quantity, the amount of selection, β , on a vector, \mathbf{z} , of traits, as follows. Walsh and Blows (2009) showed that the additive variance in relative fitness w accounted for by selection on \mathbf{z} is

$$\sigma_A(\mathbf{z}^T, w) \mathbf{G}^{-1} \sigma_A(\mathbf{z}, w) \quad (13.28a)$$

where the notation $\sigma_A(x, y)$ denotes the covariance between the breeding values of x and y . Recalling Robertson's secondary theorem (1968 version; Equation 6.24a), $\sigma_A(\mathbf{z}, w) = \mathbf{R} = \mathbf{G}\beta$ (assuming the conditions for the multivariate breeder's equation hold), yielding

$$(\mathbf{G}\beta)^T \mathbf{G}^{-1} (\mathbf{G}\beta) = \beta^T \mathbf{G}\beta \quad (13.28b)$$

The additive variance in fitness that remains unaccounted for after the effects of \mathbf{z} are removed becomes

$$\sigma_A^2(w) - \beta^T \mathbf{G}\beta \quad (13.28c)$$

In theory, if one had an estimate of $\sigma_A^2(w)$ in hand (Chapter 20), the significance of a set, \mathbf{z} , of traits can be determined. If these account for most of the variation, there is little need to consider additional traits. If these account for only a small fraction, important traits are missing.

Table 13.1 Alternate versions and extensions of the basic breeder's equation. Refer to the specific equation number for discussion and explanation of the symbols.

Version	Expression	Equation Number
Basic breeder's equation	$R = h^2 S$	13.1
Sex-specific response (sex s)	$R_s = b_{s,fa} S_{fa} + b_{s,mo} S_{mo}$	13.4
Selection intensity	$R = h^2 \bar{t} \sigma_z = \bar{t} h \sigma_A = \sigma_A^2 \bar{t} / \sigma_z$	13.6b
Response (in trait y , selection using x)	$R_y = \frac{\sigma(x,y)}{\sigma_x^2} S_x = \frac{\sigma(x,y)}{\sigma_x} \bar{t}_x$	13.10b
Accuracy (in trait y , selection using x)	$R_y = \bar{t}_x \sigma_y \rho(x,y)$	13.11a
Accuracy (breeding values)	$R = \bar{t}_x \rho(x, A) \sigma_A$	13.11c
Rate of response (per year)	$r_{year} = \left(\frac{\bar{t}_s + \bar{t}_d}{L_s + L_d} \right) h \sigma_A$	13.20
Rate of response using accuracy	$r_{year} = \left(\frac{\bar{t}_s + \bar{t}_d}{L_s + L_d} \right) \rho(A, x) \sigma_A$	13.21
Variance-standardized response	$R/\sigma_z = h^2 \bar{t}$	13.22a
Mean-standardized response	$R/\mu_z = \bar{t} h CV_A$	13.22b
Robertson's secondary theorem		
1966 version	$R = \sigma(w, A_z)$	13.7b
1968 version	$R = \sigma(A_w, A_z)$	6.24a
Univariate Lande equation	$R = \sigma_A^2 \beta$	13.8c
	$R = \sigma_A^2 \frac{\partial \ln \bar{W}}{\partial \mu}$	13.27a
Multivariate breeder's equation	$\mathbf{R} = \mathbf{GP}^{-1} \mathbf{S}$	13.23b
Multivariate Lande equation	$\mathbf{R} = \mathbf{G}\boldsymbol{\beta}$	13.26a
	$\mathbf{R} = \mathbf{G} \frac{\partial \ln \bar{W}}{\partial \boldsymbol{\mu}}$	13.27c

Finally, we can use the multivariate breeder's equation to make a connection with the classical interpretation of Fisher's fundamental theorem (Chapter 6). If the fitness determined by the vector of traits, \mathbf{z} , can be expressed as a linear regression (Equation 13.25b), then the expected change in fitness from selection response on these traits is

$$\Delta \bar{w} = \boldsymbol{\beta}^T \Delta \mathbf{z} = \boldsymbol{\beta}^T \mathbf{R} = \boldsymbol{\beta}^T \mathbf{G}\boldsymbol{\beta} \quad (13.29)$$

From Equation 13.28b, this is just the additive variance in fitness associated with these traits. Thus, we recover Fisher's theorem that the change in mean fitness equals the additive variance in relative fitness (Equation 6.17c).

LIMITATIONS OF THE BREEDER'S EQUATION

As we have seen, the basic breeder's equation has many alternative expressions and extensions (summarized in Table 13.1). All are based on Equation 13.1, which assumes a linear midparent-offspring regression with slope h^2 . This single-generation prediction is a good approximation over multiple generations provided that selection does not result in a significant change in the base-population heritability, a region we call short-term response. Chapter 16 shows that even a single generation of selection will change h^2 through the generation of linkage disequilibrium, but because this is straightforward to correct for when

Table 13.2 Summary of various factors complicating the prediction of short-term selection response in the phenotypic mean, even assuming all regressions are linear and considering just a single generation of selection from an unselected base population. Short-term response specifically refers to conditions where the effects of any allele-frequency change on the additive variance are negligible. Models of long-term response (Chapters 25–28) relax this restriction.

Major gene with dominance (Chapter 6; LW Chapter 17)	Can generate a nonlinear parent-offspring regression.
Epistasis (Chapter 15)	The component of response due to epistasis is transient. Parent-offspring covariance overestimates permanent response.
Correlated environmental effects (Chapter 15)	The component of response due to correlated environmental effects is transient.
Maternal effects (Chapters 15, 22)	The potential for complicated lags in response—the mean changes unpredictably after selection is relaxed. Possibility of reversed response.
Gametic-phase disequilibrium (Chapter 16)	Changes the additive genetic variance. Directional selection generates negative gametic-phase disequilibrium, reducing h^2 and slowing response.
Assortative mating (Chapter 16)	Generates gametic-phase disequilibrium, which either enhances (positive correlation between mates) or retards (negative correlation between mates) response.
Environmental change (Chapters 18 - 20)	A significant change in the environment can obscure the true amount of genetic change.
Drift (Chapters 18, 19)	Generates variance in the short-term response.
Environmental correlations (Chapter 20)	Environmental factors can influence both the trait and fitness, confounding both the nature of selection and the true amount of genetic change.
Associative effects (Chapter 22)	Trait influenced by both direct and social components from group members. A decline in the mean social value can swamp an increase in mean direct value. Possibility of reversed response.
Inbreeding (Chapter 23)	Response depends on additional variance components that are difficult to estimate (σ_{DI}^2 , σ_{ADI} , etc). Response has permanent and transient components.
Age-structure (Volume 3)	Several generations are required to propagate genetic change uniformly through the population.
Selection on correlated characters (Volume 3)	Response completely unpredictable unless selection on correlated characters accounted for. Possibility of reversed response.
G × E interactions (Volume 3)	Possibility of nonlinear parent-offspring regressions. Often treated as a correlated characters problem, with traits measured in different environments treated as correlated traits. Possibility of reversed response.

allele-frequency change is infinitesimal, we treat this as a special case of short-term response (details in Chapter 16). The more serious problem is that eventually allele-frequency change significantly alters the genetic variance (long-term response), and these variances changes cannot be predicted without extensive (and essentially unavailable) knowledge about the distribution of allelic effects and their frequencies (Chapters 25 and 26).

However, even over the short-term response time frame, there are a number of complications that compromise the basic breeder's equation (Table 13.2). One particularly impor-

tant (and usually unstated) assumption is that we start from an *unselected* base population. If the base population itself has been under selection, decay of transient response components from previous selection compromises the predicted single-generation response (Chapter 15). In the Price equation setting (Equation 6.12), this occurs because the mean of the population changes in the *absence* of selection, as the population regains Hardy-Weinberg proportions and linkage equilibrium following a perturbation from past selection.

Another troublesome feature of the breeder's equation is the assumption that all of the selection on the character of interest is accounted for. This is especially problematic as selection on any character correlated with the one of interest can introduce significant bias to the expected selection response. This problem is examined in Chapter 20, but generally there is no easy solution, or even any indication of a problem before an experiment or field study begins. Thus, even in the best of situations (linearity and no selection-induced changes in allele and gamete frequencies), there are still pitfalls in predicting even a single generation of response from the slope of the parent-offspring regression. The situation gets worse if the parent-offspring regression is nonlinear, as the single-generation change in the mean can then depend on higher-order moments of the genotypic distribution, and hence is not predictable from simple variance components. See Equations 5.23c and 5.27b for population-genetic expressions, Equations 6.12, 6.39, 6.40 for expressions based on the Price equation, and Chapter 24 for a detailed discussion.

Table 13.2 summarizes some of these factors compromising the breeder's equation, giving the chapters in which these complications are examined in detail. Provided one can assume linearity of the regressions of relatives, we can account for many of these concerns, as when the regression of an individual on all of its direct relatives selected in previous generations (back to the original unselected base population) remains linear, the selection response is entirely determined by the covariances between a current individual and these previous relatives (Chapter 15).

As mentioned at the start of the chapter, even if we have corrected for all of the potential complications listed in Table 13.2, the breeder's equation (using the base population h^2) is expected to become an increasingly poor predictor as selection proceeds. If there are segregating alleles of large effect, even a single generation of selection can significantly change the underlying variance components, which in turn changes the regression coefficients. Further, selection can introduce nonlinearities into an initially linear regression by perturbing the starting distribution of breeding values away from normality, although these departures are usually small (Chapter 24). In the absence of major genes, allele-frequency changes over the first few generations of selection are expected to be rather small, but *genotype* frequencies can change dramatically due to selection generating gametic-phase disequilibrium (Chapters 16 and 24). Directional selection generates negative disequilibrium, decreasing heritabilities and hence reducing the selection response, and this reduction can be significant if heritability is high. Likewise, selection on the variance itself (through disruptive or stabilizing selection) also creates disequilibrium effects on the expressed genetic variance. Chapter 16 examines the effect of such short-term changes in disequilibrium on the additive genetic variation. An additional complication occurs when there is genetic variance for the amount of environmental variability that a genotype displays, and this is discussed in Chapter 17. As selection continues over several generations, even if all loci have very small effects, allele frequencies themselves start to appreciably change (Chapters 25 and 26). Drift and mutation also become increasingly important, and these complications are examined in Chapters 26–28.

14

Short-term Changes in the Mean:

2. Truncation and Threshold Selection

Far better an approximate answer to the right question, which is often vague, than an exact answer to the wrong question, which can always be made precise. Tukey (1962)

This brief chapter first considers the general theory of truncation selection on the mean and then examines a number of more specialized (but related) topics, which may be skipped by the casual reader. Truncation selection (Figure 14.1), which occurs when all individuals with trait values on one side of a threshold are chosen, is by far the commonest form of artificial selection. One key result to be presented is that, for a normally distributed trait, the expected selection intensity, \bar{t} , is fully determined by the fraction, p , saved, provided that the chosen number of adults is large. This allows a breeder or experimentalist to predict the expected selection response, given the choice of p and knowledge of h^2 . When small numbers of adults are chosen to form the next generation, one should apply a small-sample correction, otherwise \bar{t} will be overestimated. However, as will be shown, this correction is generally relatively minor unless only a few individuals form the next generation.

We then turn our attention to the selection response for discrete traits, which (as we will show) has close connections with certain aspects of truncation-selection theory. We start with a binary (present or absent) trait, such that, when some continuous underlying **liability value** exceeds a particular (usually unknown) threshold, the trait takes on one value (or is displayed), while it takes on another (or is absent) when its liability is below the threshold (LW Chapter 25). The key assumption is that the liability value is a normally distributed trait, with the breeder's equation holding on this scale. We also examine binary-trait response in a logistic regression framework (estimating the probability that an individual exhibits the trait, given some underlying liability score).

We conclude with a few brief comments on selection response when a trait is better modeled as Poisson, rather than normally, distributed, as can occur with certain types of count data (such as number of offspring). Again, the key idea is that there is some underlying (and unobserved, or **latent**) liability scale that maps into the discrete character space.

TRUNCATION SELECTION

In addition to being the commonest form of artificial selection, truncation selection is also the most efficient, as it provides the largest selection intensity of any scheme culling the same fraction of individuals (Kimura and Crow 1978; Crow and Kimura 1979). Truncation selection is described by either the fraction, p , of the population saved or the threshold phenotypic value, T , below (or above) which individuals are **culled**. The investigator usually sets one of these (usually p) in advance of the actual selection. Hence, while S is trivially computed *after* the parents are chosen, we would like to *predict* the expected selection differential, given either p or T . Specifically, given p or T , what is the expected mean of the selected parents? In our discussion of this topic, we first assume that a large number of individuals is saved, before turning to complications introduced by finite sample size.

Selection Intensities and Differentials Under Truncation Selection

Given a threshold cutoff, T , the expected mean of the selected adults is given by the conditional mean, $E[z | z \geq T]$. Generally, it is assumed that phenotypes are normally distributed,

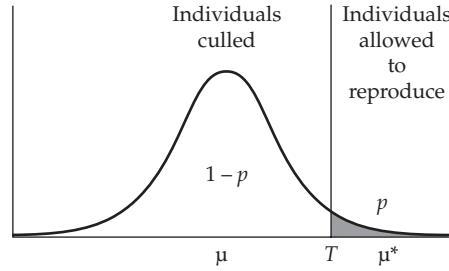

Figure 14.1 Under truncation selection, the uppermost (or lowermost) fraction, p , of a population is selected to reproduce. Alternatively, one could set a threshold level, T , in advance. To predict the selection response, given either p or T , we need to know the expected mean of the selected tail (μ^*), from which we can compute either $S = \mu^* - \mu$ or $\bar{i} = S/\sigma$, and then apply the breeder's equation.

and we use this assumption throughout (unless stated otherwise). With an initial mean of μ and variance of σ^2 , and $p = \Pr(z \geq T)$ being the fraction saved, this conditional mean is given by LW Equation 2.14, which yields the expected selection differential as

$$S = \varphi\left(\frac{T - \mu}{\sigma}\right) \frac{\sigma}{p} \quad (14.1)$$

where $\varphi(x) = (2\pi)^{-1/2} \exp(-x^2/2)$ is the unit normal density function evaluated at x .

Usually the fraction saved p (rather than T) is preset by the investigator. Given p , to apply Equation 14.1, we must first find the threshold value T_p satisfying $\Pr(z \geq T_p) = p$. Notice that T in Equation 14.1 enters only as $(T - \mu)/\sigma$, which transforms T_p to a scale with a mean of zero and unit variance. Hence,

$$\Pr(z \geq T_p) = \Pr\left(\frac{z - \mu}{\sigma} > \frac{T_p - \mu}{\sigma}\right) = \Pr\left(U > \frac{T_p - \mu}{\sigma}\right) = p$$

where $U \sim N(0, 1)$ denotes a unit normal random variable. Define $x_{[p]}$, the **probit transformation** of p (LW Chapter 11), as satisfying

$$\Pr(U \leq x_{[p]}) = p \quad (14.2a)$$

so that

$$\Pr(U > x_{[1-p]}) = p \quad (14.2b)$$

It immediately follows that $x_{[1-p]} = (T_p - \mu)/\sigma$, and Equation 14.1 yields the expected selection intensity as

$$\bar{i} = \frac{S}{\sigma} = \frac{\varphi(x_{[1-p]})}{p} \quad (14.3a)$$

Note that \bar{i} is *entirely a function of p* provided z is normal. Equation 14.3a can be approximated by

$$\bar{i} \simeq 0.8 + 0.41 \ln\left(\frac{1}{p} - 1\right) \quad (14.3b)$$

a result due to Smith (1969). Simmonds (1977) found that this approximation is generally quite good for $0.004 \leq p \leq 0.75$ and offered alternative approximations for p values outside this range, as did Saxton (1988). Montaldo (1997) gives an approximation for the standardized truncation value $z = (T - \mu)/\sigma$ in terms of \bar{i} . Finally, when one selects for the *lowest* fraction p of the population, Equation 14.3a still holds, provided we take its negative value.

