Although Bateman gradients are usually framed for dioecious species, Arnold (1994) also considered monoecious (hermaphroditic) species (for example, many flowering plants), and a much more complete treatment was offered by Anthes et al. (2010), whose approach we follow. Provided one can track the offspring produced via male and female gametes from the same individual, the generalized Bateman gradients become

$$RS_m = \text{const} + \beta_{mm} MS_m + \beta_{mf} MS_f + e_m \quad (29.13a)$$

$$RS_f = \text{const} + \beta_{ff} MS_f + \beta_{fm} MS_m + e_f \quad (29.13b)$$

RS_m and RS_f correspond, respectively, to the male RS (offspring resulting from sperm or pollen donated by the focal individual fertilizing the eggs of others) and female RS (offspring resulting from eggs from the focal individual fertilized by the sperm or pollen of others). Likewise, MS_m and MS_f correspond to the number of matings that the focal individual was involved in as a sperm or pollen donor and as an egg donor, respectively.

The various regression coefficients in Equation 29.13 can be interpreted as follows. Consider the situation in which an individual gains an additional mating in which it contributes male gametes, while the number of times it served as an egg donor is held constant (MS_m increases by one and MS_f is held constant). From Equations 29.13a and 29.13b, we expect the reproductive success from mate gametes (RS_m) to increase by β_{mm} and reproductive success from female gametes (RS_f) to change by β_{fm} . A negative value of the latter suggests a tradeoff between male and female gamete production and mating. Likewise, β_{ff} and β_{mf} are the expected changes to RS_f and RS_m , respectively, caused by a one-unit change in MS_f with MS_m held constant. Finally, when individuals can self, a third system of gradients appears,

$$RS_{s_e} = \text{const} + \beta_{s_e m} MS_m + \beta_{s_e f} MS_f + e_{s_e} \quad (29.13c)$$

where now the index s_e refers to selfing events (Anthes et al. 2010).

A final composite measure of the potential for sexual selection is the **Jones Index**

$$I_J = \beta_{ss} \sqrt{I_s} \quad (29.14a)$$

(Jones 2009). This expression shows the impact of both the number of matings to fitness relationship (β_{ss} ; Equation 29.12) and the variance in number of mates (I_s). If either one is small, there is very little sexual selection pressure on any trait. The original motivation for Equation 29.14a was to place an upper bound on the absolute change in any trait that could be generated by sexual selection. Using the same logic that led to Equation 29.6b, Jones showed that

$$|\bar{\imath}| \leq I_J \quad (29.14b)$$

Henshaw et al. (2016) suggested that the Jones index deserves a more prominent role in measures of the opportunity for sexual selection. Using data from five rather different species (one large and one small mammal, a bird, a beetle, and a fish) as a set of model organisms showing diverse mating systems, they simulated 500 biologically plausible mating systems and examined the correlation between measures of the potential sexual selection (I_s , β_{ss} , I_J , I_δ , and Q) and the actual strength of sexual selection (the actual strength of selection on the simulated mating trait). They found that the Jones index performed the best (had the highest correlation with the actual strength), especially in cases with sex-specific differences. Surprisingly, I_s and β_{ss} , while still correlated with the actual strength of sexual selection, performed the poorest, with I_δ and Q having intermediate levels of success.

The above discussion has mainly dealt with the *potential* for sexual selection, without invoking any specific *traits*. While the Bateman gradient can be thought of as a special case of a trait-fitness regression (where the trait is number of mates), our analysis has otherwise been trait-free. This is both an advantage and a limitation. The advantage is that if the Bateman gradients for both sexes are essentially zero, there is no need to search for traits under sexual selection (Equation 29.14b). The limitation is that a large Jones index (which means that both β_{ss} and I_s are large) only indicates that sexual selection is occurring, and is otherwise uninformative as to the target trait or traits.

A more direct description of the amount of sexual selection on a candidate trait follows from the Robertson-Price identity (Equation 6.10). As above, let $ms = MS/\bar{MS}$ denote the *relative* mating success (the number of mates standardized by the mean number of mates) and z_{sd} denote the variance-standardized value of a candidate trait, namely, $\sigma^2(z_{sd}) = 1$. With these definitions, Jones (2009) defined the standardized strength of sexual selection on a specific trait, the analog of $\bar{\imath} = \sigma(z_{sd}, w)$, as

$$m' = \sigma(z_{sd}, ms) \quad (29.14c)$$

This is also called the **Jones mating differential**. Using this definition with Equation 6.10 yields the **Jones equation** (Jones 2009),

$$\bar{\tau} = \beta_{ss} m' \quad (29.14d)$$

which relates the standardized strength of selection on a trait (the selection intensity, $\bar{\tau}$) with the Bateman gradient (β_{ss}) and the standardized strength of sexual selection (m').

DESCRIBING PHENOTYPIC SELECTION: INTRODUCTORY REMARKS

Thus far, we have dealt with the fitness of individuals, independent of any knowledge of the phenotypes that must be the targets of selection. We conclude this chapter by examining this latter issue of detecting which traits are under selection and describing the nature of that selection. Our ultimate interest in a particular trait might be in predicting its change over time, which requires knowledge of both the nature of selection on that trait and its variance components (Chapter 13). Alternatively, we may simply wish to explore the trait's ecological implications by examining how expected fitness changes with the character value, independently (at least initially) of any concerns about its genetics. Further, we may wish to partition trait fitness across episodes of selection to enhance our understanding of the biological implications of a trait.

Example 29.2 showed how to weight individuals—and therefore how to weight measured traits in those individuals—based on their fitnesses. Hence, one simple approach for detecting selection on a character is to compare its fitness-weighted phenotypic distributions before and after some episode of selection. Such a seemingly reasonable comparison entails a number of significant caveats. We assume that any within-generation change following an episode of selection is *not* due to selection on unmeasured traits that are phenotypically correlated with our focal trait. A closely related assumption is that no spurious fitness-trait associations are generated via unmeasured environmental variables (namely, environmental factors that influence both fitness and our focal trait). Chapter 20 discussed some partial solutions to both of these problems, and we continue this discussion in Chapter 30.

A further caveat is that the phenotypic distribution of a trait can change over time for a myriad of reasons other than selection, such as growth or other ontogenetic changes, immigration, and environmental changes, and great care must be taken to account for these factors. Further, as discussed in Chapters 5 and (especially) 28, pleiotropy can generate fitness associations for a strictly neutral trait. Under the Hill-Keightley model (Chapter 28), trait variation is maintained by the pleiotropic effects on a neutral trait from alleles with deleterious fitness effects. Individuals carrying more mutations have more extreme trait values and lower fitness, which generates apparent stabilizing selection. Similarly, if the direction of new pleiotropic mutations is biased (e.g., on average, mutations lower trait value), then a spurious signal of directional selection can also be generated, as individuals with more mutations have (in this case) lower trait values and lower fitness.

Finally, as we have already seen in this chapter, there are a number of subtle issues in assigning fitnesses to phenotypes when the fitness of a focal individual is influenced by other interacting individuals (Chapter 22). Thoughtful reviews of some of these assignment issues were given by Grafen (1988), Cheverud and Moore (1994), Wolf and Wade (2001), Hadfield and Thomson (2017), and Thomson and Hadfield (2017).

Fitness Surfaces and Landscapes

The expected fitness, $W(z) = E[W|z]$, of an individual with a phenotypic value of z , describes a **fitness surface** (or equivalently, a **fitness function** or a **fitness profile**), relating fitness and character value. The **relative fitness surface**, $w(z) = W(z)/\bar{W}$, is often more convenient than $W(z)$, and we use the two variables somewhat interchangeably. The nature of selection on a character is determined by the local geometry of the individual fitness surface over the range of phenotypic values in the population (Figure 29.5). If fitness is increasing (or decreasing) over some range of phenotypes, a population having its mean value in this interval experiences **directional selection**.

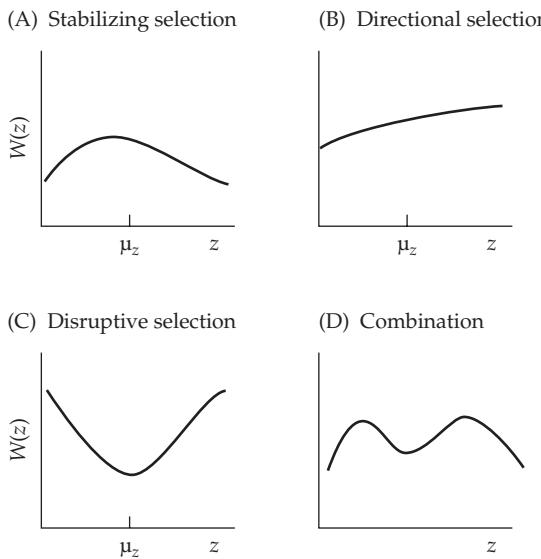

Figure 29.5 Phenotypic selection has historically been classified into three basic forms depending on the local geometry of the individual fitness surface, $W(z)$: stabilizing (**A**), directional (**B**), and disruptive (**C**). As **D** illustrates, populations can also simultaneously experience multiple forms of selection. Likewise, if the population mean (μ_z) in (**A**) does not correspond with the maximum value of $W(z)$, the population experiences directional selection as it is moved toward this value.