Example 14.1. Consider selection on a normally distributed trait for which the upper 5% of the population is saved ($p = 0.05$). Here $x_{[1-0.05]} = x_{[0.95]}$ is obtained by the R command `qnorm(0.95)`, which returns 1.645, as $\Pr[U > 1.645] = 0.05$. The R command `dnorm(x)` returns the value of $\varphi(x)$, with `dnorm(1.645)` returning a value of 0.103. Hence,

$$\bar{\tau} = \frac{\varphi(1.645)}{0.05} = \frac{0.103}{0.05} \simeq 2.06$$

More compactly, the R command for any value of p is `dnorm(qnorm(1-p))/p`. In contrast, Smith's approximation calculates the selection intensity as

$$\bar{\tau} \simeq 0.8 + 0.41 \ln\left(\frac{1}{0.05} - 1\right) \simeq 2.01$$

Finally, if we selected for the lowermost 5%, $\bar{\tau} = -2.06$.

Correcting the Selection Intensity for Finite Sample Sizes

If the number of individuals saved is small, Equation 14.1 overestimates the selection differential because of sampling effects (Nordskog and Wyatt 1952; Burrows 1972). To see this, suppose 100 observations are put randomly into ten groups of size 10 and the largest value is selected from each group. These values will be, on average, not as extreme as when selecting the best 10 from the entire 100, as the best observation within a random group of ten can be the 11th largest (or even smaller) for the entire group.

To more formally treat the effects of finite sample size, assume M adults are sampled at random from the population, with the largest N of these being used to form the next generation, yielding $p = N/M$. The expected selection coefficient is computed from the distribution of **order statistics**. We rank the M observed phenotypes as $z_{1,M} \geq z_{2,M} \dots \geq z_{M,M}$, where $z_{k,M}$ denotes the k th-order statistic (the k th largest value) when M observations are sampled. The expected selection intensity is given by the expected mean of the N selected parents, which is the average of the first N order statistics

$$E [\bar{\tau}_{(N,M)}] = \frac{1}{\sigma} \left(\frac{1}{N} \sum_{k=1}^N E [z_{k,M}] - \mu \right) = \frac{1}{N} \sum_{k=1}^N E [z'_{k,M}]$$

where $z'_{k,M} = (z_{k,M} - \mu)/\sigma$ are the **standardized order statistics**. While the properties of order statistics have been worked out for many special cases (Harter 1961; Sarhan and Greenberg 1962; Harter 1970a, 1970b; Kendall and Stuart 1977; David 1981), values for any distribution are easily be obtained via simulation. For example, Figure 14.2 plots 10,000 random draws of the largest order statistic in a sample of ten unit normals. Note that the distribution of realized differentials is asymmetric about its mean, implying that the variance alone is not sufficient for computing confidence intervals. Figure 14.3 plots the expected selection intensity for small values of N (assuming normality), showing that Equation 14.3a overestimates the intensity, although the difference will be small unless N is small.

Burrows (1972) developed a finite-sample approximation for the expected selection intensity for any reasonably well-behaved continuous distribution. Using the standardized variable $y = (z - \mu)/\sigma$ simplifies matters considerably. Letting $\phi(y)$ be the probability density

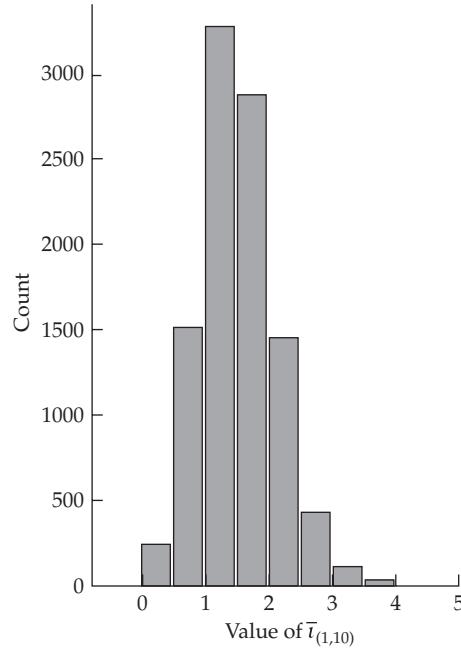

Figure 14.2 The distribution of 10,000 random draws of $\bar{t}_{(1,10)}$, the largest order statistic in a sample of ten unit normal random variables. The mean value is 1.54, as opposed to the expected value of $\bar{t} = 1.75$ for $p = 0.1$ in an infinite population (Equation 14.3a). Notice that there is a considerable spread about the mean, and that the distribution is not symmetric, but rather is skewed toward higher values.

function of the phenotypic distribution, and y_p be the truncation point (i.e., $\Pr(y \geq y_p) = p$), Burrows's approximation is

$$E[\bar{t}_{(N,M)}] \simeq \mu_{y_p} - \frac{(M-N)p}{2N(M+1)\phi(y_p)} \quad (14.4a)$$

where

$$\mu_{y_p} = E[y | y \geq y_p] = \frac{1}{p} \int_{y_p}^{\infty} x \varphi(x) dx$$

is the truncated mean (which can be obtained by numerical integration), and $\phi(y_p)$ is the height of the density function at the truncation point. Because the second term of Equation 14.4a is positive, if M is finite, the expected truncated mean overestimates the expected standardized selection differential. For a unit normal distribution, $\mu_{y_p} = \varphi(y_p)/p = \bar{t}$, yielding

$$E[\bar{t}_{(N,M)}] \simeq \bar{t} - \left[\frac{M-N}{2N(M+1)} \right] \frac{1}{\bar{t}} = \bar{t} - \left[\frac{1-p}{2p(M+1)} \right] \frac{1}{\bar{t}} \quad (14.4b)$$

where \bar{t} is given by Equation 14.3a, using $p = N/M$. Lindgren and Nilsson (1985) found this approximation to be quite accurate for $N \geq 5$. Bulmer (1980) suggested an alternative approximation under normality, using Equation 14.3a with p replaced by

$$\tilde{p} = \frac{N+1/2}{M+N/(2M)} \quad (14.4c)$$

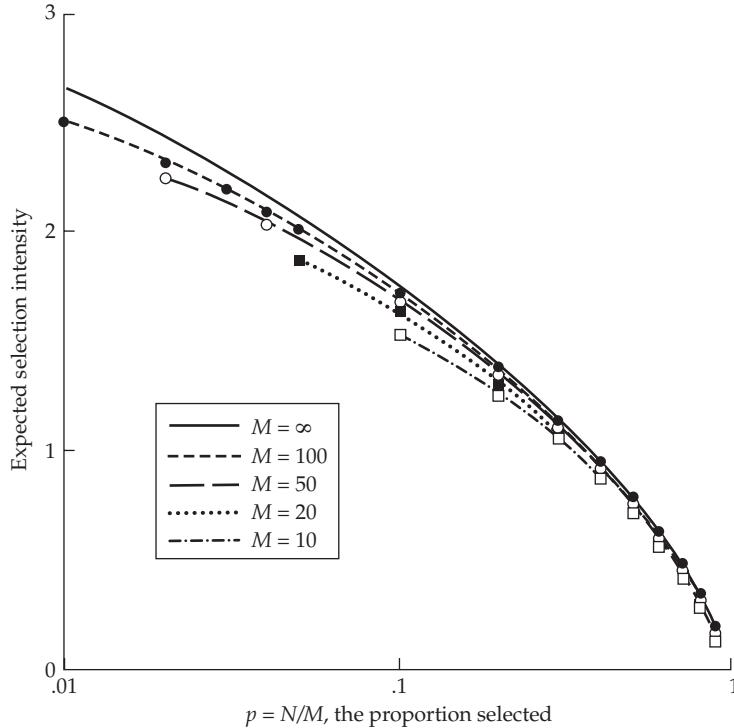

Figure 14.3 The expected selection intensity, $E[\bar{i}_{(N,M)}]$, under truncation selection on a normally distributed phenotype, as a function of the total number of individuals measured, M , and the fraction of these saved, $p = N/M$. The curve $M = \infty$ is given by Equation 14.3a, while the curves for $M = 10, 20, 50$, and 100 were obtained from the average of the expected values of the $N = pM$ largest unit normal order statistics (Harter 1961). Note that Equation 14.3a is generally a good approximation, even when N is fairly small.

Burrows (1975) provided expressions for the variance of $\bar{i}_{(N,M)}$.

A final correction for finite population size was noted by Rawlings (1976) and Hill (1976, 1977b). If families are sampled, such that n individuals are chosen per family, then the selection intensity is further reduced because there are positive correlations between family members. This effectively lowers the sample size below n —in the extreme case where all individuals are clones with little environmental variance, all have essentially the same value, and hence $n \sim 1$. If a total of M individuals is sampled, with n individuals per family, then Burrows's correction (Equation 14.4b) is modified to become

$$E [\bar{i}_{(N,M)}] \approx \bar{i} - \left[\frac{1-p}{2p(M+1)(1-\tau+\tau/n)} \right] \frac{1}{\bar{i}} \quad (14.5)$$

where τ is the intraclass correlation of family members. This important result for certain types of family selection is revisited in more detail in Chapter 21.

Example 14.2. Consider the expected selection intensity on males when the upper 5% are used to form the next generation and phenotypes are normally distributed. If the sampled number is large, $\bar{i} \approx 2.06$ (Example 14.1). Suppose, however, that just 20 males are scored (phenotyped), with only the largest allowed to reproduce, in order to yield $p = 0.05$. The expected value for this individual is the expected value of the largest order statistic for a sample of size 20. For the unit

normal, this is $\simeq 1.87$ (Harter 1961), and hence $E[\bar{t}_{(1,20)}] \simeq 1.87$. There is considerable spread about this expected value, as the standard deviation of this order statistic is 0.525 (Sarhan and Greenberg 1962). How well do the approximations of $E[\bar{t}_{(1,20)}]$ perform? Burrows's approximation (Equation 14.4b) yields

$$E[\bar{t}_{(1,20)}] \simeq 2.06 - \frac{(20-1)}{2(20+1)2.06} = 2.06 - 0.22 = 1.84$$

Bulmer's approximation (Equation 14.4c) uses

$$\tilde{p} = \frac{1 + 1/2}{20 + 1/40} \simeq 0.075$$

which returns $x_{[1-0.075]} \simeq 1.44$. Because $\varphi(1.44) = 0.1415$, $E[\bar{t}_{(1,20)}] \simeq 0.1415/0.075 \simeq 1.89$.

RESPONSE IN DISCRETE TRAITS: BINARY CHARACTERS

The Threshold/Liability Model

One application of truncation-selection theory is in the response to selection of **binary traits**, which are characterized simply by presence or absence (such as normal or diseased). The basic trait model to this point assumed a continuous character, which initially seems at odds with a binary trait. However, as discussed in LW Chapters 11 and 25, discrete characters can often be modeled by mapping an underlying (unobserved, or **latent**) continuous character, the **liability**, z , onto the observed discrete character states, $y = 0$ or $y = 1$ (Figure 14.4). The assumption is that the breeder's equation holds on the liability scale, and our goal is to predict how changes on this scale map onto changes in the frequency of a binary trait. The simplest assumption is a **threshold model**, wherein the character is present if liability exceeds some threshold value T ($z \geq T$), and otherwise is absent ($z < T$). Roff (1996) reviewed a number of examples of such threshold-determined morphological traits in animals. Our analysis is restricted to a single threshold, but extension to multiple thresholds is straightforward (Lande 1978; Korsgaard et al. 2002).

To predict the selection response, let μ_t be the mean liability and q_t be the frequency of individuals displaying the character in generation t , i.e., $q_t = \Pr(y_t = 1)$. If liability is well enough behaved to satisfy the assumptions of the breeder's equation, then $\mu_{t+1} = \mu_t + h^2 S_t$. As shown in Figure 14.4, three tasks must be performed to predict the selection response: (i) estimate the mean liability, μ_t , from the observed frequency, q_t , of the trait; (ii) estimate S on the liability scale, given the change in the frequency of the binary trait following selection; and (iii) translate μ_{t+1} into q_{t+1} . We assume liability to be normally distributed on some appropriate scale, in which case we can also choose a scale that sets the threshold value at $T = 0$ and assigns z a variance of 1.0. Because $z - \mu_t$ is a unit normal, $\Pr(z \geq 0) = \Pr(z - \mu_t \geq -\mu_t) = \Pr(U \geq -\mu_t) = q_t$, and by analogy with Equation 14.2b, where $\Pr(U \geq x_{[1-p]}) = p$, we have

$$\mu_t = -x_{[1-q_t]} \tag{14.6}$$

where $x_{[p]}$ is the probit transformation of p (Equation 14.2a), as suggested by Wright (1934). For example, if 5% of the population displays the trait, $\Pr(U \leq 1.65) = 0.95$, implying $x_{[0.95]} = 1.65$, and yielding the mean on the underlying liability scale as $\mu = -x_{[0.95]} = -1.65$. When the mean liability is at this value, only 5% of the population has a value exceeding the threshold ($T = 0$), and hence displays the trait.

The response to selection, as measured by the new frequency, q_{t+1} , of the trait in the next generation, is given by

$$\begin{aligned} q_{t+1} &= \Pr(U \geq -\mu_{t+1}) \\ &= \Pr(U \geq -\mu_t - h^2 S_t) \\ &= \Pr(U \geq x_{[1-q_t]} - h^2 S_t) \end{aligned} \tag{14.7}$$

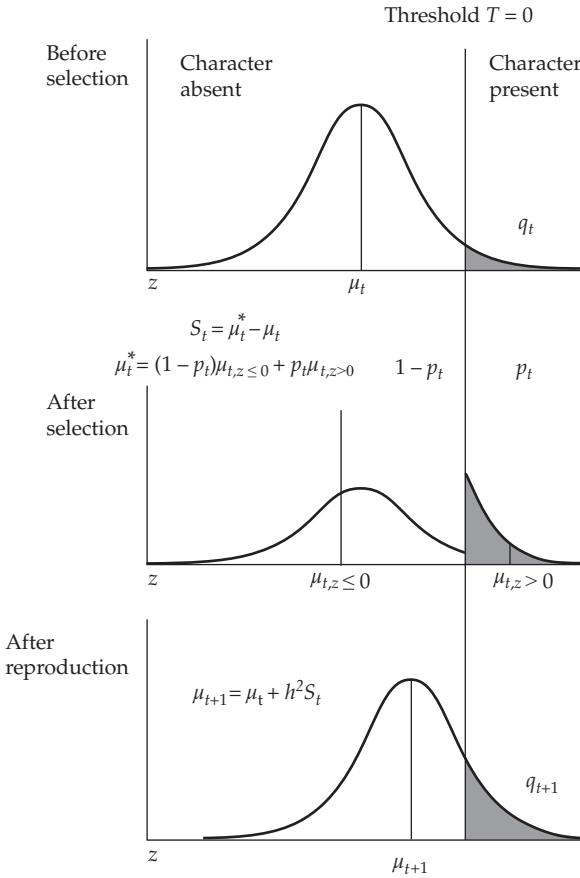

Figure 14.4 Selection response for a binary trait when the underlying liability, z , exceeds some threshold value, T . We assume that an appropriate scale can be found such that $z \sim N(\mu_t, 1)$, where μ_t is the current mean and $T = 0$. Under this scaling for T , a mean liability of zero ($\mu = 0$) implies that 50% of the population shows the trait, while $<50\%$ display the trait when $\mu < 0$ and $>50\%$ do when $\mu > 0$. Because z is normally distributed, the probit transform estimates μ_t from the frequency, q_t , of individuals displaying the character (Equation 14.6). We assume that the breeder's equation holds on the liability scale, so that $\mu_{t+1} = \mu_t + S_t h^2$, where $S_t = \mu_t^* - \mu_t$. Using properties of the unit normal allows translation of the mean liability following selection, μ_{t+1} , into the new frequency, q_{t+1} , of the trait (Equation 14.7). Note that after selection, where a fraction, p_t , of the selected parents display the trait, the mean liability value is now the weighted average of the means of two truncated normal distributions (Equation 14.8a).

It remains to obtain $S_t = \mu_t^* - \mu_t$, where μ_t^* is the mean liability value in the selected parents in generation t . While the selected population may consist entirely of adults displaying the trait, more individuals than this may be required to keep the population at a constant size, especially if q_t is small (i.e., the trait is rare). In this case, the selected adults consist of two groups of individuals: those displaying the trait (hence having $z \geq 0$) and those not displaying it ($z < 0$). Letting p_t be the fraction of selected adults displaying the character,

$$\mu_t^* = (1 - p_t) E[z|z < 0, \mu_t] + p_t E[z|z \geq 0, \mu_t] \quad (14.8a)$$

Applying LW Equation 2.14, and noting that the unit normal density function satisfies $\varphi(x) = \varphi(-x)$, yields

$$E[z|z \geq 0, \mu_t] = \mu_t + \frac{\varphi(\mu_t)}{q_t} \quad \text{and} \quad E[z|z < 0, \mu_t] = \mu_t - \frac{\varphi(\mu_t)}{1 - q_t} \quad (14.8b)$$

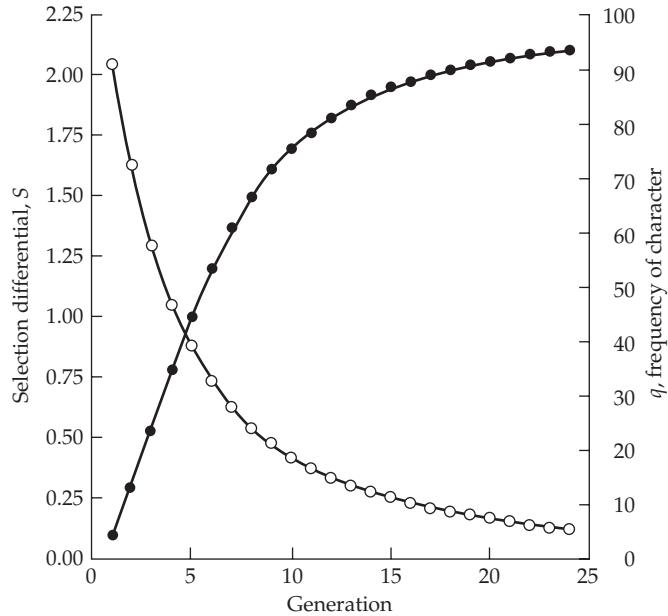

Figure 14.5 The response to selection on a threshold trait. Changes in q and S are plotted below, where solid circles denote q_t , and open circles denote S_t . See Example 14.3 for details.

where $\varphi(x)$ is the unit normal density function evaluated at x . Substituting into Equation 14.8a yields

$$S_t = \mu_t^* - \mu_t = \frac{\varphi(\mu_t)}{q_t} \frac{p_t - q_t}{1 - q_t} = \frac{\varphi(-x_{[1-q_t]})}{q_t} \frac{p_t - q_t}{1 - q_t} \quad (14.9)$$

As expected, if $p_t > q_t$, then $S_t > 0$. Maximal selection occurs if only individuals displaying the trait are saved ($p_t = 1$), in which case Equation 14.9 reduces to $S_t = \varphi(-x_{[1-q_t]})/q_t$.

Why did we not simply estimate μ_t^* using $x_{[1-q_t^*]}$, i.e., using the frequency, q^* , of the trait in the selected parents? The reason is that the distribution of z values in selected parents is a weighted average of two truncated normal density functions (Equation 14.8a), and this distribution is *not* normal (see Figure 14.4). However, we assume that normality is restored in the liability distribution at the start of the next generation due to segregation plus the addition of the environmental value. We examine the validity of this assumption in Chapter 24. Finally, a diligent reader might be concerned that this lack of normality violates the breeder's equation, and hence our assumption that $\mu_{t+1} = \mu_t + h^2 S$. However, this expression is a weighted form of truncation selection on a normally distributed trait, with a fraction $1 - p$ with $z < T$, and a fraction p with $z \geq T$, with the change in breeding value given by the weighted average of these two pools.

One important feature about selection on threshold traits is that the *response to selection is not necessarily symmetric*—a selected 5% increase in the trait may not yield the same response as a selected 5% decrease. The reason for this is that the mapping between phenotypes and their underlying liability is highly nonlinear. Even though the parent-offspring regression on the liability scale is assumed to be linear (and hence liability response is symmetric), the parent-offspring regression on the *phenotypic* level is not linear, resulting in an asymmetric response.

Example 14.3. Consider a threshold trait whose liability has a heritability of $h^2 = 0.25$ (Ex-

ample 14.4 and especially LW Chapter 25 discuss how h^2 can be estimated on this scale). What is the expected response to selection if the initial frequency of individuals displaying the character is 5% and selection is practiced by choosing only adults displaying the character? Only six generations are required to increase the frequency of the trait to 50% ($\mu = 0$). Note that even though all selected parents exhibit the trait, the selection differential rapidly declines in a nonlinear fashion (Figure 14.5).

The values plotted in Figure 14.5 were obtained as follows. As was calculated earlier, $q_0 = 0.05$, which implies $\mu_0 = -1.645$ (the mean liability is 1.65 standard deviations below the threshold). Only individuals displaying the trait are allowed to reproduce, yielding (from Equation 14.9) the resulting selection differential on the liability scale:

$$S_0 = \varphi(-1.645)/0.05 \simeq 0.106/0.05 \simeq 2.062$$

Applying the breeder's equation returns the new mean value of liability:

$$\mu_1 = \mu_0 + 0.25 \cdot S_0 = -1.645 + 0.25 \cdot 2.062 = -1.129$$

Equation 14.7 translates this new mean into the fraction of the population now above the threshold

$$q_1 = \Pr(U \geq -\mu_1) = \Pr(U \geq 1.129) = 0.129$$

Thus, after one generation of selection, the character frequency is expected to increase from 5% to 12.9%. Further iteration in this fashion recovers the rest of the values in Figure 14.5.

Example 14.4. The effectiveness of selection on wing morphs in females of the whitebacked planthopper (*Sogatella furcifera*) was examined by Matsumura (1996). While this hemipteran is a serious rice pest in Japan, it is unable to overwinter. Rather, each year it migrates from southern China to recolonize Japan. Females exhibit two wing morphs: *macropterous* females are fully winged, while *brachypterous* females have reduced wings and cannot fly. Further, increasing nymphal population density increases the frequency of macropterous females (leading to increased dispersal). Using three replicate experiments at each of three densities, Matsumura selected for increased macroptery in one replicate, decreased macroptery in another, and a control (no selection) in the third. For the replicates with a density of one nymph per container, roughly 40–90 adults were scored, and 20 were chosen to form the next generation. The resulting data for the first five generations in the up-selected line was as follows (Matsumura, pers. comm.):

Generation	q	μ	p	S	R
1	0.224	-0.76	1.00	1.34	0.35
2	0.340	-0.41	0.80	0.75	0.54
3	0.551	0.13	1.00	0.72	0.33
4	0.675	0.45	1.00	0.53	-0.07
5	0.651	0.39	1.00	0.57	0.16
6	0.708	0.55			

Here q is the frequency of macroptery before selection and p is the frequency of macroptery in the selected parents. Translation from q into the mean liability, μ , follows from Equation 14.6. The response (on the liability scale) to selection on generation 1 is

$$R(1) = \mu_2 - \mu_1 = -x_{[1-0.340]} - (-x_{[1-0.224]}) = -0.41 - (-0.76) = 0.35$$

Likewise, the total response was

$$\mu_6 - \mu_1 = 0.55 - (-0.76) = 1.31$$

Selection differentials were calculated from q and p using Equation 14.9. For example, for generation 2,

$$S_2 = \frac{\varphi(\mu_2)}{q_2} \frac{p_2 - q_2}{1 - q_2} = \frac{\varphi(-0.41)}{0.34} \frac{(0.80 - 0.34)}{1 - 0.34} = 0.75$$

The total selection differential is $\sum_i S_i = 3.91$. One key summary statistic for any selection experiment is the *realized heritability*, the ratio of response to selection differential. As detailed in Chapter 18, there are several ways to compute this for a multigeneration selection experiment. One simple estimate is the ratio of the total response to the total differential,

$$\widehat{h^2} = \frac{\sum R_i}{\sum_i S_i} = \frac{1.31}{3.91} = 0.33$$

giving an estimated heritability of the underlying liability for macroptery of around 30%.

Direct Selection on the Threshold, T

It is biologically quite reasonable to imagine that there is variation in T itself (Hazel et al. 1990). Suppose the trait of interest appears when the size of an organism exceeds some critical value, which itself varies over individuals, with certain genotypes and/or environments lowering the value of T , thus allowing individuals with a lower liability score to display the trait. Decomposing both the liability and threshold in terms of genetic and environmental factors gives $z = g_z + e_z$ and $T = g_T + e_T$. The trait appears when $z \geq T$, or

$$g_z + e_z - (g_T + e_T) = (g_z - g_T) + (e_z - e_T) = g + e \geq 0$$

Thus, even though both the liability and threshold values are variable, we can simply consider a single new **risk liability**, the difference between the liability and threshold values, and the analysis proceeds as above. If interest is simply on presence or absence of the binary trait, it does not matter whether the liability or threshold, or both, show variation. However, as Example 14.5 (below) shows, there are situations where we can directly measure the threshold value itself, in which case we can estimate the realized heritability of the threshold level by a selection experiment.

The Logistic Regression Model for Binary Traits

The threshold approach offers one model for mapping an underlying continuous liability, z , into a discrete character space, y (which is either zero or one, corresponding to trait absence or presence). This is a deterministic model, with all individuals with $z \geq T$ displaying the trait ($y = 1$), while all those with $z < T$ do not display it ($y = 0$). A potentially more realistic model is that trait presence is stochastic, with the underlying liability, z , mapping onto a probability of displaying the trait, e.g., $p(z) = \text{Prob}(y = 1 | z)$. Under the threshold model, this probability is 1.0 for $z \geq T$, and 0 otherwise. From a biological standpoint, one imagines that $p(z)$ is a monotonically increasing function of z , approaching 0 for low values and 1 for high values. One reasonable candidate that satisfies these requirements is the **logistic function**,

$$\ell(z) = \frac{\exp(z)}{1 + \exp(z)} = \frac{1}{1 + \exp(-z)} \quad (14.10a)$$

with $\ell(z) \approx 0$ for $z \ll -1$, ≈ 1 for $z \gg 1$, and $\ell(0) = 1/2$. A more general version is

$$\ell[\alpha(z - m)] = \frac{1}{1 + \exp[-\alpha(z - m)]} \quad (14.10b)$$

which has a value of 0.5 at $z = m$ and a scaling factor, α , that sets the abruptness of the transition from low to high probability. The larger the value of α , the more abrupt is the transition, approaching the threshold model for sufficiently large values (Figure 14.6). Equation 14.10b is often called a **logistic regression**.

Biologically speaking, the logistic regression and threshold models may be viewed as essentially identical. To see this, recall that the threshold model very easily extends to the

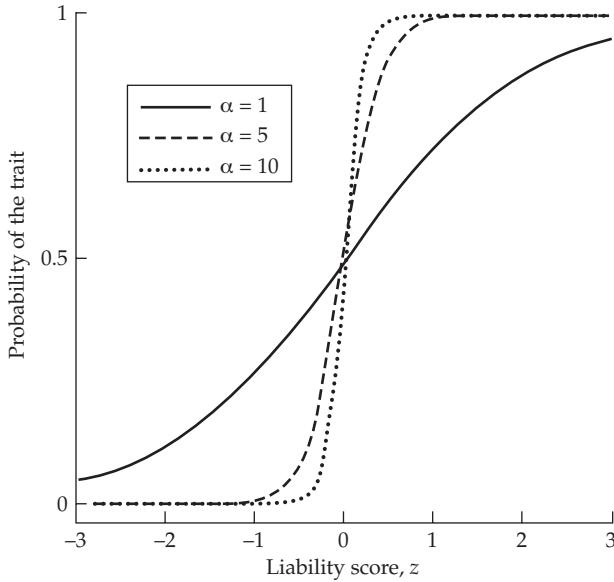

Figure 14.6 A more realistic model of threshold traits is that the liability, z (horizontal axis), determines the probability, $p(z)$, of displaying the trait (vertical axis). One flexible model is to assume that $p(z)$ follows a logistic function (Equation 14.10b) with a scale parameter of α , plotted here for values of $\alpha = 1, 5$, and 10 . For α values in excess of 5 , the logistic function essentially recovers the discrete threshold model.

case where T varies over individuals. In such cases, if the liability value of an individual is z , the trait will only be displayed if $T \leq z$. Now consider the logistic regression model where $p(z)$ denotes the probability that an individual with a liability value of z displays the trait. One source of this stochasticity could simply be population variation in T , so that $p(z)$ can be viewed as the *cumulative distribution function* (cdf; LW Chapter 2) for the threshold value T , e.g., $p(z) = \Pr(T \leq z)$. In this case, a fraction, $p(z)$, of individuals with a liability of z are above the threshold, and hence display the trait.

If the logistic gives the cdf of random threshold values, then the **logistic distribution**, $\phi(x, \alpha, m)$, gives the actual distribution of T . From the definition of a cumulative distribution function,

$$\int_{-\infty}^z \phi(x, \alpha, m) dx = \frac{1}{1 + \exp[-\alpha(z - m)]} \quad (14.11a)$$

Taking derivatives of both sides yields

$$\phi(x, \alpha, m) = \frac{\alpha \exp[-\alpha(z - m)]}{(1 + \exp[-\alpha(z - m)])^2} \quad (14.11b)$$

Johnson and Kotz (1970b) gave the first three moments of this distribution as

$$\mu = m, \quad \sigma^2 = \frac{1}{3} \left(\frac{\pi}{\alpha} \right)^2, \quad \text{and} \quad \mu_3 = 0 \quad (14.11c)$$

As shown in Figure 14.7, the normal and logistic distributions have very similar cumulative distribution functions. Indeed, for a unit normal random variable, U ,

$$\Pr(U \leq x) \simeq \frac{1}{1 + \exp(-\alpha x)}, \quad \text{where} \quad \alpha = \frac{\pi}{\sqrt{3}} \quad (14.12)$$

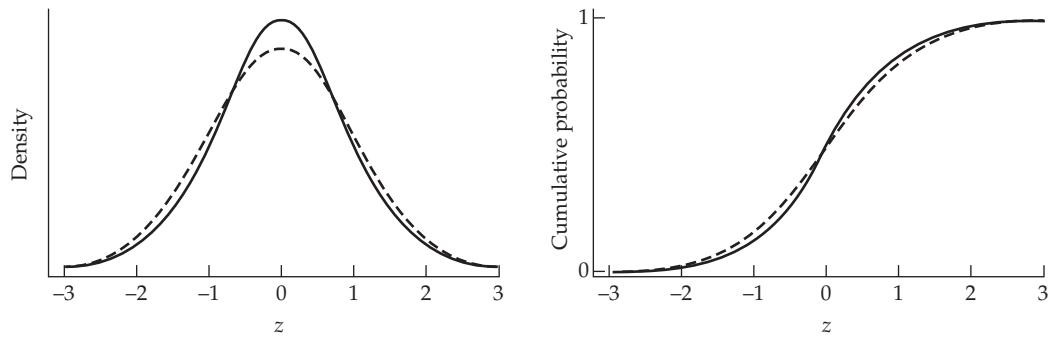

Figure 14.7 A comparison of the unit normal and unit logistic ($\mu = 0, \sigma^2 = 1$) distributions (dashed and solid curves, respectively), with the horizontal axis denoting the value of z . **(Left)** Probability density functions: the logistic is more peaked, with positive kurtosis. **(Right)** The cumulative distribution functions are extremely similar.

which is the logistic distribution with a variance of 1 (see Equation 14.11c).

An interesting biological interpretation of the scale parameter, α (that sets the abruptness of the transition of the logistic regression), is as a measure of the strength of developmental canalization. When α is small, small changes in the liability usually map into small changes in the probability of the trait being displayed ($\alpha = 1$ in Figure 14.6). When α is large, one sees robustness when the liability is away from the mean, m , as small changes in the liability have very little impact on the probability of the trait being displayed. However, when near m , small liability changes can result in dramatically different probabilities of displaying the trait. Chevin and Lande (2013) essentially used this idea to explore the conditions under which a relatively continuous norm of reaction changes into a very discrete step-function (i.e., the conditions leading to the evolution of a large α value).

Thus, we have two approaches for mapping liability values into binary traits: the strict threshold approach (a deterministic mapping of liability onto the discrete trait) and the logistic regression approach (a stochastic mapping translating a liability value into a probability of observing the trait). Given the very close connection between the threshold and logistic regression models, for most purposes using the simple threshold model is a reasonable approach, even if the underlying mapping is stochastic, and as illustrated above, it can easily be used to predict selection response. One setting where the logistic regression is more appropriate is in the actual analysis of the behavior of the threshold when one either knows the liability value or has at least a strong proxy (such as size).