The curvature of the fitness surface is important as well. If $W(z)$ contains a local maximum at $z = \theta$, a population with members within an interval encompassing θ is said to experience **stabilizing selection**. If the population is distributed around a local minimum, **disruptive selection** occurs. More generally, we can have negative curvature (downward or **concave**; with a negative second derivative) without having a maximum over the observed range of phenotypes and thus we will not formally have stabilizing selection. Likewise, positive curvature (upward or **convex**; with a positive second derivative) can occur without having a minimum over the observed range of phenotypes and hence will not formally have disruptive selection. As illustrated in Figure 29.5D, when the local geometry of the fitness surface over the range spanned by a population is complex (e.g., multimodal), the simplicity of description offered by these types of quadratic selection surfaces (which can have only a single maximum or minimum) breaks down. Further, $W(z)$ can vary over genotypic and environmental backgrounds. In some situations, the fitness of a phenotype depends on the frequency of other phenotypes in the population (e.g., sexual selection, dominance hierarchies, truncation selection, and when predators have search images). In this case, fitnesses are said to be **frequency-dependent**.

A second important geometry describes how \bar{W} , the expected fitness of the *population*, varies as function of the distribution of phenotypes ($p(z|\Theta)$; where Θ is the vector of distribution parameters, such as the mean and variance) in that population,

$$\bar{W}(\Theta) = \int W(z) p(z|\Theta) dz$$

Mean fitness is a function of both individual fitness, $W(z)$, and the parameters, Θ , of the phenotypic distribution of z , and we are interested in how changes in one or more of the distribution parameters change \bar{W} . For example, if z is normally distributed, we may wish to plot the function, $\bar{W}(\mu_z)$, of mean fitness as a function of μ_z for a given value of σ_z^2 . More generally, one can consider the three-dimensional surface, $\bar{W}(\mu_z, \sigma_z^2)$, of how \bar{W} jointly varies with μ_z and σ_z^2 .

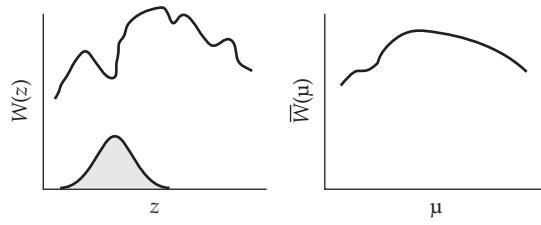

Figure 29.6 In this example, a small change in z is associated with a large change in the *individual fitness surface*, $W(z)$. However, because the mean population fitness, $\bar{W}(\mu_z)$, averages individual fitnesses over the phenotypic distribution (the filled curve in the left panel), small changes in μ_z result in only small changes in $\bar{W}(\mu_z)$. As a result, the corresponding fitness landscape is much smoother than the underlying individual fitness surface.

To stress this distinction between the $W(z)$ and \bar{W} fitness geometries, the former is referred to as the **individual fitness surface**, and the latter as the **mean fitness surface** or (preferably) the **fitness landscape**. The term *landscape* traces back to Simpson (1944, 1952), who called $\bar{W}(\Theta)$ the **adaptive landscape** as an extension (to changes in trait means in phenotypic space) of Wright's notion of an adaptive topography for allele-frequency change in genotypic space (Equation 5.5b). Knowledge of the individual fitness surface allows us to compute the fitness landscape for any specified phenotypic distribution, $p(z)$, but the converse is not true. Given this important distinction between the two different geometries, Lande (1976), Arnold (2003), and Morrissey and Sakrejda (2013) suggested restricting the term *surface* to individual fitnesses, $W(z)$, and the term *landscape* to mean population fitnesses, $\bar{W}(\Theta)$, and we follow this convention here.

Populations, not *individuals*, evolve, and the fitness landscape provides the connection between the fitness of individuals and the evolution of the population. When the breeder's equation holds, the partial derivatives of \bar{W} with respect to the first two phenotypic moments (μ_z and σ_z^2) describe the changes in mean and variance (Example 24.9). More generally, partials of \bar{W} with respect to higher phenotypic moments describe the dynamics of selection in the Barton-Turelli selection-response equations (Equations 24.26 and 24.28). The individual fitness surface may have discontinuities and rough spots, for example, regions where very small changes in phenotypic values result in large changes in individual fitness. As shown in Figure 29.6, such regions are smoothed (at least to some extent) by the averaging of $W(z)$ over $p(z)$ in the fitness landscape, and this smoothing facilitates the existence of the various partials of mean fitness used in the Barton-Turelli equations.

DESCRIBING PHENOTYPIC SELECTION: CHANGES IN PHENOTYPIC MOMENTS

Selection for particular phenotypes changes the trait distribution (although it need not change all moments; for example, the mean may be unchanged). Thus, selection on a target trait can be detected by testing for differences between the distribution of phenotypes before and after some episode of selection. While complete distributions can be compared (e.g., using the d statistic from the DSD approach, as discussed below), the most common procedure for detecting selection acting on a trait is to test for changes in its first few phenotypic moments. Standard statistical tests for differences in means (t tests) and variances (F tests) can be used, but these tests rely on normality assumptions that are often violated, and nonparametric tests may be more appropriate. Differences in means can be tested using the Wilcoxon-Mann-Whitney test, while Conover's squared rank test (Conover 1999) can be used to test for changes in variances. Other nonparametric tests for changes in variance exist, but care must be exercised, as some (e.g., the Siegel-Tukey test) are quite sensitive to differences in means; see Conover (1999) and Sprent and Smeeton (2007). While these issues are important, the main problem in detecting whether selection is occurring on a particular

trait is that changes in the moments may be due entirely to selection on phenotypically correlated characters (Chapters 20 and 30). Keeping this important caveat in mind, we now examine measures of selection for single characters.

Henshaw's Distributional Selection Differential (DSD)

While various nonparametric approaches can be used to compare a distribution of phenotypes before and after an episode of selection, simply finding a significant difference is not particularly informative. Henshaw (Henshaw et al. 2016; Henshaw and Zemel 2017) proposed a metric, the **distribution selection differential (DSD)**, whose statistic is denoted by d , that uses differences in the shape of the entire distribution to quantify the nature and strength of selection. The original definition (Henshaw et al. 2016) was

$$d = \int_{-\infty}^{\infty} |F^*(z) - F(z)| dz, \quad \text{where } F(z) = \int_{-\infty}^z p(x)dx \quad (29.15a)$$

namely, the total difference in the cumulative distribution functions of a trait before and after selection, $F(z)$ and $F^*(z)$, respectively. Empirically, this metric is estimated by

$$\hat{d} = \sum_{i=1}^{n-1} \left[(z_{i+1} - z_i) \cdot \left| \sum_{j=1}^i \frac{1-w_j}{n} \right| \right] \quad (29.15b)$$

where we have ordered phenotypes from smallest (z_1) to largest (z_n), with w_j indicating the relative fitness of the j th-ranked phenotypic value.

Henshaw and Zemel (2017) demonstrated that Equation 29.15a is equivalent to several other definitions, including a generalized Price-Robertson covariance expression (see their paper for details). They also noted two additional useful features of the DSD. First, under strictly directional selection, in which $W(z)$ is a monotonic function of z ,

$$d = |\bar{\tau}| \quad (29.15c)$$

Hence, when computed using a variance-standardized trait, d equals the selection intensity (Equation 13.6a). This observation implies that

$$d_N = d - |\bar{\tau}| \quad (29.15d)$$

provides a measure of the amount of residual selection remaining after the strictly directional component has been removed (the so-called **nondirectional selection fraction**). Second, again for a variance-standardized trait, d is bounded by the variance, I , in relative fitness,

$$d \leq \sqrt{I} \quad (29.15e)$$

which shows that the bound from the opportunity for selection (Equation 29.6b) also extends to the DSD. See Henshaw and Zemel (2017) for a discussion of additional features and extensions of the DSD concept to multiple traits.

Directional Selection

Turning to moment-based comparisons, three measures of the within-generation change in phenotypic mean have been previously introduced: the **directional selection differential**, S (Equation 13.7); the variance-standardized directional selection differential (the **selection intensity**), $\bar{\tau} = S/\sigma$ (Equation 13.6a); and the **directional selection gradient**, $\beta = S/\sigma^2$ (Equation 13.8b). While these measures are interchangeable for selection acting on a single trait (using an appropriate scaling factor, as all have identical values when $\sigma_z^2 = 1$), the multivariate extension of the gradient (the vector β) is the measure of choice when multiple characters are considered (Chapter 30). This is because the elements of β fully adjust for the effects of selection on phenotypically correlated traits *among the set of traits included in the regression*, thereby quantifying the amount of direct selection on a trait. In contrast, S and $\bar{\tau}$ confound these direct and indirect effects (Equation 30.3), and consequently, they are often called measures of **total selection** (the sum of the forces, direct and indirect, acting on a trait), while β is a measure of **direct selection**.