Example 14.5. An interesting analysis of selection on a threshold trait using logistic regressions was provided by Wesselingh and de Jong (1995), who studied the connection between plant size (measured by the proxy of dry weight) and flowering in hound's-tongue (*Cynoglossum officinale*). This species is a facultative biennial, which means that, like an annual plant, it flowers only once, but unlike an annual, it may live several years before flowering. This strategy represents a tradeoff between reduced survival and a larger seed set from a larger size at flowering. For *Cynoglossum*, it has been shown that vernalization (cold treatment) followed by an appropriate photoperiod is required for flowering. However, unless plants are at (or above) a certain threshold size, they are unresponsive to vernalization, and will grow without flowering through the next growing cycle. The authors were interested in the threshold size that triggers the binary trait (vernalization sensitivity), and in particular whether this size is both variable and heritable. To examine this, they grew plants for different numbers of days (ranging from 31 to 86) to generate individuals of different sizes before the vernalization treatment. This generated two selection groups based on threshold size: the smallest plants that flowered following vernalization were chosen as the low-line (low-threshold) parents, while those plants that did

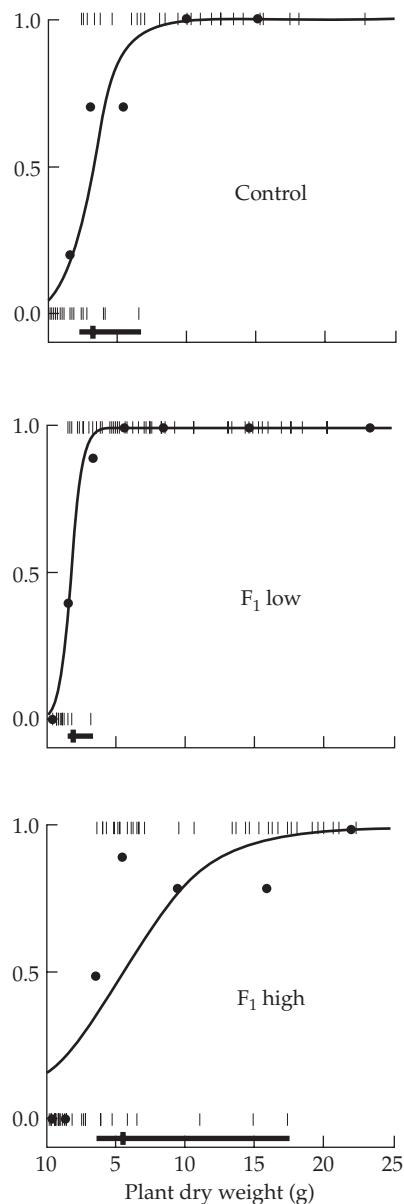

Figure 14.8 The logistic regressions for the relationship between dry weight and flowering in hound's-tongue (*Cynoglossum officinale*). Data were obtained from Wesselingh and de Jong (1995). Regressions are given for control, high, and low lines, grown contemporaneously. See Example 14.5 for further details.

not respond to the first vernalization treatment were allowed to grow a second cycle and were chosen as the parents for the high lines. The response to a single generation of selection can be assessed by comparing the offspring from the low (or high) selected parents against those from an unselected control, as plotted in Figure 14.8.

The data available to the authors were 0 or 1 (insensitive or sensitive to vernalization) values as a function of size. To estimate the distribution of threshold sizes, they performed a logistic regression on these data, using maximum likelihood (LW Appendix 4) to fit the α and mean (m) terms of Equation 14.10b. Data for the high and low lines are plotted in Figure 14.8 along with the ML solution for the logistic regression. Each individual has a 0 or 1 data point (individual ticks), while the circles represent the average value for weight classes with more than ten individuals.

Logistic regressions were estimated for progeny from the low- and high-line parents and for

a control line grown contemporaneously with these progeny. The ML estimates of the mean, m (which corresponds to the weight yielding 50% flowering), and value of α for these regressions were

Line	m	α
Control	3.30	0.97
Low	1.85	2.58
High	5.41	0.31

Note that the low line not only had a smaller mean size for vernalization (1.85), but also a much larger α value (2.58), and therefore a more abrupt transition between insensitivity and sensitivity. Using these estimates, Equation 14.10b yields the expected percent of vernalization sensitivity (flowering) for a given weight. For a 3 gram plant, this is 0.43 in the control line and 0.32 in the high lines, but 0.95 in the low line.

By estimating both the response, R , to selection as well as the within-generation change, S , we can estimate the heritability of this trait by calculating R/S . First, the response to selection (change in m) can be estimated by using the contemporaneously grown control line as a standard. From the previous table, the response in the high line is $5.41 - 3.30 = 2.11$, while the response in the low line is $1.85 - 3.30 = -1.45$. Turning to estimating S , the selection truncation point for the low line is the largest low parent (2.74 grams, or 25.5% of the left tail of the founding source population), while the smallest flowering high parent was 9.95 grams (corresponding to the upper 12.2% of the founding source population). From Equation 14.3a, these translate into selection intensities of $\bar{t} = -1.26$ and 1.66 , respectively. To obtain the selection differentials, S , for each line, recall that $S = \bar{t}\sigma_p$. To estimate σ_p , the authors note that the 0.25 quartile for a normal distribution is 0.674σ from the mean. Although the assumption is that the threshold values follow a logistic distribution, the cumulative probability functions are rather similar for both the normal and the logistic (Figure 14.7). Hence, taking the observed 0.25 quartile (in the founding lines) of 2.68, and its mean of 5.12, suggests

$$\sigma_p = \frac{5.12 - 2.68}{0.674} = 3.63$$

The response (change in m), selection intensity, and estimated heritability, $\widehat{h}^2 = R/S$, for the high and low lines are

Line	\bar{t}	S	R	$\widehat{h}^2 = R/S$
Low	-1.26	-4.58	-1.45	0.32
High	1.66	6.02	2.11	0.35

Thus, there is heritable variation in threshold size, as there was response to selection for both larger and smaller threshold sizes. Further, the estimated heritability (based on the single-generation response to selection) was around 0.3.

BLUP Selection With Binary Data: Generalized Linear Mixed Models

Animal breeders routinely use the **general linear mixed model** to obtain BLUP estimates of breeding values for normally distributed traits, where the expected value of the phenotype, y_i , of individual i can be written as

$$E[y_i] = \mu_i = \mu + \sum \beta_k x_{k,i} + A_i \quad (14.13a)$$

Here A_i is an individual's breeding value and the β_k are fixed effects (such as adjustments for age and sex, whose values in individual i are given by the $x_{k,i}$). A particular realization (i.e., a scored phenotype) from this individual can be written as

$$y_i = \mu_i + e_i \quad (14.13b)$$

where the residual, e_i , is normally distributed with a mean of zero, implying that y_i is also normally distributed. Putting these together, an observation from individual i can be written as

$$y_i = \mu + \sum \beta_k x_{k,i} + A_i + e_i \quad (14.13c)$$

As described in Chapters 13, 19, 20, and LW Chapters 26 and 27, in addition to its observed phenotype, y_i , additional information to estimate A_i is borrowed from the y values of relatives through the relationship matrix \mathbf{A} . In a selection scheme, those individuals with the largest estimated A values are then chosen to form the next generation.

This same strategy can be extended to cases where the mean μ_i is *not* a simple linear function of A_i and where the residual error is not normally distributed. In particular, the phenotype, y_i , of a binary trait takes on a value of either 0 or 1. The expected value of y_i is just the probability of displaying the trait, i.e., the trait is **Bernoulli-distributed** (a binomial with a single draw), so that y_i is either 0 or 1 given this mean μ_i (its success parameter in the Bernoulli). Equation 14.13a is generally not applicable in this setting as μ_i is constrained (being a probability) to the 0 to 1 range, while no such constraints occur on Equation 14.13a. A second issue is that the residual error structure is not normal.

The solution to both satisfying this constraint and using the correct residual distribution relies on the use of **generalized** (as opposed to general) **linear mixed models**. These extend Equation 14.13c to cases where the expected value of y conditioned on the variables of interest is *not* a linear function of breeding value, and the residuals about this expected value are not necessarily normal (Bolker et al. 2009; de Villemereuil et al. 2016). The basic structure of a generalized linear model can be thought of as an extension of the liability model to more general functions.

Let the liability value (z_i) for individual i be some linear function of the breeding value, A_i , an environmental value, E_i , plus (potentially) fixed effects,

$$z_i = \mu + \sum \beta_k x_{k,i} + A_i + E_i \quad (14.14a)$$

which is mapped onto a mean trait value, y , by a monotonic function, g . Specifically, the conditional expectation of y given z is

$$E[y | z] = g(z) \quad (14.14b)$$

where

$$g^{-1}(E[y | z]) = z = \mu + \sum \beta_k x_{k,i} + A_i + E_i \quad (14.14c)$$

The inverse g^{-1} is called the **link function**, as it transforms the conditional expectation into a linear model. The function g imposes the desired constraint on the mean of y , mapping some unconstrained value, z , into the desired constraint space (such as 0 to 1).

For binary data, Equation 14.14b becomes $E[y | z] = g(z) = p(z)$, where $p(z) = \Pr(y = 1 | z)$, the success parameter, with y following a Bernoulli distribution. Thus, we desire some function that maps the underlying liability, z , onto a value, $p(z)$, constrained to the space [0, 1]. As we have seen, one candidate function is the simple logistic function, $\ell(z)$ (Equation 14.10a). The corresponding link function (Equation 14.14c), which is the inverse of the logistic function, is given by the **logit function**, defined as

$$\text{logit}(p) = \ln \left(\frac{p}{1-p} \right) \quad (14.15a)$$

namely, the log of the odds ratio (probability of the trait being present divided by probability that the trait is absent). If $\ell(z) = p$, then $\text{logit}(p) = z$, so that a logit-transformed p value recovers the liability value,

$$\text{logit}(p|z_i) = z_i = \mu + \sum \beta_k x_{k,i} + A_i + E_i \quad (14.15b)$$

Under this framework, BLUP selection for individuals with the highest breeding values for a binary trait proceeds by taking the 0/1 binary data from a set of individuals (along with other fixed, and possibly random, effects of interest) and using either maximum likelihood or Bayesian approaches to estimate the breeding values on the liability scale given by Equation

14.15b (Foulley et al. 1983; Foulley 1992; Vazques et al. 2009). This approach can be extended to $k \geq 2$ thresholds in the mapping of liability into k character states (Korsgaard et al. 2002).

RESPONSE IN DISCRETE TRAITS: POISSON-DISTRIBUTED CHARACTERS

Discrete characters with a large number of possible states, such as numbers of leaves on a tree, can be treated as a continuous trait. However, what about a discrete trait with a rather compact distribution? A common example is the number of offspring, such as the clutch size of a bird, which might range from 0 to 10 eggs in an observed sample. This discreteness is of special concern when the trait has a significant probability mass at a particular value (especially zero), as often happens with offspring number (corresponding to failure to reproduce).

A natural way to model such traits is to use the **Poisson distribution**, where the probability of observing a trait value of k is given by

$$\Pr(y = k) = e^{-\lambda} \frac{\lambda^k}{k!} \quad (14.16)$$

where $\lambda = E[y]$ is the expected value of the trait, which is constrained to $\lambda > 0$. Motivated by the previous treatment of binary traits, one might imagine some underlying liability value, z , with additive effects (Equation 14.14a) mapped onto a mean value, λ , constrained to be positive. For example, we can use

$$\lambda = \exp(z) \quad (14.17a)$$

ensuring that $\lambda > 0$ for all z and hence is a proper expectation for a Poisson. In the context of generalized linear models, $g(z) = \exp(z)$, so that the link function $g^{-1}(z)$ is simply $\ln(z)$, as $g^{-1}[g(z)] = \ln[\exp(z)] = z$, yielding

$$\ln(\lambda) = z = \mu + \sum \beta_k x_{k,i} + A_i + e_i \quad (14.17b)$$

This is called a **log-linear model**, as the log of the distribution parameter, λ , is a linear function of the variables of interest (in particular, the breeding value).

On this log scale, both the breeding and environmental values are assumed to be normal, with a mean of zero and variances of σ_A^2 and σ_e^2 . As with binary traits, BLUP selection based on this generalized linear model framework can be used to estimate the A_i values (Foulley 1993; Foulley and Im 1993; Korsgaard et al. 2002; Vazques et al. 2009; Morrissey 2015; de Villemereuil et al. 2016). Other models are also possible, such as a **zero-inflated Poisson**, which has extra probability mass at zero relative to a standard Poisson (e.g., Rodrigues-Motta et al. 2007; see Chapter 29). A trait can also be underdispersed relative to the Poisson (as seems to consistently be the case for bird clutch size; J. Hadfield, pers. comm.), in which case other distributions, such as a **zero-truncated Poisson** (the nonzero data follow a Poisson distribution) can be used (Chapter 29). A nice discussion of estimation issues under generalized linear models (beyond the binary and log-linear models presented here) is given by de Villemereuil et al. (2016), while Morrissey (2015) presented the theory of selection response under more general settings (which we will examine in Volume 3).

Under the log-linear model, the liability, z , of an individual yields an expected value of $\lambda = \exp(z)$, with a realization (e.g., the number of offspring for an individual with trait value z) drawn from a Poisson to return the observed trait value. For example, if the latent value, λ_i , for individual i has a value of 0.2, then (from Equation 14.16) the probability this individual has a trait of value zero is $\exp(-0.2) \simeq 0.82$, the probability they have value 1 is $0.2 \cdot \exp(-0.2) \simeq 0.16$, value 2 is $0.2^2 \cdot \exp((-0.2)/2!) \simeq 0.02$, and so on.

The resulting mean trait value in a population under the log-linear model becomes

$$\begin{aligned} E[y] &= E[\lambda] = E[\exp(z)] \\ &= E[\exp(\mu) \cdot \exp(A) \cdot \exp(e)] \\ &= \exp(\mu) \cdot E[\exp(A)] \cdot E[\exp(e)] \end{aligned} \quad (14.18)$$

where the last step follows because (by construction) A and e are uncorrelated (and thus independent if they are bivariate normal, as is usually assumed), while μ is a constant. To compute these expectations, recall that the expression $E[e^{tx}]$ is the **moment-generating function** of the random variable, x (Johnson and Kotz 1970a). For $x \sim N(\mu, \sigma^2)$,

$$E[e^{tx}] = \exp\left(\mu t + \frac{\sigma^2}{2}t^2\right) \quad (14.19a)$$

In this case, with a mean, μ , equal to zero and variance of σ^2 , setting $t = 1$ yields

$$E[e^x] = \exp\left(\frac{\sigma^2}{2}\right) \quad (14.19b)$$

Substituting into Equation 14.18 shows that the expected mean trait value is a function of both the mean, μ , and variance, σ_z^2 , of the underlying liability value, with

$$E[y] = \exp(\mu) \cdot \exp\left(\frac{\sigma_A^2 + \sigma_e^2}{2}\right) = \exp(\mu) \cdot \exp(\sigma_z^2/2) \quad (14.20a)$$

One might initially expect that if A is the breeding value for liability, then the mean phenotype of an individual would simply be $\exp(\mu + A)$. However, Equation 14.20a shows that if we condition on the breeding value being A , the conditional mean now becomes $\mu + A$ and the variance, σ_A^2 , vanishes, leaving

$$E[y | A] = \exp(\mu + A) \cdot \exp\left(\frac{0 + \sigma_e^2}{2}\right) = \exp(\mu + A) \cdot \exp(\sigma_e^2/2) \quad (14.20b)$$

Following a single generation of selection, the distribution of liability values has approximately the same variance, but now the mean is shifted to $\mu + h^2S$ (where S is the selection differential *on the liability scale*). Applying Equation 14.20a, the response on the phenotypic scale becomes

$$\begin{aligned} R &= E[y_{t+1}] - E[y_t] \\ &= [\exp(\mu + h^2S) - \exp(\mu)] \cdot \exp(\sigma_z^2/2) \\ &= [\exp(h^2S) - 1] \cdot \exp(\mu) \cdot \exp(\sigma_z^2/2) \\ &= [\exp(h^2S) - 1] \cdot E(y_t) \end{aligned} \quad (14.21)$$

Notice that, as was the case for selection on a binary trait, the response to selection is not symmetric, as $S = +\delta$ does not give the same increment of response as $S = -\delta$.