Quadratic Selection

Metrics can also be defined to quantify the change in variance. At first blush, this change seems best described by $\sigma_{z^*}^2 - \sigma_z^2$, where $\sigma_{z^*}^2$ is the phenotypic variance following selection. The limitation of this metric as a measure of selection acting on the population variance of a trait is that strictly directional selection also reduces the variance. In particular, Lande and Arnold (1983) showed that

$$\sigma_{z^*}^2 - \sigma_z^2 = \sigma [w, (z - \mu_z)^2] - S^2 \quad (29.16a)$$

This result is derived in Example 30.2. Hence, directional selection *decreases* the phenotypic variance by S^2 . With this in mind, Lande and Arnold suggested a corrected measure for the change in variance, their **stabilizing selection differential**,

$$C = \sigma_{z^*}^2 - \sigma_z^2 + S^2 \quad (29.16b)$$

which describes the nature of selection acting directly on the variance. Correcting for the effects of directional selection is important, as apparent signals of stabilizing selection based on a reduction in variance following selection could simply be the reduction in variance caused by directional selection. Similarly, signals of disruptive selection (an *inflated* postselection trait variance) can be masked by directional selection (e.g., Example 29.10).

The term *stabilizing selection differential* is actually a misleading description of C . One can have a negative value of C without having a fitness maximum over the range of phenotypes that is observed, and hence formally there will be no stabilizing selection. Because $C < 0$ ($C > 0$) is *consistent* with stabilizing (disruptive) selection, but is not *sufficient* in and of itself, following Phillips and Arnold (1989), we refer to C as the **quadratic selection differential**.

Analogous to S equaling the covariance between z and relative fitness, Equation 29.16a shows that C is the covariance between relative fitness and the squared deviation of a trait value from its mean,

$$C = \sigma [w, (z - \mu)^2] \quad (29.17)$$

A positive value of C indicates selection to increase the variance (convex selection, as would occur with disruptive selection), with fitness (on average) *increasing* for trait values further from the mean. Conversely, a negative value of C indicates selection to reduce the variance (concave selection, as would occur with stabilizing selection), with fitness (on average) *decreasing* as trait values move away from the mean.

As was the case with S , the opportunity for selection ($I = \sigma_w^2$) bounds the maximum possible within-generation change in variance (Arnold 1986). If we recall that $\sigma(x, y) = \rho_{xy}\sigma(x)\sigma(y)$, Equation 29.17 implies that $C = \rho_{w,(z-\mu)^2}\sigma_w\sigma[(z - \mu)^2]$. Because $\rho^2 \leq 1$,

$$C^2 \leq \sigma_w^2 \sigma^2[(z - \mu)^2] = I \cdot (\mu_{4,z} - \sigma_z^4) \quad (29.18a)$$

where $\mu_{4,z} = E[(z - \mu)^4]$. The last step in Equation 29.18a follows if we recall that

$$\sigma^2[(z - \mu)^2] = E[(z - \mu)^4] - \{E[(z - \mu)^2]\}^2 = \mu_{4,z} - (\sigma_z^2)^2$$

Thus,

$$|C| \leq \sqrt{I(\mu_{4,z} - \sigma_z^4)} \quad (29.18b)$$

Furthermore, if z is normally distributed, then $\mu_{4,z} = 3\sigma_z^4$ (Kendall and Stewart 1977), implying that

$$\frac{|C|}{\sigma_z^2} \leq \sqrt{2I} \quad (29.18c)$$

Finally, the quadratic analog of β , the **quadratic** (or **stabilizing**) **selection gradient**, γ , was defined by Lande and Arnold (1983) as

$$\gamma = \frac{\sigma [w, (z - \mu)^2]}{\sigma_z^4} = \frac{C}{\sigma_z^4} \quad (29.19)$$

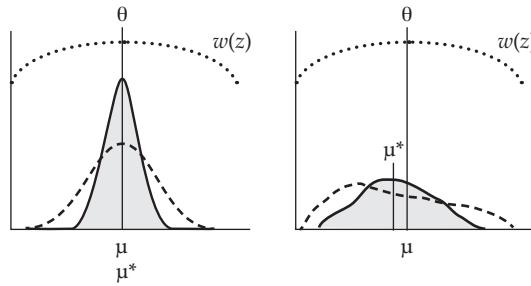

Figure 29.7 Even when a population is under strict stabilizing selection, the mean can change if the phenotypic distribution is skewed. One standard fitness function for stabilizing selection is Wright's quadratic, namely $W(z) = 1 - b(z - \theta)^2$ (Equation 28.3a). O'Donald (1968) found that when the population mean is at the optimum value ($\mu_z = \theta$), S is nonzero when the skew is nonzero ($\mu_{3,z} \neq 0$), as $S = -(b\mu_{3,z})/(1 - b\sigma_z^2)$. The dashed line and solid line (the latter with the corresponding filled curve), respectively, represent the preselection and postselection phenotypic distributions (both standarized to unit area). **Left:** If phenotypes are symmetrically distributed about the mean ($\mu_{3,z} = 0$), the distribution after selection has the same mean when $\mu_z = \theta$. **Right:** When the distribution is skewed, the longer tail experiences more selection than the shorter tail, which changes the mean.

As was the case for β , in its univariate form, γ appears as a simple rescaling of C , while its multivariate form (the matrix γ) accounts for the influence of phenotypic correlations among the measured traits (Chapter 30).

As with C , the interpretation of γ can be *extremely misleading* when the fitness surface is not well approximated by a quadratic over the range of scored phenotypes. We examine this issue in some detail both later in this chapter and in Chapter 30. A final complication in interpreting C is that if the phenotypic distribution is skewed, selection on the variance changes the mean (e.g., Equations 5.27b, 24.27, and 24.28a). This results in a nonzero value of S , which in turn inflates C (Figure 29.7).

Under Trait Normality, Gradients Describe the Local Geometry of the Fitness Landscape

A number of expressions equating β and γ to different gradient functions of fitness surfaces and landscapes appear in the literature. A potential source of confusion is that while these gradient functions are formally different (Geyer and Shaw 2008), they turn out to be equivalent when traits are normally distributed (Lande and Arnold 1983), and hence are used somewhat interchangeably in the literature.

We have frequently used the gradient of mean fitness with respect to the population mean,

$$\frac{\partial \ln \bar{W}}{\partial \mu_z} = \frac{1}{\bar{W}} \frac{\partial \bar{W}}{\partial \mu_z} \quad (29.20a)$$

We refer to gradients involving the mean fitness landscape as **landscape gradients**, and the particular gradient with respect to the population mean (Equation 29.20a) as the **landscape directional selection gradient**. Equations 24.26 and 24.27 show that landscape gradients with respect to higher moments of the phenotypic distribution appear in the general expression (free of normality assumptions) for selection response. When the trait is normally distributed and individual fitnesses are frequency-independent, the landscape directional selection gradient (Equation 29.20a) equals the directional selection gradient, $\beta = S/\sigma^2$ (Equation 13.8b); see Example A6.3 for the derivation.

A second class of gradients, based on the *individual* fitness surface, also appears in the literature. In particular, the **average directional selection gradient**,

$$\int \frac{\partial w(z)}{\partial z} p(z) dz = E_z \left[\frac{\partial w(z)}{\partial z} \right] \quad (29.20b)$$

is the average slope of the individual fitness surface, the expectation being taken over the phenotypic distribution for the population being studied. Similarly, the **average quadratic selection gradient**

$$\int \frac{\partial^2 w(z)}{\partial z^2} p(z) dz = E_z \left[\frac{\partial^2 w(z)}{\partial z^2} \right] \quad (29.20c)$$

is the average curvature of the individual fitness surface. Lande and Arnold (1983) showed that, provided z is normally distributed, Equation 29.20b equals β (the multivariate version is proved in Chapter 30) and Equation 29.20c equals γ (Equation 29.19).

Thus, β and γ provide measures of the geometry of the individual fitness surface averaged over the population being considered, *provided* z is normally distributed. When z is not Gaussian, Equations 29.20a and 29.20b need not equal β and Equation 29.20c need not equal γ . Indeed, unless the individual fitness function is of the form of a generalized exponential (Equation 29.34c), the postselection distribution is *expected* to depart from normality. Hence, after the first episode of selection, the fitness-weighted distribution is likely nonnormal, and these equalities can fail. This fact may be lost on an investigator examining selection over several episodes, as the *actual* distribution of phenotypes may not have changed, yet their *fitness-weighted* distributions may depart considerably from normality (for example, in a population before and after a episode of mate choice).