15

Short-term Changes in the Mean: 3. Permanent Versus Transient Response

The phenotypic gains from selecting for epistatic differences come from distorting the gametic array and soon disappear after selection is relaxed, as the gametic array returns to random. By contrast, the gains from changes in gene frequency are permanent. Lush (1948)

While the basic breeder's equation is the foundation for much of the theory of selection response in quantitative traits, its elegant form of $R = h^2 S$ arises because of certain simplifying assumptions (Table 13.2). One interesting complication is that the selection response can have both transient and permanent components, and this chapter examines common situations where this can occur (also see Chapter 23). Selection can change allele and genotype frequencies, generate linkage disequilibrium, and create nonrandom associations among environmental values, all of which can contribute to the response. Of these, only allele-frequency changes are permanent, as any such changes remain after selection stops. In contrast, random mating eventually ensures there will be Hardy-Weinberg frequencies for genotypes, linkage equilibrium, and random associations of environmental effects. The contributions to the selection response generated by departures from these equilibrium values are therefore **transient**, decaying to zero following the cessation of selection.

Transient components of response can be both positive and negative, so the selection response may decay or increase following the cessation of selection. In the extreme situation, a **reversed response** occurs, wherein a trait selected to increase actually *decreases* due to a negative transient component overwhelming a positive permanent response. The potential of transient contributions from previous generations of selection is one reason why the breeder's equation requires an unselected base population.

Our treatment starts with a brief discussion of why the breeder's equation focuses on h^2 , even though other factors can also contribute to the selection response. We then turn to two genetic situations that generate transient components to response: additive epistasis in diploids and dominance in autotetraploids. This leads to a discussion of the method of using ancestral regressions to determine the conditions under which a component of response is transient. The implications of correlated environmental effects between relatives are considered next, as we examine the selection response when the parent-offspring covariance is entirely due to shared environmental effects (which also serves as model for epigenetic effects). We conclude by considering the complications introduced by the presence of heritable maternal effects, which show share properties seen with shared environmental values.

WHY ALL THE FOCUS ON h^2 ?

As discussed in LW Chapters 7 and 17, epistasis or environmental effects shared between parents and their offspring can cause the parent-offspring regression to deviate significantly from $h^2/2$, thus altering the response from that predicted by the breeder's equation. If we allow for epistasis (among unlinked loci) and correlation between parental and offspring environmental values, the single parent-offspring slope will be

$$b_{op} = \frac{\sigma(z_p, z_o)}{\sigma_z^2} = \frac{1}{\sigma_z^2} \left(\frac{\sigma_A^2}{2} + \frac{\sigma_{AA}^2}{4} + \frac{\sigma_{AAA}^2}{8} + \frac{\sigma_{AAAA}^2}{16} + \dots + \sigma(E_p, E_o) \right) \quad (15.1a)$$

If we assume there is a linear biparental regression with identical slopes for both parents,

the response to a single generation of selection becomes

$$R = 2b_{op}S = h^2S + \frac{S}{\sigma_z^2} \left(\frac{\sigma_{AA}^2}{2} + \frac{\sigma_{AAA}^2}{4} + \frac{\sigma_{AAAA}^2}{8} + \dots + \sigma(E_{fa}, E_o) + \sigma(E_{mo}, E_o) \right) \quad (15.1b)$$

which can deviate significantly from h^2S . Why, then, is so much attention focused on h^2 ?

The reason is that we are generally interested in the **permanent response** to selection. Selection changes allele frequencies, which in turn changes the mean genotypic value. Under the infinitesimal model, very small changes in allele frequencies over a large number of loci can generate a significant change in the mean without much change in the additive variance (Chapter 24), and these changes are reflected in the response component, h^2S . Any additional response from epistasis or shared environmental effects arises because of gametic-phase disequilibrium or nonrandom associations of environmental values. Recombination and the randomization of environmental effects cause these associations to decay to zero under random mating. Conversely, changes in allele frequencies are permanent, as once selection stops, the new allele frequencies will be stable (ignoring the longer-term effects of drift). Hence, as will be shown shortly, the permanent response under the conditions leading to Equation 15.1b is $h^2 S$. One exception, discussed in Chapter 23, is when significant inbreeding occurs. In this case, σ_{AA}^2 , and other nonadditive variance components specific to inbred populations (σ_{DI}^2 and σ_{ADI} ; introduced in Chapter 11), can contribute to permanent response.

GENETIC SOURCES OF TRANSIENT RESPONSE

Diploid parents undergoing sexual reproduction pass along single alleles at each locus to their offspring, with a parent's breeding value being the sum of its allelic effects over all loci (LW Chapter 4). Genotypic values are generally different from breeding values, with deviations representing interaction terms, such as dominance (between alleles at the same loci) or epistasis (between alleles at different loci). Such interactions are often not passed to an offspring of a randomly mating diploid parent, as their transmission requires that the parent pass along all of the component parts of the interaction (such as both alleles at a locus for dominance). As such, only part of an exceptional genotypic value of a selected parent is passed on to its offspring. However, there are two common settings where at least some of these interaction terms can be passed to an offspring under random mating—additive epistasis in a diploid (and higher ploidy) and dominance in an autotetraploid. When non-random mating occurs, such as inbreeding, the possibility exists that other interactions can be passed on to an offspring (such as dominance in a diploid); see Chapter 23.

Additive Epistasis

Pairwise epistasis involves interactions between either single alleles at different loci (additive-by-additive epistasis, $A \times A$), between entire genotypes at different loci (dominance-by-dominance epistasis, $D \times D$), or between an allele at one locus and the genotype at a second (additive-by-dominance epistasis, $A \times D$). Because a randomly mating diploid passes along a single allele at each locus to its offspring, additive ($A \times A$, $A \times A \times A$, etc.) interactions between alleles at different loci can be passed from a parent to its offspring. Under random mating in a diploid, any epistatic term involving dominance ($A \times D$, $D \times D$, etc.) cannot be passed along, as a parent must contribute *both* alleles at a given locus to its offspring to transmit a D component.

Before proceeding, it is important to realize the important distinction between epistatic *effects* (the expected multilocus value does not equal the sum of the single-locus values) and epistatic *variances*. The former can be quite large and yet the latter can still remain small. In large part this is due to the additive genetic variance being the variance accounted for by the best linear fit of a potentially highly nonlinear system, so that (as is the case for dominance) epistatic effects are partly accounted through σ_A^2 (Crow 2010; LW Chapter 5). Under fairly general patterns of multilocus interactions, extreme allele frequencies (near zero or one),

as would be expected under drift (Chapter 2), result in most of the *genetic variance* being additive even when the *genotypic values* have a highly nonadditive basis (Hill et al. 2008; Mäki-Tanila and Hill 2014). Our concern here is how the residual nonadditive effects (e.g., σ_{AA}^2) that are not absorbed into additive variance influence the selection response.

Although Lush (1948) and Kempthorne (1957) clearly grasped the key idea that the component of selection response from additive epistasis is transient, the first quantitative analysis was by Griffing (1960a, 1960b), who assumed the infinitesimal model. Under the assumptions that (i) phenotypes are normally distributed, (ii) effects at any particular locus are very small relative to the total phenotypic variation, and (iii) no third- (or higher-) order additive epistasis is present, the response to one generation of selection is

$$R = S \left(h^2 + \frac{\sigma_{AA}^2}{2\sigma_z^2} \right) \quad (15.2)$$

One might expect that $R(t)$, the cumulative response after t generations of selection, is simply t times the result given by Equation 15.2. However, any increased response (relative to Sh^2) due to epistasis is only temporary, reflecting gametic-phase disequilibrium generated by selection. As disequilibrium decays under recombination, so does the component of response due to epistasis. This occurs because the $A \times A$ contribution comes from favorable combinations of alleles at different loci, above and beyond their individual contributions (which are accounted for by changes in the mean breeding value of the selected parents, h^2S). Recombination breaks down these combinations, removing the epistatic contribution. Griffing showed that for two linked loci separated by a recombination fraction of c , the response when a generation of selection is followed by τ generations of random mating is

$$S \left(h^2 + (1 - c)^\tau \frac{\sigma_{AA}^2}{2\sigma_z^2} \right) \quad (15.3)$$

which converges to h^2S as $\tau \rightarrow \infty$. Equation 15.3 follows by noting that the probability of a gamete containing specific alleles from both loci remaining intact following one generation of recombination is $1 - c$. Thus, after τ generations, only $(1 - c)^\tau$ of the favorable two-locus combinations selected at $\tau = 0$ remain unaltered by recombination. This transient component of response from epistasis is often called the **Griffing effect**.

Summing Equation 15.3 over t yields the cumulative response after t generations with a constant selection differential, S , as

$$R(t) = t h^2 S + R_{AA}(t) \quad (15.4a)$$

where

$$R_{AA}(t) = S \frac{\sigma_{AA}^2}{2\sigma_z^2} \left(\sum_{i=1}^t (1 - c)^{i-1} \right) = S \left(\frac{1 - (1 - c)^t}{c} \right) \left(\frac{\sigma_{AA}^2}{2\sigma_z^2} \right) \quad (15.4b)$$

denotes the cumulative additive \times additive epistatic contribution. The last equality follows using the partial sum of a geometric series

$$\sum_{i=1}^n x^{i-1} = \sum_{i=0}^{n-1} x^i = \frac{1 - x^n}{1 - x} \quad (15.5a)$$

A related result (used later in the chapter) is that

$$\sum_{i=1}^n x^i = \frac{1 - x^{n+1}}{1 - x} - 1 = \frac{x(1 - x^n)}{1 - x} \quad (15.5b)$$

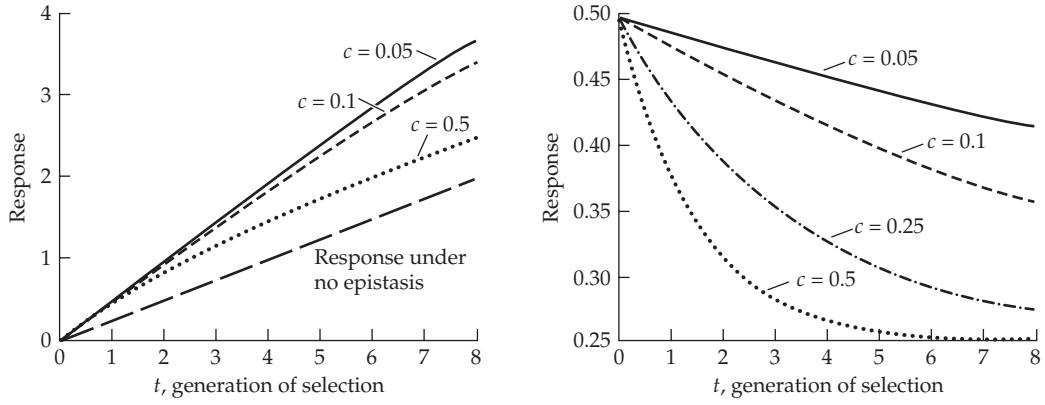

Figure 15.1 The permanent and transient response to selection (scaled in units of S) assuming pairwise epistasis in a diploid, with $h^2 = 1/4$ and $\sigma_{AA}^2/\sigma_z^2 = 1/2$. **Left:** The cumulative response assuming a constant amount of selection for various values of c . Note that even with this large amount of epistasis (σ_{AA}^2 accounts for half the total variance), it is difficult to distinguish the curvilinear response with epistasis from a linear response. **Right:** The decay of response following a single generation of selection due to the decay of the contribution from epistasis. Provided $c > 0$, the cumulative response eventually decays to $h^2S = S/4$, the expectation under no epistasis.

If loci are completely linked ($c = 0$), $R_{AA}(t) = t S \sigma_{AA}^2 / (2\sigma_z^2)$, but provided $c > 0$, the total epistatic contribution approaches a limiting value of

$$\tilde{R}_{AA} = \lim_{t \rightarrow \infty} R_{AA}(t) = \frac{1}{c} \left(S \frac{\sigma_{AA}^2}{2\sigma_z^2} \right) \quad (15.6a)$$

\tilde{R}_{AA} represents the balance between selection generating disequilibrium and its removal by recombination. Equation 15.6a shows that the limiting contribution is $1/c$ times the epistatic response in the first generation. For unlinked loci ($c = 0.5$), this is simply twice the initial response. With tight linkage, the total response can be significantly larger.

The expected time, $t_{1/2}$, for half the total epistatic response to accumulate, $R_{AA}(t_{1/2}) = \tilde{R}_{AA}/2$, is obtained by noting from Equations 15.4b and 15.6a that this occurs when $1 - (1 - c)^{t_{1/2}} = 1/2$, or

$$t_{1/2} = \frac{-\ln(2)}{\ln(1 - c)} \quad (15.6b)$$

For small value of c , this is approximately $\simeq 0.68/c$. As linkage becomes tighter, the total cumulative epistatic response increases, as does the time for half of this total response to occur (Figure 15.1).

Once selection stops, the epistatic contribution decays to zero. With t generations of selection followed by τ generations of random mating, the cumulative response under the infinitesimal model is

$$t h^2 S + (1 - c)^\tau R_{AA}(t) \quad (15.7)$$

which (for large τ) converges to $R = t h^2 S$, the value predicted from the breeder's equation. The half-life for decay of the epistatic response, R_{AA} , is also given by Equation 15.6b.

The presence of epistasis can result in a curvilinear selection response if σ_{AA}^2/σ_z^2 is sufficiently large. However, as Figure 15.1 shows, any such curvilinearity is usually difficult to distinguish from a linear response, especially given the very noisy nature of selection response data (Chapter 18). Unless there is tight linkage, most of the nonlinearity occurs in the first few generations (Equation 15.6b). With a constant selection differential, the additional increment to response from epistasis decreases in each generation as R_{AA} approaches its

limiting value, \tilde{R}_{AA} , at which point the per-generation response is simply $h^2 S$ and linear over future generations.

Under the infinitesimal model, once selection is relaxed, the total response decays back to that predicted from the breeder's equation. It is interestingly that this situation mimics the effects of natural selection counteracting artificial selection, which also result in a decay of the cumulative response once artificial selection stops. Thus, in order to predict the *permanent* response correctly, we must know h^2 . If only the parent-offspring slope is estimated, this may overestimate the final amount of response due to the inclusion of σ_{AA}^2 and higher-order (additive) epistatic variances, although the bias is generally likely to be small, as the values of the higher-order variances are expected to be small relative to σ_A^2 .

Griffing's analysis is restricted to two loci, and hence limited to only pairwise (additive \times additive) epistasis. In contrast, Equation 15.1 gives the single-generation response for arbitrary levels of additive epistasis, provided the biparental offspring regression is linear. These higher-order contributions also rapidly decay under random mating. Again assuming the infinitesimal model (and unlinked loci), Bulmer (1980) found that the response due to a single generation of selection (Equation 15.1) decays after one generation of random mating to

$$R = S \left(h^2 + \frac{1}{4} \frac{\sigma_{AA}^2}{\sigma_z^2} + \frac{1}{16} \frac{\sigma_{AAA}^2}{\sigma_z^2} + \frac{1}{64} \frac{\sigma_{AAAA}^2}{\sigma_z^2} + \dots \right) \quad (15.8)$$

which again rapidly converges to $R = h^2 S$ after several generations of random mating. For n -locus additive epistasis (e.g., $\sigma_{A\dots A}^2$, where there are n A 's), the per-generation decay rate for unlinked loci is $(1/2)^{n-1}$, which is the probability that a parental gamete containing specific alleles at n unlinked loci is passed on intact to an offspring. The probability that such a gamete will remain unchanged after t generations is $2^{-t(n-1)}$, which rapidly converges to zero. Example 15.2 (below) uses the method of ancestral regressions to more fully examine the response under n -locus additive epistasis. A final caveat is that these results apply to infinite populations. As shown in Chapter 11, in finite populations, some of the additive epistatic contribution can be permanent due to some of σ_{AA}^2 being transformed into simple additive variation by drift.

Dominance in Autotetraploids

Polyplody, which is very common in plants and occurs in some animals (e.g., salmonid fishes), can introduce complications in predicting selection response (Gallais 2003). In particular, the dynamics of selection response for autotetraploids with dominance is very similar to the dynamics of diploids with epistasis. From LW Equation 7.22 and LW Table 7.5, the tetraploid parent-offspring covariance when dominance (but no epistasis) is present is

$$\sigma(z_p, z_o) = \frac{\sigma_A^2}{2} + \frac{\sigma_D^2}{6}$$

The inflation of the parent-offspring covariance over that for a diploid is due to dominance interactions between the two alleles per locus that each tetraploid parent passes on to its offspring. Thus, like additive epistasis in diploids, favorable combinations of alleles can be passed down from parent to offspring in polyploids. With equal amounts of selection on both sexes (e.g., selection occurs before pollination), the resulting response (assuming linearity of the parent-offspring regression) is

$$R = S \left(h^2 + \frac{\sigma_D^2}{3\sigma_z^2} \right) \quad (15.9)$$

If selection occurs after pollination, S is replaced by $S/2$. Gallais (1975) extended Griffing's (1960a) method (and hence assumed normally distributed phenotypes, with each gene having very small effects on the character) to obtain the response after t generations of selection with a constant differential of S ,

$$R(t) = th^2S + R_D(t) \quad (15.10a)$$

where

$$R_D(t) = S \frac{3}{2} \left[1 - \left(\frac{1}{3} \right)^t \right] \frac{\sigma_D^2}{3\sigma_z^2} \quad (15.10b)$$

which converges to a limiting value of

$$\tilde{R}_D = S (\sigma_D^2 / 2\sigma_z^2) \quad (15.10c)$$

This is just a 50% increase over the first-generation dominance response. Thus, as with the contribution from epistasis in diploids, the total contribution from dominance in polyploids approaches a limiting value representing the balance between selection favoring specific combinations of alleles and reproduction reshuffling those combinations.

Again, as with epistasis, the contribution from dominance decays upon the cessation of selection as genotype frequencies return to their Hardy-Weinberg values. As discussed in LW Chapter 4, the rate of approach to tetraploid Hardy-Weinberg expectations depends on the probability, c , of a double reduction. This is the chance that a gamete contains two copies of one of the four alleles in the parent, an event that requires a crossover (see LW Figure 4.3). In the absence of double reduction ($c = 0$), as would occur for a locus completely linked to the centromere, the difference in the frequency of pairs of alleles from Hardy-Weinberg expectation decays by one third in each generation (and this is assumed in obtaining Equation 15.10b). In such a setting, the response to t generations of selection followed by τ generations of random mating is

$$t h^2 S + (1/3)^\tau R_D(t) \quad (15.10d)$$

which again rapidly converges to $t h^2 S$. More generally, if c is the per-generation probability of a double reduction, the decay rate of $(1/3)^t$ is replaced in Equations 15.10b and 15.10d by $[(1 - c)/3]^t$. Swanson et al. (1974) found that if some double reductions occur ($c > 0$), the additive genetic variance is slightly inflated over the value expected with no double reductions ($c = 0$), which permanently increases selection response. This results from the slight excess of homozygotes at equilibrium over the Hardy-Weinberg expectation (see LW Chapter 4).

Wricke and Weber (1986) discussed additional topics on tetraploid selection, while selection under single-locus tetraploid models was examined by R. Hill (1971; Hagg and Hill 1974; Hill and Hagg 1974; Rowe and Hill 1984). By far the most complete treatment of selection with polyploids was presented by Gallais (2003).

ANCESTRAL REGRESSIONS

A general approach for examining which components of response are transient is to consider the expected value of an offspring as a function of all of its direct relatives that have been under selection (Pearson 1898; Bulmer 1971b, 1980). If this **ancestral regression** is linear (as would occur if the joint distribution of the phenotypic values of all relatives is multivariate normal), the selection response can be described by specifying the regression coefficients via an obvious extension of the biparental regression, to now include all selected relatives back to the original unselected base population. For example, if selection starts in generation 0, the response in the first generation is $R(1) = 2\beta_{1,0} S_0$, where $\beta_{1,0}$ is the regression of offspring at generation 1 on a parent from generation 0 (this assumes that both parents have the same regression coefficients and selection differentials, an assumption that will be relaxed shortly). Likewise, the total response after two generations, $R(2) = 4\beta_{2,0} S_0 + 2\beta_{2,1} S_1$, depends on the nature of selection on the four grandparents (S_0) and both parents (S_1) as well as on the transmission from grandparent to grandchild ($\beta_{2,0}$) and that from parent to

offspring ($\beta_{2,1}$). Note that this formulation allows the parent-offspring regression to change through time (e.g., $\beta_{2,1}$ need not equal $\beta_{1,0}$), as can happen with inbreeding (Chapter 23). Similarly, the response following three generations of selection depends upon the nature of selection on that individual's eight great-grandparents, four grandparents, and two parents

$$R(3) = 8\beta_{3,0}S_0 + 4\beta_{3,1}S_1 + 2\beta_{3,2}S_2$$

Proceeding in this fashion gives the total response by generation T as

$$R(T) = \sum_{t=0}^{T-1} 2^{T-t} \beta_{T,t} S_t \quad (15.11a)$$

where $\beta_{T,t}$ is the partial regression coefficient for the phenotype of an individual in generation T on one (out of 2^{T-t}) of its ancestors in generation $t < T$ (with selection starting at generation 0). Because the total response is simply the sum of the independent contributions from each generation, the regression coefficients are simply standard univariate regression coefficients (i.e., $\beta_i = \sigma(y, x_i)/\sigma_{x_i}^2$), yielding

$$R(T) = \sum_{t=0}^{T-1} 2^{T-t} \frac{\sigma_G(T, t)}{\sigma^2(z_t)} S_t \quad (15.11b)$$

where $\sigma_G(T, t) = \sigma(z_T, z_t)$ is the **cross-generation covariance**, the phenotypic covariance between an individual in generation t and its descendant in generation $T > t$. We usually assume that $\sigma(z_T, z_t)$ is entirely genetic (e.g., Examples 15.1 and 15.2), and hence denote it by $\sigma_G(T, t)$, although environmental factors shared across generations can also contribute to $\sigma(z_T, z_t)$.

With pure selfing, each individual has only a single relative, so the 2^{T-t} term in Equation 15.11a is absent, which makes the ancestral regression

$$R(T) = \sum_{t=0}^{T-1} \beta_{T,t} S_t \quad (15.11c)$$

As we will see in Chapter 23, ancestral regression offers a powerful approach for the analysis of selection under inbreeding, where the cross-generation covariances depend on *both* T and t , rather than simply on the number of generations ($T - t$) between the ancestor and the descendant. For example, the parent-offspring covariance changes over generations as inbreeding proceeds.

If different relatives in the same generation experience different amounts of selection, with $S_{k,i}$ being the selection differential on relative i in generation k , then

$$R(T) = \sum_{t=0}^{T-1} \left[\beta_{T,t} \left(\sum_{i=1}^{n(t,T)} S_{t,i} \right) \right] \quad (15.12a)$$

where $n(t, T)$ is the number of relatives in generation t that contribute to response in generation T . Note for the case of pure selfing, $n(t, T) = 1$, which reduces Equation 15.12a to Equation 15.11c. Finally, we can also allow for different regression coefficients on each relative to completely generalize this approach

$$R(T) = \sum_{t=0}^{T-1} \left(\sum_{i=1}^{n(t,T)} \beta_{T,t,i} S_{t,i} \right) \quad (15.12b)$$

where $\beta_{T,t,i}$ is the regression coefficient of the phenotype of an individual in generation T on its i th relative in generation t .

To apply ancestral regression for predicting response, we require that the regression remain linear and that *selection-induced* changes in the variances and covariances be negligible. Thus, while we allow changes in $\beta_{T,t}$ due to the particular genetic system being considered (e.g., selfing, wherein the additive genetic variance decreases by a predictable amount in each generation in the absence of selection), we assume that selection does not confound these changes. Bulmer (1980) showed that the joint distribution of an offspring and all its direct ancestors is multivariate normal, and hence the ancestral regression is linear (LW Chapter 8), under the infinitesimal model. Because selection does not change allele frequencies under the infinitesimal model, this might suggest that the regression coefficients, $\beta_{T,t}$ are unaffected by selection. The problem, however, is that selection generates gametic-phase disequilibrium, which can significantly alter the genotypic moments (Chapters 16 and 24). For now, we assume that these changes are small enough to be neglected. In Chapter 19 we show that BLUP estimates of breeding values are a type of ancestral regression, with the relationship matrix, \mathbf{A} , accounting for drift and disequilibrium.

The behavior of the regression coefficients over time informs us about the permanency of the response. Consider the contribution from generation τ at t generations later, so that in the notation of our previous expressions, $T = t + \tau$. Equation 15.11a shows that unless $2^t \beta_{\tau+t,\tau}$ remains constant as t increases, the contribution to cumulative response from selection on adults in generation τ changes over time. For strictly additive loci (under random mating), $\sigma_G(\tau + t, \tau) = 2^{-t} \sigma_A^2(\tau)$ and thus $2^t \beta_{\tau+t,\tau} = h_\tau^2$, the standard result from the breeder's equation. Conversely, any term of $\sigma_G(\tau + t, \tau)$ that decreases by more than one half in each generation contributes only to the transient response, as $2^t \sigma_G(\tau + t, \tau) \rightarrow 0$ as $t \rightarrow \infty$. An exception to this condition occurs under pure selfing. Here, an individual has only a single ancestor t generations ago (as opposed to 2^t ancestors under random mating), resulting in the total contribution in generation $t + \tau$ from an ancestor in generation τ of $\sigma_G(\tau + t, \tau)$. Hence, any term contributing to $\sigma_G(\tau + t, \tau)$ that decreases to 0 as $t \rightarrow \infty$ contributes only to the transient response.

Example 15.1. As an application of ancestral regressions, consider the situation that arises with additive-by-additive epistasis. In this case, Cockerham (1984b) found (under the infinitesimal model) that for two linked loci, the cross-generation covariance is

$$\sigma_G(\tau + t, \tau) = \frac{\sigma_A^2(\tau)}{2^t} + \frac{\sigma_{AA}^2(\tau)}{2} \left(\frac{1-c}{2} \right)^t$$

yielding

$$2^t \sigma_G(\tau + t, \tau) = \sigma_A^2(\tau) + (1-c)^t \frac{\sigma_{AA}^2(\tau)}{2}$$

Provided the genetic variances remain constant, applying Equation 15.11a recovers Equation 15.3.

Example 15.2. Consider the expected response under arbitrary levels of additive epistasis (under the infinitesimal model with unlinked loci). LW Equation 7.12 shows the genetic covariance between relatives x and y as

$$\begin{aligned} \sigma_G^2(x, y) &= (2\Theta_{x,y}) \sigma^2(A) + (2\Theta_{x,y})^2 \sigma^2(AA) + \cdots + (2\Theta_{x,y})^i \sigma^2(A^i) \\ &= \sum_{i=1}^n (2\Theta_{x,y})^i \sigma^2(A^i) \end{aligned}$$

where $\sigma^2(A^i)$ denotes the genetic variance due to i th-order additive epistasis. The coefficient of coancestry $\Theta_{t,t+\tau}$ between a parent in generation t and a direct descendant in generation $t + \tau$ under random mating is

$$\Theta_{t,t+\tau} = \left(\frac{1}{2}\right)^{\tau+1}$$

Using this result, the contribution, $\sigma_{G,i}(t + \tau, t)$, to the total genetic covariance due to i th-order additive epistasis (A^i) becomes

$$\sigma_{G,i}(t + \tau, t) = (2\Theta_{t+\tau,t})^i \sigma^2(A^i) = 2^i \left(\frac{1}{2}\right)^{(\tau+1)i} \sigma^2(A^i) = \left(\frac{1}{2}\right)^{\tau i} \sigma^2(A^i)$$

and the ancestral regression terms involving $\sigma^2(A^i)$ become

$$2^\tau \frac{\sigma_{G,i}(t + \tau, t)}{\sigma^2(A^i)} = 2^\tau \frac{(1/2)^{\tau i} \sigma^2(A^i)}{\sigma^2(A^i)} = 2^\tau 2^{-\tau i} = \left(\frac{1}{2}\right)^{\tau(i-1)} = \left(\frac{1}{2^{i-1}}\right)^\tau$$

With constant selection, S , the contribution to total response from i th-order additive epistasis follows from Equation 15.11b:

$$R_{A^i}(t) = S \frac{\sigma^2(A^i)}{\sigma_z^2} \sum_{\tau=1}^t \left(\frac{1}{2^{i-1}}\right)^\tau \quad (15.13a)$$

Recalling Equation 15.5b,

$$\sum_{\tau=1}^t \left(\frac{1}{2^{i-1}}\right)^\tau = \frac{x(1-x^t)}{1-x}, \quad \text{where } x = (1/2)^{i-1} \quad (15.13b)$$

The limit of this sum (as $t \rightarrow \infty$) is

$$\frac{x}{1-x} = \frac{(1/2)^{i-1}}{1-(1/2)^{i-1}} = \frac{1}{2^{i-1}-1} \quad (15.13c)$$

Because the scaled initial contribution, $R_{A^i}(1)/[S\sigma^2(A^i)/\sigma_z^2]$, equals $(1/2)^{i-1}$, the additional total increment to response beyond that seen in the first generation follows from Equations 15.13a and 15.13c:

$$\frac{\tilde{R}_{A^i} - R_{A^i}(1)}{S\sigma^2(A^i)/\sigma_z^2} = \frac{1}{2^{i-1}-1} - \frac{1}{2^{i-1}} = \frac{1}{(2^{i-1}-1)2^{i-1}}$$

The response in generation one, $R(1)$, and at the limit, \tilde{R} (both scaled in units of $S\sigma^2(A^i)/\sigma_z^2$), and the fraction of total response occurring in the first generation, $R(1)/\tilde{R}$, are as follows:

	AA	AAA	AAAA	AAAAA
$R(1)/[S\sigma^2(A^i)/\sigma_z^2]$	0.500	0.250	0.125	0.063
$\tilde{R}/[S\sigma^2(A^i)/\sigma_z^2]$	1.000	0.333	0.143	0.067
$R(1)/\tilde{R}$	0.500	0.750	0.875	0.938

As shown in the second line of this table, the limiting contribution, \tilde{R} , is small for higher-order additive epistasis among unlinked loci. For example, for four-way additive epistasis, the total response is $\sim 14\%$ ($0.143/1.000$) of the expected response under two-way additive epistasis when the two variance components are equal, $\sigma^2(AA) = \sigma^2(AAAA)$. Further, as the final line in the table shows, $\sim 88\%$ of the total response from four-way additive epistasis occurs in the first generation of selection.

RESPONSE DUE TO ENVIRONMENTAL CORRELATIONS

Imagine a situation where a bird is large by chance, enabling it to defend a larger and more productive breeding location. As a result, its offspring are better provisioned and are larger themselves, above and beyond any genetic effects on size. This is an example of a **shared environmental effect** and is a special case of the more general setting where at least part of the environment experienced by an individual is a function of the phenotypes of other individuals with which they interact (Chapter 22). Rossiter (1996), Bonduriansky and Day (2009), and Bonduriansky et al. (2012) reviewed a number of such shared environmental effects, while Day and Bonduriansky (2011) modeled the expected response in a number of different settings using the Price equation framework (Chapter 6).

As Equation 15.1a indicates, shared parent-offspring environmental effects—a nonzero value of $\sigma(E_p, E_o)$ —can influence the selection response. This contribution is also transient. Consider a character whose variation is *entirely* environmental, in which case the phenotypic value can be decomposed as

$$z = \mu + E = \mu + e_{fa} + e_{mo} + e$$

where μ is the mean value of the character when environmental effects are randomly distributed, and the environmental value, E , has been decomposed into the maternal and paternal contributions to the offspring due to shared environmental effects (e_{mo} and e_{fa}) and a residual due to special environmental effects (e), where $E[e] = 0$. In order to predict the shared environmental contribution from a parent, we assume the simplest model, wherein a fraction, b , of the total environmental value of a parent is passed on to its offspring.