Under Trait Normality, Gradients Appear in Selection Response Equations

A final advantage of β and γ is that they appear as the only measure of phenotypic selection in the standard (i.e., normality-based) equations describing selection response. We have already seen (Equation 13.8c) that under the constraints of the breeder's equation, $R = \Delta\mu = \sigma_A^2\beta$, which is independent of any other measure of phenotypic selection. Similarly, under the infinitesimal model, the expected change in variance from a single generation of selection is given by Equation 16.7b,

$$\Delta\sigma_z^2 = \frac{h^4}{2} \delta_{\sigma_z^2} = \frac{\sigma_A^4}{2\sigma_z^4} (C - S^2) = \frac{\sigma_A^4}{2} (\gamma - \beta^2) \quad (29.21)$$

which decomposes the change in variance into the change due to selection on the variance (γ) and the change due to directional selection (β^2). More generally, when normality assumptions fail, the selection response equations for the variance involve various partials of landscape gradients (Equations 24.26 and 24.33c).

Again, while the distinction between differentials and gradients seems almost trivial in the univariate case (only a scale difference), their multivariate versions are *considerably different* from each other. As we will see in Chapter 30, gradients have the extremely important feature of removing the effects of phenotypic correlations among the set of *measured* traits, and the multivariate extensions of β and γ are what appear in the multivariate breeder's and Bulmer equations (Volume 3).

Partitioning Changes in Means and Variances Into Episodes of Selection

Suppose the total amount of within-generation selection is partitioned into k episodes of selection. Let μ_j and σ_j^2 be the (fitness-weighted) mean and variance after the j th episode of selection ($\mu = \mu_0$ and $\sigma^2 = \sigma_0^2$ are the baseline mean and variance before the first measured episode of selection). The definitions of S and C suggest that their appropriate counterparts for the j th episode of selection are calculated by

$$S_j = \mu_j - \mu_{j-1} \quad (29.22a)$$

$$C_j = \sigma_j^2 - \sigma_{j-1}^2 + S_j^2 \quad (29.22b)$$

(Arnold and Wade 1984a). The properties for S and C hold for each episode of selection, with

$$S_j = \sigma(w_j, z) \quad \text{and} \quad C_j = \sigma[w_j, (z - \mu_{j-1})^2] \quad (29.22c)$$

where w_j is the relative fitness for the j th episode of selection. Likewise, substituting $I_j = \sigma^2(w_i)$ for I in Equations 29.6 and 29.18c bounds the possible values of S_j and C_j .

How do these individual-episode measures relate to their total measure (i.e., over all episodes)? The partition of the total differentials, S_T and C_T , into those components are additive, with

$$S_T = \mu_k - \mu_0 = \sum_{j=1}^k (\mu_j - \mu_{j-1}) = \sum_{j=1}^k S_j \quad (29.22d)$$

and

$$\begin{aligned} C_T &= \sigma_k^2 - \sigma_0^2 + S_T^2 = \sum_{j=1}^k (\sigma_j^2 - \sigma_{j-1}^2) + S_T^2 \\ &= \sum_{j=1}^k (C_j - S_j^2) + S_T^2 = \sum_{j=1}^k C_j + \left(S_T^2 - \sum_{j=1}^k S_j^2 \right) \end{aligned} \quad (29.22e)$$

Example 29.8. For Example 29.2, following male body size over two episodes of selection, we find that $\hat{S}_1 = \bar{z}_1 - \bar{z}_0 = -1.14$, $\hat{S}_2 = \bar{z}_2 - \bar{z}_1 = 0.02$, and $\hat{S}_T = -1.12$. Likewise,

$$\hat{C}_1 = \text{Var}[z_1] - \text{Var}[z_0] + \hat{S}_1^2 = 30.5 - 59.5 + (-1.12)^2 \simeq -27.7$$

Similar calculations yield $\hat{C}_2 \simeq 13.19$ and $\hat{C}_T \simeq -14.55$. Based on this limited dataset, there appears to be directional selection to reduce body size during the first episode. In addition, there appears to be selection to reduce the variance in body size during the first episode (mate choice) countered by selection to increase this variance during the second episode (fertility per mating).

Partitioning β and γ requires a little more care, as we have to account for changes in the phenotypic variance following each episode. From their definitions, the appropriate gradients for the j th episode of selection are

$$\beta_j = \frac{S_j}{\sigma_{j-1}^2} \quad \text{and} \quad \gamma_j = \frac{C_j}{\sigma_{j-1}^4} \quad (29.23a)$$

In their original paper, Arnold and Wade (1984a) initially defined gradients for each episode using the baseline variance, σ_0^2 , throughout. With this definition, gradients are additive across episodes, as their numerators (being covariances) are additive and the denominators are unchanged. This approach is often called the **additive partition** (or more correctly, the **unweighted additive partition**), as $\beta_T = \sum \beta_j^0$, where $\beta_j^0 = S_j / \sigma_0^2$. Kalisz (1986) and Wade and Kalisz (1989) noted that the correct definition for an episodic gradient depends upon the trait variance at the *start* of each episode (Equation 29.23a), and the variance is expected to change during each episode. Writing $S_j = \beta_j \sigma_{j-1}^2$ gives

$$\beta_T = \frac{S_T}{\sigma_0^2} = \sum_{j=1}^k \frac{S_j}{\sigma_0^2} = \sum_{j=1}^k \frac{\beta_j \sigma_{j-1}^2}{\sigma_0^2} = \sum_{j=1}^k \beta_j a_j, \quad \text{where } a_j = \frac{\sigma_{j-1}^2}{\sigma_0^2} \quad (29.23b)$$

Equation 29.23b defines the **variance-weighted additive partition** of gradients, where the total selection gradient is now a weighted sum of the individual gradients associated with each episode. The partition of γ follows in a similar manner, with

$$\gamma = \sum_{j=1}^k \gamma_j a_j^2 + \frac{1}{\sigma_0^4} \left[S_T^2 - \sum_{j=1}^k S_j^2 \right] \quad (29.23c)$$

where γ_j is calculated by Equation 29.23a. McGlothlin (2010) presented the multivariate version of Equation 29.23c and also revealed a key feature of Equation 29.23c. Note that γ can be nonzero even when *all* of the values of γ_j are zero. Further, when directional selection is occurring, the sign of γ can be different from the sign of the average value of γ_k .

Choice of the Reference Population: Independent Partitioning

Using the above partitioning schemes, selection differentials and gradients for a particular episode are based on their fitness-weighted values from the previous episode and are (with appropriate weighting) additive across episodes. Several authors have suggested that a slightly different approach, **independent partitioning**, may provide additional details about the nature of selection (Koenig and Albano 1987; Conner 1988; Koenig et al. 1991; Preziosi and Fairbairn 2000). Here, one uses the *observed* distribution of phenotypes as the reference population (as opposed to the *fitness-weighted* distribution) when computing statistics for each episode. While an independent partition provides a misleading picture of *evolutionary response* (by not weighting for previous selection), it may provide additional insight into the *nature of selection* in a particular episode. Further, if episodes are *not* sequential, the additive partition is not appropriate, while the independent partition can still be used to evaluate potential targets of selection. Fitness components estimated by the additive partition take into account any constraints imposed by prior selection, while independent partitioning ignores these prior constraints.

To see how using both partitions can provide additional insight into the nature of selection, consider the work of Koenig et al. (1991), who applied the additive and independent partitions to Howard's (1979) bullfrog dataset (Example 29.2). Howard concluded that larger frogs have more matings and produce more eggs and hatchlings. Fitness-component analysis (Example 29.2) using the additive partition showed that selection was largely on the number of mates, with no significant impact of body size on fertility per mate or hatching success (Arnold and Wade 1984b). Using an independent partition also found strong selection for body size via mating success, but, additionally, revealed strong selection for hatching success (offspring survivorship) as a function of body size. Thus, the independent partition suggested an additional interaction that was missed by the additive partition, thus generating new potential hypotheses for further testing (e.g., larger males may be better at defending eggs from predators or reside in better territories).

Example 29.9. To illustrate the difference between the additive and independent partitions, Koenig et al. (1991) presented the following hypothetical dataset for six individuals relating body size with natural (survival) and sexual (mating rate) selection.

Size z	Survivorship (Days alive), W_1	Mating rate (Mates/days alive), W_2	Total mates $W_1 W_2$
11	1	3	3
12	1	2	2
13	1	1	1
11	10	1	10
12	10	2	20
13	10	3	30

Here, the mean body size before selection is 12. Focusing on total mates, the mean number of mates is 11, and the fitness-weighted trait mean (Equation 29.2b) becomes

$$\frac{1}{6} \left[11 \left(\frac{3+10}{11} \right) + 12 \left(\frac{2+20}{11} \right) + 13 \left(\frac{1+30}{11} \right) \right] = 12.3$$

Thus, the total selection differential on size due to differences in number of mates is $12.3 - 12 = 0.3$. However, the selection differential for survivorship is 0 (the fitness-weighted trait mean is 12), and so the positive differential on total mates arises entirely via the fitness-weighted

differences in mating rate (W_2).