This model serves as a useful introduction to some of the dynamics that can occur for certain models of maternal effects (examined in the next section). It also serves as a model for selection response under **epigenetics**, wherein a nongenetic modification is passed through generations (e.g., factors bound to the DNA that alter the expression level of a gene). While much excitement is made by some on the role of such epigenetic inheritance in evolution, as we will see, its impact is transient if there is even the smallest amount of imperfection in transmission.

To simplify matters further, assume that this regression coefficient is independent of the sexes of the parent and offspring, although this condition can easily be relaxed. Here the expected contribution from a father to his offspring is $e_{fa} = b E_{fa} = b(z_{fa} - \mu)$, where E_{fa} is the father's total environmental value. Further assuming that the parents and the offspring have the same phenotypic variance, then $b = \rho/2$, where ρ is the slope of the midparent-offspring regression. In principal, b can be negative under some environmental conditions, e.g., if parents and offspring compete for a limited common resource, and larger parents gather a disproportionate share of resources, resulting in smaller offspring.

Provided E_{fa} and E_{mo} are uncorrelated, the expected value of an offspring from parents with phenotypic values of z_{fa} and z_{mo} is

$$E[z_o | z_{mo}, z_{fa}] = \mu + \frac{\rho}{2}(z_{fa} - \mu) + \frac{\rho}{2}(z_{mo} - \mu) \quad (15.14a)$$

where μ is the population baseline mean under randomized environmental effects. Denoting the mean of adults selected in generation t by μ_t^* , the mean at generation $t + 1$ is given by

$$\mu_{t+1} = \mu + \rho(\mu_t^* - \mu) \quad (15.14b)$$

where $(\mu_t^* - \mu)$ is the average environmental deviation of the selected parents at generation t , a fraction, ρ , of which is passed on to their offspring. If shared environmental effects are only passed on through one parent, $\rho/2$ replaces ρ in Equation 15.14b. Rewriting the mean after selection as $\mu_t^* = \mu_t + S_t$,

$$\mu_{t+1} = \mu + \rho(\mu_t + S_t - \mu) \quad (15.15)$$

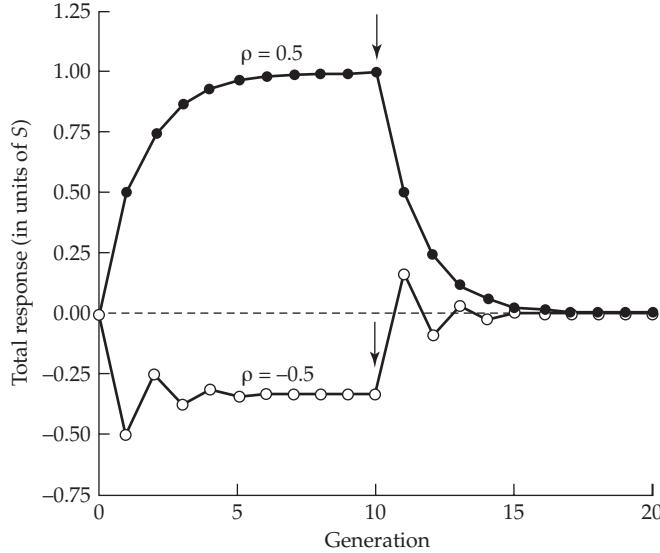

Figure 15.2 The response when resemblance between relatives is due entirely to correlation between environmental values in parents and offspring. Selection with a constant value of S starts at $t = 0$ and continues until generation 10 (indicated by the arrow), at which point selection is stopped. Note the interesting dynamics that occur if environmental values are negatively correlated, wherein the response to selection is reversed with respect to the selection differential. In this case, selection for *increased* character value results in a *decreased* mean value, with the total response in this example eventually converging to $-S/3$ (for $\rho = -0.5$). Once selection is relaxed (denoted by the arrows), there is an initial positive response (generation 11), which then quickly decays to zero.

and defining the change in mean as $\Delta\mu_t = \mu_{t+1} - \mu_t$ yields

$$\begin{aligned}\Delta\mu_t &= [\mu + \rho(\mu_t + S_t - \mu)] - [\mu + \rho(\mu_{t-1} + S_{t-1} - \mu)] \\ &= \rho[(\mu_t - \mu_{t-1}) + (S_t - S_{t-1})] \\ &= \rho[\Delta\mu_{t-1} + (S_t - S_{t-1})]\end{aligned}\quad (15.16a)$$

Suppose that constant selection (with a differential of S) is applied starting at generation 1. Here, $\Delta\mu_0 = 0$, $S_0 = 0$, and $S_t = S$ for $t \geq 1$. Equation 15.16a then gives $\Delta\mu_1 = \rho S$. Further iterations yield the increment from selection in generation t to the total response as

$$\Delta\mu_t = \rho^t S \quad (15.16b)$$

which (like epistasis) decreases in each generation, and approaches zero for large values of t . Hence, even under continued selection, the total response to selection eventually reaches a limit. Note that if $\rho < 0$, the sign of the increment-specific response switches in each generation (Figure 15.2).

The reason for this decline in the per-generation rate of response, $\Delta\mu_t$, can be seen from Equation 15.16a. The change in the character mean due to previous selection decays, counteracting the gain from selection in the current generation. Only a fraction, ρ , of the change from generation $t - 1$ is passed on, and in general, only ρ^k of the response from generation $t - k$ persists by generation t . Summing over Equation 15.16b, the total response to selection after t generations is

$$R(t) = \mu_t - \mu_0 = \sum_{i=1}^t \Delta\mu_i = S \sum_{i=1}^t \rho^i \quad (15.16c)$$

Recalling the partial sum of a geometric series (Equation 15.5b), this reduces to

$$R(t) = S \frac{\rho}{1 - \rho} (1 - \rho^t) \quad (15.17a)$$

Note from Equation 15.17a that the sign of the total response does not change over t (as $|\rho| < 1$) and equals the sign of ρ . While the per-generation response, $\mu_{t+1} - \mu_t = \rho^t S$ (Equation 15.16b), may change sign each generation (provided $\rho < 0$), the absolute magnitude of this per-generation change rapidly decreases with t , resulting in no change of sign in the total response.

As was the case for epistasis, the total cumulative response reaches an equilibrium value representing the balance between the generation of correlations by selection and their removal by reproduction, with

$$\tilde{R} = \lim_{t \rightarrow \infty} R(t) = S \frac{\rho}{1 - \rho} \quad (15.17b)$$

Thus, no matter how long selection is applied, the mean can never change by more than $S\rho/(1 - \rho)$. Further, none of this response is permanent. Suppose selection is stopped after t generations, resulting in $S_t = S$, $S_{t+\tau} = 0$ for $\tau \geq 1$. If we substitute these values of S into Equation 15.16a and use Equation 15.16b, the expected change in generation $t + \tau$ is

$$\Delta\mu_{t+\tau} = \rho^\tau (\Delta\mu_t - S) = \rho^\tau (\rho^t S - S) = -S \rho^\tau (1 - \rho^t) \quad (15.18)$$

Using this result, by generation $t + \tau$, the cumulative response is

$$R(t + \tau) = R(t) + \sum_{i=1}^{\tau} \Delta\mu_{t+i} = R(t) - S (1 - \rho^t) \sum_{i=1}^{\tau} \rho^i = \rho^\tau R(t) \quad (15.19a)$$

The last step follows if we first note from Equation 15.17a that $S(1 - \rho^t) = [(1 - \rho)/\rho]R(t)$. Using this identity, and applying Equation 15.15b with $x = \rho$ and $n = \tau$, yields

$$-S (1 - \rho^t) \sum_{i=1}^{\tau} \rho^i = - \left[R(t) \frac{1 - \rho}{\rho} \right] \left[\frac{\rho(1 - \rho^\tau)}{1 - \rho} \right] = -(1 - \rho^\tau) R(t) \quad (15.19b)$$

Observe that Equation 15.19a converges to zero, with the rate of decay set by ρ (Figure 15.2). The half-life, $t_{1/2}$, of the decay in response follows from solving $\rho^{t_{1/2}} = 1/2$, or

$$t_{1/2} = -\frac{\ln(2)}{\ln(\rho)} \quad (15.19c)$$

Hence, while there can be some selection response when the resemblance between relatives is entirely environmental, any response is transient and decays away once selection stops. Further, no matter how long selection proceeds, the total response asymptotes to a limit beyond which no further response is excepted (Equation 15.17b).

As mentioned, these results bear on the role of epigenetic inheritance. The correlation, ρ , is a measure of the **persistence of an epigenetic modification** (be it cultural, hormonal, or from proteins bound to DNA). When the persistence of an effect is high (ρ is close to one), a trait can achieve a significant selection response under purely epigenetic inheritance (Equation 15.17b), and the response can persist for several generations following the cessation of selection (Equation 15.19a). For example if $\rho = 0.95$ (a 5% loss of the effect each generation), then a total response of $S \cdot 0.95/0.05 = 19S$ can be achieved. After selection stops, half this expected gain is lost in $-\ln(2)/\ln(0.95) \approx 14$ generations (Equation 15.19c). While impressive, from an evolutionary standpoint, none of this short-term gain translates into a long-term, permanent, selection response.

SELECTION IN THE PRESENCE OF HERITABLE MATERNAL EFFECTS

A mother can influence the phenotype of her offspring in two ways. The usual assumption simply involves gene transmission (including those genes on organelle genomes). Together with paternally derived genes, these maternally transmitted genes create the genotype of the offspring, and the expression of this genotype, together with the environment it experiences, determines the phenotype. The second route is through **maternal effects**, which are traits or genes *expressed in the mother* that influence offspring phenotypes (Wolf and Wade 2009). These can be thought of as influencing the *environment* that a mother's offspring experiences, which can, in turn, influence its phenotype. Examples include **maternal performance characters** such as her body size, amount of care invested in offspring, milk yield, and endosperm production, all of which can influence a variety of progeny traits. These maternal performance traits can themselves have a genetic basis, and hence can also respond to selection, thus creating potentially very complex dynamics even in the simplest settings.

Paternal effects are also possible, especially in situations where the father plays a role in caring for the offspring. While not considered here, they can be treated in exactly the same fashion as maternal effects. There is an extensive literature on maternal effects and their evolutionary implications (reviewed by Roach and Wulff 1987; Bernardo 1996; Rossiter 1996; Mousseau and Fox 1998; Reinhold 2002; Räsänen and Kruuk 2007; Mousseau et al. 2009). Here we introduce some of the basic ideas, with additional material developed in Chapters 22, 29, and 30.

Example 15.3. Maternal effects include genes expressed in the mother that influence the very early development of her offspring, with the maternal phenotype of these genes being extremely difficult to measure in the mother. For many metazoans, much of the gene expression during the first few rounds of cell division in a newly fertilized zygote is due to the translation of maternal mRNAs deposited in the egg. The resulting maternal gene products provide information for early key development steps in the nascent embryo, with the impact of these maternal genes seen in the trait values of the offspring, but not in the mother's own phenotype. A classic example involves the work of Sturtevant (1923) on right- versus left-handed shell coiling of the snail *Limnaea*, where the genotype of the mother, not the offspring, determines offspring phenotype. Offspring from a mother homozygous for the *sinistral* allele are all left-handed, independent of their genotype, whereas the presence of at least one *dextral* allele in the mother yields all right-handed offspring. While the maternal trait is easy to assay from observations on her offspring, it cannot be assayed using just the mother alone, as the products from the *sinistral/dextral* locus are still unknown, although Kuroda et al. (2009) have showed that the direction of coiling is determined at the eight-cell stage of the embryo.

Decomposing Maternal Effects

Assuming a maternal effect, the environmental value, E , for the focal trait in an individual can be decomposed as $E = M + e$, comprised of a **maternal performance** component, M , contributed by the mother plus an environmental deviation, e , resulting in a trait value of

$$z = G + E = G + M + e \quad (15.20a)$$

The genotypic value, G , of the offspring is often referred to as the **direct (or intrinsic) effect** on the trait, reflecting the inherent genetics of the individual. If M is entirely environmental in basis, the results of the previous section (on correlated environmental values) apply, and any contribution from maternal effects is transient. However, there is often a *genetic* component to M , with the result that selection can change the population means of *both* the direct and the maternal values (Dickerson 1947; Willham 1963, 1972; Cheverud 1984a;

Riska et al. 1985; Kirkpatrick and Lande 1989). In this case, $M = G_m + E_m$, where G_m is the contribution to the offspring value resulting from the mother's genotypic value for the maternal performance character, while E_m is the contribution resulting from the environmental value of the maternal performance character (reviewed in LW Chapter 23). Thus, although M is treated as an environmental effect from the offspring's standpoint, it can have both a genetic and an environmental basis in the mother.

Letting G_d denote the genotypic value of the direct effect (previously G), the phenotypic value of an individual can be written in terms of direct and maternal contributions

$$z = G + M + e = G_d + G_m + E_m + e \quad (15.20b)$$

This significantly complicates the selection response, as if the correlation between G_d and G_m is negative, selection to increase a trait might result in an improved direct value ($\Delta\mu_{G_d} > 0$) but a decreased maternal value ($\Delta\mu_{G_m} < 0$). In the extreme, this can result in a *reversed selection response*, with the decline in maternal environment overwhelming any improvement in direct effects. Because trait value, z , is a function of two potentially correlated genetic components, G_d and G_m , this is formally a multiple-trait problem and can be attacked with the machinery of multivariate selection (Cheverud 1984a; Kirkpatrick and Lande 1989, 1992; Lande and Kirkpatrick 1990). However, we first consider the simplest case, where M is a function of the value of the focal trait in the mother, which collapses the model to a single-trait problem, but with much more complicated dynamics than suggested by the simple breeder's equation. We then very briefly discuss a two-trait model, while Volume 3 examines maternal effects in the full multivariate framework.

An important point to note is that maternal-effects models are a special case of **associative effects** (or **social**, or **indirect genetic effects**) models, where the phenotype of an individual within a group is a function of both its direct value plus the associative values from members of its group. Here the group is an offspring and its mother. Both kin and group selection, which are special cases of this more general formulation, are examined in detail in Chapter 22.

Selection Response Under Falconer's Dilution Model

One of the simplest models of maternal effects (motivated by the inheritance of litter size in mice) is that of Falconer (1965): the value of the focal trait in the mother determines M (reviewed in LW Chapter 23). Falconer reasoned that offspring from large litters receive less maternal resources per individual than those in smaller litters, and that this can have carryover effects when they become mothers themselves.

Assume that the maternal contribution is a linear function of the maternal phenotype, z_{mo} (the size of her litter), so that $M = mz_{mo}$ and, upon substitution of this result into Equation 15.20a, the phenotypic decomposition becomes

$$z = G + M + e = G + m z_{mo} + e \quad (15.21)$$

Conceivably, M could be a nonlinear function of z_{mo} , but linearity is assumed for tractability. Equation 15.21 is called the **dilution model**, because the effect of the maternal phenotype becomes diluted over successive generations (for $|m| < 1$). The parameter m can be regarded as the partial regression coefficient (i.e., holding the offspring's genotypic value, G , constant) of offspring phenotype on maternal phenotype and can be estimated as the difference between slopes of the maternal- and paternal-offspring regressions (LW Equation 23.13).

Negative estimates of m have been reported: values of -0.15 for litter size in mice (Falconer 1965); of -0.58 and -0.40 for age of maturity in two replicate lines of the springtail insect, *Orchesella cincta* (Janssen et al. 1988); of -0.25 for clutch size in the collared flycatcher, *Ficedula albicollis* (Schluter and Gustafsson 1993); and of -0.29 for juvenile growth rate in the red squirrel *Tamiasciurus hudsonicus* (McAdam and Boutin 2003).

If we further assume that the joint distribution of phenotypes and breeding values in parents and offspring is multivariate normal and there is an absence of epistasis, the

expected phenotypic value of an offspring whose mother has a phenotypic value of z_{mo} is

$$E[z_o | A_{mo}, A_{fa}, z_{mo}] = \frac{A_{mo}}{2} + \frac{A_{fa}}{2} + m z_{mo} \quad (15.22a)$$

where A_{mo} and A_{fa} are the maternal and paternal breeding values. Averaging over the selected parents, the mean in generation t becomes

$$\mu_z(t+1) = \frac{A_{fa}^*(t) + A_{mo}^*(t)}{2} + m \mu_{mo}^*(t) \quad (15.22b)$$

where $A_{fa}^*(t)$ and $A_{mo}^*(t)$ are the mean breeding values of the selected parents and $\mu_{mo}^*(t)$ is the mean phenotypic value of selected mothers in generation t . The first term is the expected breeding value in the offspring, $\mu_A(t)$, and the second term is the additional maternal contribution.