Suppose, however, that one simply followed mating success per day and had no knowledge of survivorship. If one weights all six individuals equally (1/6) as the reference population, $\bar{W}_2 = 2$, which yields the mean after selection as

$$\frac{1}{6} \left[11 \left(\frac{3+1}{2} \right) + 12 \left(\frac{2+2}{2} \right) + 13 \left(\frac{1+3}{2} \right) \right] = 12$$

Thus, the selection differential on mating rate using this reference population is zero. If we ignore differences in survival, there are no effects of body size on mating rate. Despite the fact that both the survival and mating rate differentials are zero, the differential for total mates is not. This occurs because individuals with lower fitness in the first episode are given less weight when computing the additive partition, while they are equally weighted under an independent partition.

This example, along with Example 29.1, highlights the critical importance of accounting for all phases of selection. If this study followed just survivorship or just mates per day, no trait-fitness associations would have been seen. Grafen (1988) has coined the very appropriate term **invisible fraction** for that part of the population undergoing selection that is not seen by the investigator. Such missing data can significantly bias estimates of selection (e.g., Bennington and McGraw 1995; Hadfield 2008).

Standard Errors for Estimates of Differentials and Gradients

Because it is difficult to measure all of the individuals in a population, the effects of selection are usually estimated from a sample. This is also true in most longitudinal studies, with the cohort usually viewed as representative of phenotypes from the population. There are, however, occasional exceptions, such as when cohort members are intentionally chosen to include the most extreme phenotypes at much higher frequencies than their population levels.

There are a number of statistical issues involved in extrapolating from samples to the entire population, many of which still are unresolved. For example, individual fitness is usually measured with error. Further, there is generally a bias toward *underestimating* individual fitness—for example, marked individuals may not be recaptured and hence recorded as having zero fitness even if they survived. Likewise, the number of mates or offspring can be easily undercounted.

Assuming individual fitness is measured without error, the methods of LW Appendix 1 can be used to obtain approximate large-sample variances for estimators of differentials and gradients. The exact sampling variance for the directional selection differential is

$$\sigma^2(\hat{S}_j) = \frac{\sigma_j^2}{n_j} + \frac{\sigma_{j-1}^2}{n_{j-1}} \quad (29.24a)$$

where n_j is the sample size for the j th episode. Using the delta-method approximation from LW Appendix 1, the large-sample variance for C is approximately

$$\begin{aligned} \sigma^2(\hat{C}_j) &\simeq 4S_j^2 \sigma^2(\hat{S}_j) + 8S_j \left(\frac{\mu_{3,j}}{n_j} + \frac{\mu_{3,j-1}}{n_{j-1}} \right) \\ &\quad + \frac{\mu_{4,j} - \sigma_j^4}{n_j} + \frac{\mu_{4,j-1} - \sigma_{j-1}^4}{n_{j-1}} \end{aligned} \quad (29.24b)$$

where μ_3 and μ_4 are the third and fourth central moments around the mean, $\mu_i = E[(z-\mu)^i]$. If phenotypes are normally distributed ($\mu_3 = 0, \mu_4 = 3\sigma^4$), this reduces to

$$\sigma^2(\hat{C}_j) \simeq 4S_j^2 \sigma^2(\hat{S}_j) + 2 \left[\frac{\sigma_j^4}{n_j} + \frac{\sigma_{j-1}^4}{n_{j-1}} \right] \quad (29.24c)$$

If the scaled skewness, κ_3 (LW Equation 2.8), and kurtosis, κ_4 (LW Equation 2.12a), are small, this normal approximation is still appropriate.

Example 29.10. Boag and Grant (1981) observed intense natural selection in Darwin's medium ground finch (*Geospiza fortis*) during a severe drought on Daphne Major Island in the Galápagos. The estimated mean and variance of body weight in 642 adults before the drought were, respectively, 15.79 and 2.37, while the estimated mean and variance of 85 surviving adults after the drought were 16.85 and 2.43. Thus, $\hat{S} = 16.85 - 15.79 = 1.06$ and Equation 29.24a returns the standard deviation of this estimate as

$$\text{SE}(\hat{S}) \simeq \sqrt{\frac{2.37}{642} + \frac{2.43}{85}} \simeq \sqrt{0.0323} \simeq 0.180$$

implying that the directional selection differential on body size was significantly positive.

There appears to be very little selection on the variance when the uncorrected change in variance, $\text{Var}(z^*) - \text{Var}(z) = 2.43 - 2.37 = 0.06$, is used. However, using the quadratic selection differential to correct for the reduction in the variance from directional selection gives $\hat{C} = 0.06 + 1.06^2 = 1.14$, consistent with selection to increase the variance (convex selection, whereby selection favors extreme individuals). From Equation 29.24c, assuming body size is normally distributed before and after the drought,

$$\text{SE}(\hat{C}) \simeq \sqrt{4 \cdot (1.06)^2 \cdot 0.0323 + 2 \left[\frac{(2.37)^2}{642} + \frac{(2.43)^2}{85} \right]} \simeq 0.549$$

Thus, \hat{C} is 2.08 standard errors above 0, suggesting that it is (at least) close to being significant.

DESCRIBING PHENOTYPIC SELECTION: INDIVIDUAL FITNESS SURFACES

The fitness (W) of an individual with a trait value of z can be decomposed into the sum of its **expected fitness**, $W(z) = E[W|z]$, plus a **residual deviation**, e_W ,

$$W = E[W|z] + e_W = W(z) + e_W$$

The residual variance for a given z , $\sigma_{e_W}^2(z)$, measures the variance in fitness among individuals with a phenotypic value of z . Estimation of the individual fitness surface is thus a generalized regression problem, with the goal being to choose a candidate function for $W(z)$ that minimizes the average residual variance, $E_z[\sigma_{e_W}^2(z)]$. Because the total variance in fitness (σ_W^2) equals the sum of the within-group (individuals with the same trait value) and among-group variances in fitness,

$$\frac{\sigma_W^2 - E_z[\sigma_{e_W}^2(z)]}{\sigma_W^2} = 1 - \frac{E_z[\sigma_{e_W}^2(z)]}{\sigma_W^2}$$

is the fraction of individual fitness variation accounted for by a particular estimate of $W(z)$, providing a metric for comparing different estimates of the fitness function.

There are at least two sources of variation that contribute to the fitness residual, e_W . First, there can be errors in measuring the actual fitness of an individual (these are almost always ignored, although they induce serious biases; see Hadfield 2008). Second, the *actual* (or **realized**) fitness of any particular individual is a random variable distributed around its *expected value*. Generally, these residual deviations are heteroscedastic, with the residual

variance varying with z (Mitchell-Olds and Shaw 1987; Schluter 1988). As we will see later, aster models provide a general strategy for accounting for such errors structures.

Consider fitness measured by survival to a particular age. While $W(z) = p_z$ is the probability of survival for an individual with a character value of z , the fitness for a particular individual is a Bernoulli random variable, as it either survives (value of one) or does not (value of zero). The resulting residual has only two possible values, $e_W = 1 - p_z$ with probability p_z , and $e_W = -p_z$ with probability $1 - p_z$, giving

$$\sigma_{e_W}^2(z) = E[(e_W)^2] = (1 - p_z)^2 p_z + p_z^2(1 - p_z) = p_z(1 - p_z)$$

Unless p_z is constant over z , the residuals are heteroscedastic. Note that after accounting for phenotypic-specific differences (here, the p_z values), there still remains substantial variance in individual fitness. This within-class variance is most extreme at intermediate survival rates ($p_z \simeq 1/2$).

Finally, inferences about the individual fitness surface are limited by the range of phenotypes in the population. Unless this range is very large, only a small region of the fitness surface can be explored with any precision. Estimates of the fitness surface at the tails of the current phenotypic distribution are extremely imprecise yet potentially very informative, as they suggest patterns of selection for populations at the margins of the observed range of phenotypes. A further complication is that the fitness surface can change as the environment changes, so that year-to-year estimates can differ (e.g., Kalisz 1986). Such change may require an investigator to choose between a time-averaged fitness surface (which can impart bias) versus a series of year-specific estimates (which suffer from lower power). Finally, as emphasized in Chapter 22, organisms often modify their environments as they evolve, implying that the biotic environment, and hence $W(z)$, also evolves.

Linear and Quadratic Approximations of $W(z)$

The individual fitness surface, $W(z)$, can be very complex, and a wide variety of functions may be chosen to approximate it. The simplest and most straightforward approach is to use a low-order polynomial (typically a linear or a quadratic; Lande and Arnold 1983). One justification for this approach is that in a sufficiently local region, even a highly nonlinear surface can be reasonably approximated by a quadratic function (this is simply a Taylor series approximation). Put another way, for a sufficiently small range of phenotypes, even a rather rough fitness surface can appear to be locally smooth.

Consider first the simple linear regression of *relative* fitness, w , as a function of phenotypic value, z . Because the directional selection gradient is defined as $\beta = S/\sigma_z^2 = \sigma(w, z)/\sigma_z^2$, it follows from regression theory (LW Equation 3.14b) that β is the slope of the least-squares linear regression of relative fitness on z ,

$$w = a + \beta z + e \quad (29.25a)$$

which makes $\hat{w}(z) = a + \beta z$ the best linear predictor of relative fitness (Geyer and Shaw 2008). Because the regression passes through the expected values of w and z (1 and μ_z , respectively), Equation 29.25a can be rewritten as

$$w = 1 + \beta(z - \mu_z) + e \quad (29.25b)$$

giving $\hat{w}(z) = 1 + \beta(z - \mu_z)$.

If we assume that the fitness function (for the range of phenotypes scored) is well described by a linear regression, β is the expected change in relative fitness, given a unit change in z . Usually, **standardized regressions** are used, where the trait value is translated (shifted) and then variance-standardized to give it a mean of zero and a variance of one, with the standardized value, $z_{sd} = (z - \mu)/\sigma_z$, replacing z in the regression. The standardized version of the Lande-Arnold regression becomes

$$w = 1 + \beta_{sd} z_{sd} + e \quad (29.25c)$$

where β_{sd} gives the expected change in fitness given a standard deviation change in the trait. For example, a value of $\beta_{sd} = 0.2$ implies that a change of one standard deviation in the trait value increases relative fitness by 20%.

Note that fitness in the regression given by Equation 29.25c is *mean-standardized* (we use w in place of W), so our use of the term *standardized regression* is different from its use in many statistical packages, where *both* the dependent (w) and the predictor (z) variables are variance-standardized. Hence, it is best to directly feed in the transformed data (i.e., trait-standardized to a mean of zero and a variance of one, fitness-standardized to a mean of one) into a regression package, rather than worry about how a particular package will standardize the raw data before performing the regression.

As a consequence of standardization, we have

$$S_{sd} = \bar{t}_z \quad (29.25d)$$

showing that the selection differential for a standardized trait is simply the selection intensity, \bar{t}_z , of the trait on the original (untransformed) scale, allowing for an easy comparison of the relative strengths of selection among focal traits. Further, note (from the Robertson-Price identity) that because $S_{sd} = \sigma(z_{sd}, w)$, and hence $\beta_{sd} = \sigma(z_{sd}, w)/\sigma^2(z_{sd}) = S_{sd}$, yielding

$$\beta = \frac{\sigma(z, w)}{\sigma_z^2} = \frac{\sigma(z/\sigma_z, w)}{\sigma_z} = \frac{\sigma(z_{sd}, w)}{\sigma_z} = \frac{\beta_{sd}}{\sigma_z} \quad (29.25e)$$

From LW Equation 3.17, the fraction of variance in individual fitness accounted for by a linear regression in z is

$$r_{z,w}^2 = \frac{[\sigma(z, w)]^2}{\sigma^2(z) \cdot \sigma^2(w)} = \hat{\beta}^2 \frac{\sigma^2(z)}{\hat{I}} \quad (29.26a)$$

as obtained by Moorad and Wade (2013). For a standardized regression, this reduces to

$$r_{z_{sd},w}^2 = \hat{\beta}_{sd}^2 / \hat{I} \quad (29.26b)$$

Rearranging Equation 29.26a,

$$\hat{I}r_{z,w}^2 = \hat{\beta}^2 \sigma^2(z) = \frac{\sigma^2(z, w)}{\sigma^4(z)} \sigma^2(z) = \frac{\sigma(z, w)}{\sigma^2(z)} \sigma(z, w) = \hat{\beta} S \quad (29.26c)$$

which shows that the amount of the variance in relative fitness (I) accounted for by directional selection on a focal trait is $\hat{\beta}S$ (Moorad and Wade 2013).

If the individual fitness surface shows curvature, as expected if there is stabilizing or disruptive selection, a **quadratic regression** is more appropriate,

$$w = a + b_1 z + b_2(z - \mu_z)^2 + e \quad (29.27a)$$

Because the regression passes through the mean of all variables,

$$E[w] = 1 = a + b_1 E[z] + b_2 E[(z - \mu_z)^2] = a + b_1 \mu_z + b_2 \sigma_z^2$$

Solving for the intercept (a) and substituting back into Equation 29.26b yields

$$w = 1 + b_1(z - \mu_z) + b_2 [(z - \mu_z)^2 - \sigma_z^2] + e \quad (29.27b)$$

The trait-standardized version ($\mu_{z_{sd}} = 0, \sigma^2(z_{sd}) = 1$) becomes

$$w = 1 + b_{sd,1} z_{sd} + b_{sd,2} (z_{sd}^2 - 1) + e \quad (29.27c)$$

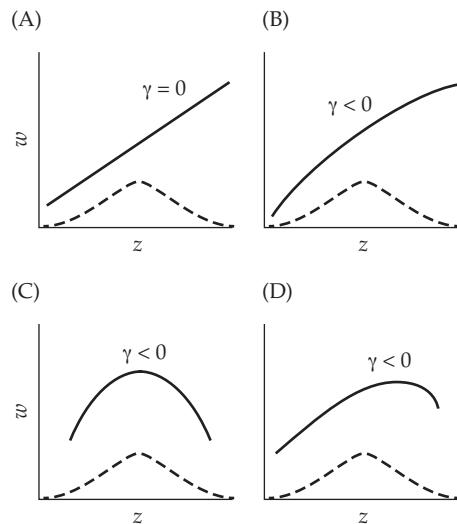

Figure 29.8 The relationship between γ and curvature of a quadratic fitness function (solid line). The dashed curve represents the distribution of z . **A:** $W(z)$ is strictly linear, hence $\gamma = 0$. **B:** $W(z)$ curves downward (is concave), but has no maximum over the range of z examined. Hence, $\gamma < 0$, implying stabilizing selection by the Lande-Arnold criterion, when in fact selection is entirely directional. **C:** Stabilizing selection only, as there is no change in the mean. **D:** A combination of directional and stabilizing selection, as the population mean is not at the optimal fitness value. (After Mitchell-Olds and Shaw 1987.)

which is also written as

$$w = a + b_{sd,1}z_{sd,1} + b_{sd,2}z_{sd}^2 + e \quad (29.27d)$$

A positive quadratic term (b_2 or $b_{sd,2} > 0$) indicates that the best-fitting quadratic approximation of the individual fitness surface has an upward (convex) curvature, while a negative value ($b_2 < 0$) implies that the curvature is downward (concave). Lande and Arnold (1983) suggested that $b_2 > 0$ indicates disruptive selection while $b_2 < 0$ indicates stabilizing selection. Their reasoning follows from elementary geometry in that a *necessary* condition for a local minimum is that a function must be convex over some interval, while a necessary condition for a local maximum is that the function is concave. However, Mitchell-Olds and Shaw (1987) and Schlüter (1988) noted that this condition is not *sufficient* for the presence of a local extrema. Stabilizing selection is generally defined as the presence of a local maximum in $w(z)$ and disruptive selection by the presence of a local minimum, while b_2 indicates *curvature* rather than the presence of local extrema. As Figure 29.8B shows, a quadratic fitness function can curve downward without the population experiencing a local maximum. It can also curve upward without having a local minimum. Because of these issues, the current usage is to denote $b_2 < 0$ as concave selection and $b_2 > 0$ as convex selection.

Lande-Arnold Fitness Regressions

We solve for the regression coefficients b_1 and b_2 by transforming Equation 29.27a into a standard multiple regression problem by setting $x_1 = z$ and $x_2 = (z - \mu_z)^2$ and applying the methods of LW Chapter 8. To proceed, we need expressions for $\sigma(x_1, x_2)$, $\sigma(x_1, w)$, and $\sigma(x_2, w)$. From LW Equation A1.14, $\sigma(x_1, x_2) = \sigma(z, [z - \mu_z]^2) = \mu_{3,z}$, the skew of the phenotypic distribution before selection. Likewise, from Equations 13.7a and 29.17, $\sigma(x_1, w) = \sigma(z, w) = S$ and $\sigma(x_2, w) = \sigma([z - \mu_z]^2, w) = C$. Substituting these values into the results from LW Example 8.3 (which gives exact expressions for the partial regression

coefficients of a bivariate regression), and note that $\sigma^2([z - \mu_z]^2) = \mu_{4,z} - \sigma_z^4$, we obtain

$$b_1 = \frac{\sigma^2(x_2) \cdot \sigma(x_1, w) - \sigma(x_1, x_2) \cdot \sigma(x_2, w)}{\sigma^2(x_1) \cdot \sigma^2(x_2) - \sigma^2(x_1, x_2)} = \frac{(\mu_{4,z} - \sigma_z^4) \cdot S - \mu_{3,z} \cdot C}{\sigma_z^2 \cdot (\mu_{4,z} - \sigma_z^4) - \mu_{3,z}^2} \quad (29.28a)$$

$$b_2 = \frac{\sigma^2(x_1) \cdot \sigma(x_2, w) - \sigma(x_1, x_2) \cdot \sigma(x_1, w)}{\sigma^2(x_1) \cdot \sigma^2(x_2) - \sigma^2(x_1, x_2)} = \frac{\sigma_z^2 \cdot C - \mu_{3,z} \cdot S}{\sigma_z^2 \cdot (\mu_{4,z} - \sigma_z^4) - \mu_{3,z}^2} \quad (29.28b)$$

The estimators of b_1 and b_2 are obtained by replacing $\mu_{k,z}$ with their sample estimates and using \hat{C} and \hat{S} .