To proceed in using this model to predict response, we first use the regression of breeding value on phenotype

$$A = \mu_A + b_{A|z} (z - \mu_z) + e$$

In particular, we can rewrite $A_{mo}^*(t) = E_s[A_{mo}]$, the expected breeding values in selected mothers, as

$$\begin{aligned} A_{mo}^*(t) &= E_s[A_{mo}(t)] = E_s \left[\mu_A(t) + b_{A|z} [z_{mo} - \mu_z(t)] + e \right] \\ &= \mu_A(t) + b_{A|z} S_{mo}(t) \end{aligned} \quad (15.22c)$$

where $E_s[\cdot]$ denotes the expected value over the selected parents and S_{mo} denotes the selection differential on the trait in mothers in generation t . A similar expression for $A_{fa}^*(t)$ includes the selection differential, S_{fa} , on fathers. In the absence of maternal effects, $b_{A|z} = h^2$. However, the dilution model generates an equilibrium covariance between M and A , specifically $\sigma_{A,M} = m \sigma_A^2 / (2 - m)$, which in turn alters the covariance between z and A (Falconer 1965; Kirkpatrick and Lande 1989; see LW Equation 23.12a). The resulting regression slope (at equilibrium) is

$$b_{A|z} = h^2 \frac{2}{2 - m} \quad (15.23a)$$

The expected breeding value in the offspring is the average of the breeding values of the selected parents, which (from Equations 15.22c and 15.23a) yields

$$\mu_A(t+1) = \frac{A_{mo}^*(t) + A_{fa}^*(t)}{2} = \mu_A(t) + \frac{h^2}{2 - m} (S_{mo}(t) + S_{fa}(t)) \quad (15.23b)$$

Substituting this result for the average of the breeding values in Equation 15.22b and using $\mu_{mo}^*(t) = \mu_z(t) + S_{mo}(t)$ yields

$$\mu_z(t+1) = \mu_A(t) + \frac{h^2}{2 - m} (S_{mo}(t) + S_{fa}(t)) + m (\mu_z(t) + S_{mo}(t)) \quad (15.24)$$

The change in population mean over one generation, $\Delta\mu_z(t)$, is thus

$$\begin{aligned} \Delta\mu_z(t) &= \mu_z(t+1) - \mu_z(t) = \left[\mu_A(t) + \frac{h^2}{2 - m} (S_{mo}(t) + S_{fa}(t)) + m (\mu_z(t) + S_{mo}(t)) \right] \\ &\quad - \left[\mu_A(t-1) + \frac{h^2}{2 - m} (S_{mo}(t-1) + S_{fa}(t-1)) + m (\mu_z(t-1) + S_{mo}(t-1)) \right] \end{aligned}$$

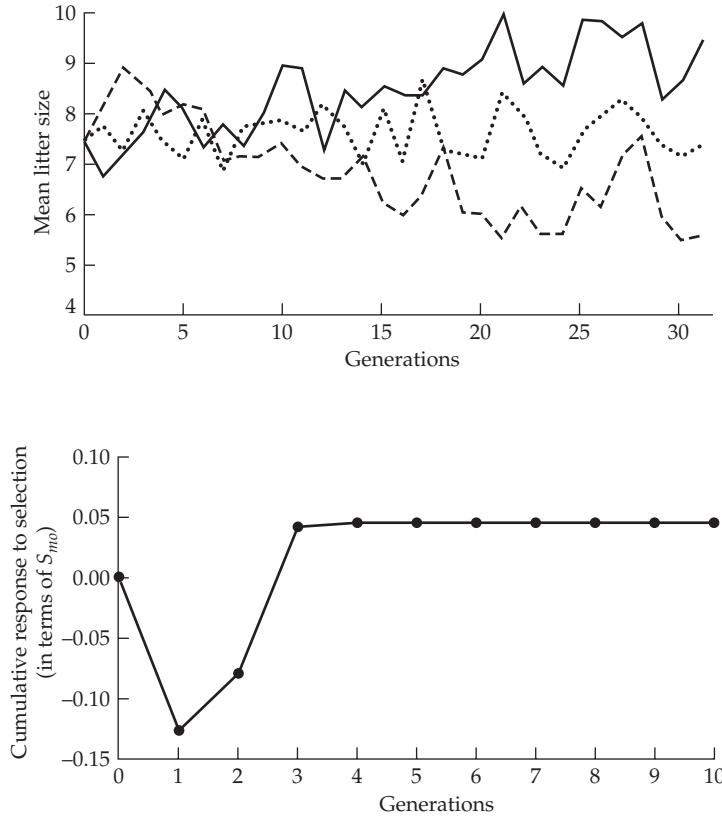

Figure 15.3 **Top:** Falconer's experiments on selection response for litter size in mice. The dashed line is the response to selection for smaller litters, the thick line is the response to selection for larger litters, and the dotted line is the control. Note the reversed response in the first generation in both the up- and down-selected lines. (After Falconer 1960b.) **Bottom:** The predicted change in population mean following a single generation of selection on females with $S_{mo} > 0$ (using Falconer's estimated values of $h^2 = 0.11$ and $m = -0.13$). There is a reversed response in the first generation, even though the net genetic change is to increase the character. By generation 3, the net nongenetic change in phenotypic mean has largely decayed away, revealing the net genetic change of $S_{mo} h^2 / [(1 - m)(2 - m)] = 0.044 \cdot S_{mo}$ (Equation 15.33).

which, using Equation 15.23b, simplifies to

$$\Delta\mu_z(t) = \frac{h^2}{2-m} \left(S_{mo}(t) + S_{fa}(t) \right) + m S_{mo}(t) + m \left(\Delta\mu_z(t-1) - S_{mo}(t-1) \right) \quad (15.25)$$

This result can be interpreted as follows: the first two terms are the change in character value resulting from selection in generation t due to genetic ($h^2 / [2 - m]$) and maternal (m) contributions. The final term, which can be expressed as $m [\mu_z(t) - \mu_z^*(t-1)]$, represents the decay in the maternal contribution from the previous generation.

Assuming that an equilibrium for maternal effects has been reached such that Equation 15.23a holds and then starting with an unselected base population, the response to a single generation of selection is

$$\Delta\mu_z(1) = \frac{h^2}{2-m} \left(S_{mo}(1) + S_{fa}(1) \right) + m S_{mo}(1) \quad (15.26)$$

An interesting implication of Equation 15.26 is that if $m < 0$, there is some possibility of a reversed response, with $\Delta\mu_z$ being opposite in sign from S . If $S_{fa} = S_{mo} = S$, a reversed response is expected if

$$m < 1 - \sqrt{1 + 2h^2} \quad (15.27a)$$

If selection is only occurring on females, this condition is

$$m < 1 - \sqrt{1 + h^2} \quad (15.27b)$$

An example of an apparent maternally induced reversed response was seen by Falconer (1960b, 1965) in his selection experiments on litter size in mice. This character shows a negative maternal effect, with m and h^2 estimated to be -0.13 and 0.11 , respectively. Because selection for litter size occurs only in females, Equation 15.27b implies that a reversed response in the first generation is expected (as $1 - \sqrt{1 + 0.11} \approx -0.05 > m = -0.13$). As Figure 15.3 shows, a reversed response was indeed observed.

An observed reversed response can be misleading because the *permanent* response is expected to have the same sign as S , while the initial observed response also includes a transient component that (in this case) is of the opposite sign and of a larger magnitude than the permanent response component. It may take several generations for this transient component to decay to the point that the actual genetic changes are revealed (Figure 15.3). For a single generation of selection, the expected genetic change is $2S h^2 / [(2-m)(1-m)]$, as shown by Equation 15.33 (below).

The possibility of a reversed selection response hints at some of the complicated dynamics that can appear when maternal effects are present. To examine these dynamics in more detail, consider the dilution model with constant directional selection occurring equally on both sexes, i.e., $S_{fa}(t) = S_{mo}(t) = S$ for $t \geq 1$. Iteration of Equation 15.25 yields

$$\Delta\mu_z(t) = S \left[\frac{2h^2}{(1-m)(2-m)} \left(1 - m^t \right) + m^t \right] \quad (15.28a)$$

which (for $|m| < 1$) converges to

$$\Delta\mu_z = S \frac{2h^2}{(1-m)(2-m)} \quad (15.28b)$$

Hence, after a sufficient number of generations, the per-generation change is constant. If $|m|$ is near zero, the per-generation response rapidly converges to this asymptotic value, while if $|m|$ is near one, the rate of convergence is considerably slower. Summing over the single-generation changes (Equation 15.28a) and recalling Equation 15.5b, the cumulative response to t generations of selection is

$$R(t) = \sum_{i=1}^t \Delta\mu_z(i) = \frac{S}{1-m} \left[t \frac{2h^2}{2-m} + m(1-m^t) \left(1 - \frac{2h^2}{(1-m)(2-m)} \right) \right] \quad (15.29a)$$

which converges (for $|m| < 1$) to

$$\frac{S}{1-m} \left[\frac{2h^2}{2-m} \left(t - \frac{m}{1-m} \right) + m \right] \quad (15.29b)$$

How much of this response is permanent? Suppose selection ends at generation t , and suppose we denote by τ the number of generations since selection was stopped. Iterating Equation 15.25 with $S(t) = S$, $S(t+\tau) = 0$ for $\tau \geq 1$ yields

$$\Delta\mu_z(t+\tau) = m^\tau [\Delta\mu_z(t) - S] \quad (15.30)$$

where $\Delta\mu_z(t)$ is given by Equation 15.28a. Thus, *the selection response continues even after the cessation of selection* (Figure 15.3), a feature that Kirkpatrick and Lande (1989) called **evolutionary momentum**. Using Equation 15.5b to sum Equation 15.30 over τ yields the cumulative response *following* the last generation of selection

$$R^*(\tau) = \frac{m(1-m^\tau)}{1-m} [\Delta\mu_z(t) - S] \quad (15.31)$$

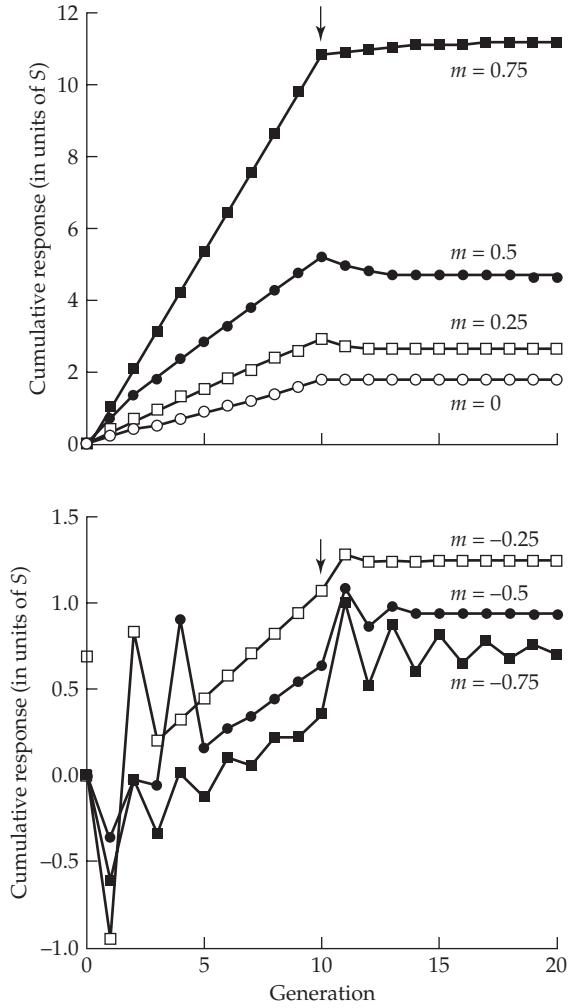

Figure 15.4 Examples of the predicted selection response with maternal effects under Falconer’s dilution model. Selection starts at generation 0, with $S_{fa} = S_{mo} = S$ until generation 10 (arrows), at which point selection stops. We assume that $h^2 = 0.35$ throughout, with the different curves corresponding to different maternal effect coefficients, m . **Top:** Positive maternal effects ($m > 0$). For this value of h^2 , Equation 15.34a gives the critical m value (below which some erosion of response occurs upon cessation of selection) as 0.52, meaning that the selection response continues (for a few generations) after selection is relaxed for $m = 0.75$, while response decays for $m = 0.5$ and 0.25. **Bottom:** Negative maternal effects ($m < 0$). The dynamics here are considerably more interesting, with additional response following the cessation of selection for all values of $m < 0$.

which, as $\tau \rightarrow \infty$, converges to

$$R^* = S \frac{m(1-m^t)}{1-m} \left[\frac{2h^2}{(1-m)(2-m)} - 1 \right] \quad (15.32)$$

Summing Equations 15.29a and 15.32, the *permanent* response to t generations of selection is

$$R(t) + R^* = t h^2 S \frac{2}{(1-m)(2-m)} \quad (15.33)$$

which is just t times the asymptotic response (Equation 15.28b). If R^* is opposite in sign to S , there is some erosion of the cumulative response upon relaxation of selection (we have already seen a special case of this with reversed response). For $|m| < 1$, erosion in response occurs if

$$0 < m < \frac{3 - \sqrt{1 + 8h^2}}{2} \quad (15.34a)$$

On the other hand, if maternal effects are either negative ($m < 0$) or sufficiently large

$$m > \frac{3 - \sqrt{1 + 8h^2}}{2} \quad (15.34b)$$

the response *will continue* for a few generations following the relaxation of selection. This occurs by the transient component of response decaying away to reveal the actual permanent response due to changes in breeding values. Figure 15.4 plots some sample trajectories.

In summary, the presence of maternal effects introduces several complications even under this simplest of models (in which the direct and maternal trait are the same). First, predicting the response to selection in a given generation requires, not only knowledge of the inheritance parameters (m, h^2) and current selection differential, but also knowledge of *previous selection*, namely, $\Delta\mu_z(t-1)$ and $S_{mo}(t-1)$. Second, after selection is stopped, the mean is likely to continue to change due to lag effects (e.g., Figure 15.4). If $m < 0$, the response will continue, while if $m > 0$, the response may either continue or partly decay. This clearly causes problems if we are trying to estimate the nature of selection acting on a character by comparing changes in means between generations. For example, an observed cross-generation decrease in a character could be due to four very different causes: (i) $S < 0$, (ii) $S > 0$ and there is a reversed response due to maternal effects, (iii) there is no selection in the observed generation but a previous history of $S > 0$, with the decrease in mean due to a positive maternal effect (reflecting a decay in response), or (iv) there is no current selection but a previous history of $S < 0$, with the decrease in mean due to a negative (or sufficiently large positive) maternal effect (reflecting a continuation of response).

Separate Direct and Maternal Traits

In contrast to Falconer's simple model of maternal effects, where the direct trait has a dual role as the maternal trait, a more general model allows us to separate the direct and maternal traits, e.g., weight in an offspring and milk production in its mother. In this case, Equation 15.21 becomes

$$z = G_d + m z_{m,mo} + e \quad (15.35a)$$

where z is the value of the focal (direct) trait in an offspring (e.g., its weight), and $z_{m,mo}$ is the value of the maternal trait in its mother (e.g., her milk production, which influences offspring weight). Clearly, this expression generalizes to a vector, \mathbf{z}_d , of direct traits that depends on a vector, \mathbf{z}_m , of maternal traits, as modeled by Kirkpatrick and Lande (1989, 1992) and Lande and Kirkpatrick (1990). We examine their full multivariate treatment in detail Volume 3. Here, we briefly comment on the bivariate case (a single direct trait, $z = z_d$, and a single, and distinct, maternal trait, z_m). Note that the selection response in z depends on two components, a direct response, R_d , due to changes in G_d and a response, R_m , due to changes in the maternal trait (which influences the phenotype of the direct trait), hence

$$R_z(t) = \Delta\mu_z(t) = R_d(t) + mR_m(t-1) \quad (15.35b)$$