It is important to stress that the distributional assumptions leading to the solutions offered by Equation 29.28 are simply those of ordinarily least-squares (OLS), namely, homoscedastic and uncorrelated residuals (Chapter 18; LW Chapter 8). To this point, *no other assumptions* have been made about either the distribution of the trait values or the distributional form of the residuals (i.e., normality of the residuals is *not* required for Equation 29.28). Standard errors for parameter estimates follow from LW Equation 8.33b (again, requiring no assumptions on the distribution of residuals other than OLS). However, if we wish to turn standard errors into confidence intervals or to perform hypothesis testing, further distributional assumptions on residuals (such as normality) are required.

Provided z is normally distributed before selection, then $\mu_{3,z} = 0$ and $\mu_{4,z} - \sigma_z^4 = 2\sigma_z^4$. In this case, Equations 13.8b and 29.19 imply, respectively, that $b_1 = S/\sigma_z^2 = \beta$ and $b_2 = C/[2\sigma_z^4] = \gamma/2$, giving the univariate version of the **Lande-Arnold regression** (1983)

$$w = 1 + \beta(z - \mu_z) + \frac{\gamma}{2}([z - \mu_z]^2 - \sigma_z^2) + e \quad (29.29a)$$

As this expression was also motivated by Pearson (1903), we occasionally refer to Equation 29.29a as the **Pearson-Lande-Arnold regression**. In standarized form,

$$w = a + \beta_{sd}z_{sd} + \frac{\gamma_{sd}}{2}z_{sd}^2 + e \quad (29.29b)$$

Equations 29.29a and 29.29b provide a connection between selection gradients (directional and stabilizing, β and γ , respectively) and quadratic approximations of the individual fitness surface, *provided* z is normally distributed and residuals follow the OLS assumption.

An important point from Equation 29.28a is that if skew is present in the trait distribution ($\mu_{3,z} \neq 0$), then $b_1 \neq \beta$, and hence the slope (β) in the linear regression (the best *linear* fit) of $w(z)$ differs from the linear slope term (b_1) in the the best *quadratic* fit of $w(z)$. This inequality arises because the presence of skew generates a covariance between z and $(z - \mu_z)^2$. The biological significance of this inequality can be seen by reconsidering Figure 29.7, where the presence of skew in the phenotypic distribution results in a change in the mean of a population under strict stabilizing selection (defined as the population mean being at the optimum of the individual fitness surface). From the Robertson-Price identity (Equation 6.10), the within-generation change in the mean equals the covariance between phenotypic value and relative fitness. Because covariances measure the amount of *linear* association between variables, in describing the change in mean, the correct measure is the slope of the best *linear* fit of the individual fitness surface, which is unbiased by skew (Lande and Arnold 1983). If skew is present, using b_1 from the quadratic regression to describe the change in mean is incorrect, as this quadratic regression removes the effects on relative fitness from a linear change in z due to the correlation between z and $(z - \mu_z)^2$.

Observe from Equation 29.28b that the presence of skew (and kurtosis) also results in $2b_2$ being a biased estimator of γ . Despite this bias, $2b_2$ remains the standard estimate for γ in the literature. Shifting the trait to give it a mean of zero, a less-biased estimator of γ follows from a quadratic regression with no linear term,

$$w = a + bz^2 + e \quad (29.29c)$$

From standard regression theory (LW Chapter 3), the slope of Equation 29.29c is $b = \sigma(z^2, w)/\sigma^2(z^2)$, and using the covariances obtained for Equation 29.28 yields

$$b = \frac{\sigma(z^2, w)}{\sigma^2(z^2)} = \frac{C}{\mu_{4,z} - \sigma_z^4} \quad (29.29d)$$

Recall that the scaled kurtosis is $\kappa_4 = (\mu_4 - 3\sigma_z^4)/\sigma_z^4$ (LW Equation 2.12a). Therefore, rearranging yields $\mu_{4,z} - \sigma_z^4 = \sigma_z^4(\kappa_4 + 2)$, or

$$b = \frac{C}{\sigma^4(\kappa_4 + 2)} = \frac{\gamma}{\kappa_4 + 2} \quad (29.29e)$$

For a normal, $\kappa_4 = 0$, and $2E[b] = \gamma$. When kurtosis is present, using the sample estimate of $\hat{\kappa}_4$ yields

$$\hat{\gamma} = \hat{b}(\hat{\kappa}_4 + 2) \quad (29.29f)$$

which is an improved estimate of the quadratic gradient. Finally, despite these corrections, we should point out that bias induced by skewness and kurtosis is a matter of degree. Both of these moments have their own sampling problems, and using poor estimates of them to correct β and γ can be problematic.

The Geometry of Quadratic Fitness Functions

As we have seen, when traits are normally distributed, β and γ provide summary statistics of the geometry of the individual surface and mean fitness landscape, either by measuring the average slope or curvature of the individual fitness surface (average selection gradients; Equations 29.20b and 29.20c) or the slope or curvature (evaluated at the current mean, μ_z) of the fitness landscape (landscape selection gradients; Equation 29.20a). Table 30.1 summarizes these (and other) features for the multivariate versions of β and γ . *These expressions hold for any form of $w(z)$, provided z is normally distributed.*

Moreover, when $w(z)$ is exactly a quadratic, similar expressions hold for *any* distribution of z . Taking the first two partial derivatives of Equation 29.27a yields

$$\frac{\partial w(z)}{\partial z} = b_1 + 2b_2(z - \mu_z) \quad \text{and} \quad \frac{\partial^2 w(z)}{\partial z^2} = 2b_2 \quad (29.30a)$$

Evaluating these derivatives at the current mean ($z = \mu_z$) returns

$$\left. \frac{\partial w(z)}{\partial z} \right|_{z=\mu_z} = b_1 \quad \text{and} \quad \left. \frac{\partial^2 w(z)}{\partial z^2} \right|_{z=\mu_z} = 2b_2 \quad (29.30b)$$

Hence, one interpretation of the regression coefficients in Equation 29.27a is that they describe the slope (b_1) and the curvature ($2b_2$) of a quadratic fitness surface at the population mean. A second interpretation (along the lines of Equation 29.20b and 29.20c) is that these coefficients also equal the average slope (b_1) and average curvature ($2b_2$) of the quadratic fitness surface over the entire distribution of z (i.e., they are average selection gradients). To see this, note that Equation 29.20b yields an average directional selection gradient of

$$E_z \left[\frac{\partial w(z)}{\partial z} \right] = E_z [b_1 + 2b_2(z - \mu_z)] = b_1 + 2b_2 E_z [z - \mu_z] = b_1 \quad (29.30c)$$

Likewise, from Equation 29.20, the average quadratic selection gradient is

$$E_z \left[\frac{\partial^2 w(z)}{\partial z^2} \right] = E_z [2b_2] = 2b_2 \quad (29.30d)$$

Even when the trait distribution (before selection) is normal, if $w(z)$ is not a quadratic, then the *average* slope and curvature need not equal the slope or the curvature of $w(z)$ that

is evaluated at μ_z . In other words, the average of the function need not equal the value of the function evaluated at the average. Assuming a normally distributed trait, Phillips and Arnold (1989) performed Taylor-series expansions (around $z = \mu_z$) of Equations 29.20b and 29.20c, showing how the expected slope and curvature relate to the slope and curve at the mean,

$$\int \frac{\partial w(z)}{\partial z} p(z) dz = \left. \frac{\partial w(z)}{\partial z} \right|_{z=\mu_z} + \left(\frac{\sigma_z^2}{2} \frac{\partial^3 w(z)}{\partial z^3} + \frac{\sigma_z^4}{8} \frac{\partial^5 w(z)}{\partial z^5} + \dots \right) \Big|_{z=\mu_z} \quad (29.30e)$$

$$\int \frac{\partial^2 w(z)}{\partial z^2} p(z) dz = \left. \frac{\partial^2 w(z)}{\partial z^2} \right|_{z=\mu_z} + \left(\frac{\sigma_z^2}{2} \frac{\partial^4 w(z)}{\partial z^4} + \frac{\sigma_z^4}{8} \frac{\partial^6 w(z)}{\partial z^6} + \dots \right) \Big|_{z=\mu_z}$$

While trait normality ensures that the slope of the *mean fitness landscape*, \bar{W} , evaluated at the trait mean equals the average slope of $w(z)$, it *does not* ensure that the *average* slope or curvature of $w(z)$ equals the slope or curvature of $w(z)$ as is evaluated at the trait mean. As Equation 29.30e shows, this only happens when $w(z)$ is quadratic (and hence partials of order three and higher vanish). While this point may seem overly technical, it is important to stress because much of the elegant symmetry of the connections between β and γ and quantities of interest (average geometries of the fitness surface, regression coefficients, and important parameters in evolutionary equations for predicting response) only hold when the quadratic is an excellent approximation of the true fitness surface or when z is normal (before selection). See Geyer and Shaw (2008) for an extended discussion of this issue.

Finally, note that for a quadratic fitness function, for any distribution of z

$$\bar{W} = E_z [a + b_1 z + b_2 (z - \mu)^2] = a + b_1 \mu + b_2 \sigma_z^2 \quad (29.30f)$$

which implies that

$$\frac{\partial \bar{W}}{\partial \mu} = b_1 \quad (29.30g)$$

It is important to stress that throughout, we have defined $\beta = S/\sigma_z^2$ (Equation 13.8b) and $\gamma = C/\sigma_z^4$ (Equation 29.19), making no assumptions about either the trait distribution or the individual fitness function. While alternative expressions (e.g., Equations 29.20 and 29.30) exist for β and γ under certain distributional (normality) or fitness function (quadratic) assumptions, these are simply equalities under certain conditions that follow given our (distributional and fitness function-independent) definitions of β and γ . The importance of β and γ is that they appear as the sole measures of selection in the breeder's equation (13.8c) and Bulmer equation (29.21) for predicting changes in means and variances. When the normality assumptions underlying the simple forms of these two selection-response (mean and variance, respectively) equations fail, the response depends, in complex ways, on the underlying genetic details and various partials of the mean fitness landscape (Equation 24.26).

Hypothesis Testing, Approximate Confidence Intervals, and Model Validation

While there is a large body of theory for testing the significance of regression coefficients, much of it assumes homoscedastic and normally distributed residuals, $e_w \sim N(0, \sigma_{e_w}^2)$, where the residual variance ($\sigma_{e_w}^2$) is a constant (i.e., independent of z). As mentioned above, these two assumptions are almost always violated with fitness data, invalidating standard tests for significance (Mitchell-Olds and Shaw 1987). Fortunately, a variety of resampling methods available for hypothesis testing are robust to heteroscedasticity and nonnormal residuals, and we briefly mention three of these procedures: jackknife confidence intervals, randomization tests of significance, and cross-validation. A fair amount of this material is presented for historical reasons, as the aster-model framework discussed at the end of the chapter provides a more statistically rigorous approach than the resampling approximations presented here.

Jackknife estimates were introduced by Tukey (1958) as a generalized statistical tool; see Miller (1974), Wu (1986), Shao and Tu (1996), and Manly (1997) for reviews, and Mitchell-Olds and Shaw (1987) and Mitchell-Olds and Bergelson (1990) for applications to fitness regressions. The idea is simple, **resampling**. Namely, base parameter estimates on the behavior of the distribution of estimates from subsamples of the original data. Consider the estimator of β for the linear regression given by Equation 29.25a. Denote by $\hat{\beta}$ the standard least-squares estimate of β using the full dataset of n individuals, and we let $\hat{\beta}_i$ denote the estimator using the complete dataset minus data for the i th individual. The resulting jackknife estimator is

$$\hat{\beta}_{jack} = \frac{1}{n} \sum_{i=1}^n \phi_i = \bar{\phi} \quad \text{where} \quad \phi_i = n\hat{\beta} - (n-1)\hat{\beta}_i \quad (29.31a)$$

which has an approximate large-sample variance of

$$\text{Var}(\hat{\beta}_{jack}) \simeq \frac{1}{n(n-1)} \sum_{i=1}^n (\phi_i - \bar{\phi})^2 \quad (29.31b)$$

Approximate large-sample confidence intervals follow using Equation 29.31b and the fact that $\hat{\beta}_{jack}$ is approximately t -distributed with $n-1$ degrees of freedom. The jackknife estimator and its sampling variance are well behaved even when the residuals are heteroscedastic, thus allowing for valid hypothesis testing (Wu 1986). Wu presented a slightly improved jackknife estimator by weighting the ϕ_i values, but the difference between the weighted and unweighted estimates is usually small for large sample sizes.

Another resampling approach involves **randomization tests** for the significance of a regression. Again, the idea behind this class of tests is simple. A value of $\hat{\beta}$ under the hypothesis of no association between fitness and trait value (z) is generated by assigning the n individual fitness values at random to the observed phenotypic values and estimating β for this scrambled (**randomized**) dataset. Repeating this resampling procedure several thousand times generates a distribution of regression coefficients under the null hypothesis of no association between individual fitness and character value. For example, suppose we obtain a standard least-squares estimate (assuming a linear regression) of $\hat{\beta} = 1.25$, and upon subsequent randomization of the same dataset we find that only 14 out of 1000 randomized datasets have $|\hat{\beta}|$ values in excess of 1.25, which suggests a p value of 0.014. Moore (1990) and Hews (1990) both illustrated applications of randomization tests to fitness data.

A final issue concerns the validity of the particular model chosen to fit $W(z)$. This is a difficult task because fitness data are inherently noisy—the residual variance can be rather large, even if we have perfectly fit $W(z)$. One approach for comparing models is not to contrast their goodness-of-fit (i.e., least-squares solutions), but rather to compare their *predictive* ability: if some of the data are ignored, how well are their fitnesses predicted using a model built from the remaining data? This **cross-validation** procedure (Snee 1977; Picard and Cook 1984) can be used both to assess how well a model predicts the data and as a model-selection approach. The latter follows by choosing the model (from a set of candidates) with the smallest prediction error (Chapter 30 further discusses issues in model selection). Different schemes for splitting the data into **training** (model-building) and **validation** (testing) sets have been proposed. At one extreme is **leave-one-out** cross-validation, wherein the first observation is left out, after which a model built from the remaining data and its fitness prediction of the removed value is assessed, proceeding in this fashion through all of the observations to yield a prediction error variance for a given model. **Generalized cross-validation** (Craven and Wahba 1979) estimates a smoothing parameter to yield a less rugged solution.

A computationally less intense approach is **k-fold** cross-validation, wherein data are randomly assigned to k groups (or **folds**), with the data from the first $k-1$ groups used

to fit the model, and the data from the last group used to check its prediction accuracy. This procedure is repeated so that all k groups are used as test groups, typically with k somewhere between 4 and 10. The k -fold approach may be more appropriate when model fitting is computationally intense, as only $k \ll n$ models must be fitted. It is important to stress that fitting the model to existing data and predicting new data are quite different tasks, and that a model that fits the observed data well may not have good predictive ability.

Power

Another critical issue is the power of a regression to detect selection. As discussed in LW Appendix 5, power is the probability of detecting (i.e., declaring to be significant) an effect, given a preset significance level. Our main focus is on the power to detect a directional selection gradient (β) in a univariate regression. A convenient way to compute the power of this regression is to consider the correlation between the trait value and relative fitness,

$$\rho = \frac{\sigma(z, w)}{\sigma_z \sigma_w} = \frac{S}{\sigma_z \sigma_w} = \frac{\bar{i}}{\sqrt{I}} \quad (29.32a)$$

which is the ratio of the selection intensity to the square root of the opportunity for selection (Hersch and Phillips 2004). Note that we can alternatively express ρ in terms of either a unstandardized (β) or standardized directional selection gradient (β_{sd}), with

$$\rho = \frac{S}{\sigma_z \sigma_w} = \frac{S}{\sigma_z^2 \sigma_w} \sigma_z = \beta \frac{\sigma_z}{\sigma_w} = \frac{\beta_{sd}}{\sigma_w} \quad (29.32b)$$

where the last identity follows from Equation 29.25e. Thus, the power to detect a directional selection gradient is a function of *both* the strength of selection (the selection intensity, $\bar{i} = \beta \sigma_z = \beta_{sd}$) and the variance in total fitness ($I = \sigma_w^2$). A strong amount of selection (a large value of \bar{i}) per se does not ensure high power: rather, it is the strength of selection *relative to the total variance in fitness* (\bar{i}/\sqrt{I}) that is critical. Hersch and Phillips (2004) worked with the adjusted sample correlation, which is defined as

$$r' = \sqrt{\frac{\text{Var}(w)}{\sigma_w^2}} \cdot \sqrt{\frac{\sigma_z^2}{\text{Var}(z)}} \cdot r \quad (29.32c)$$

where Var denotes a sample variance (for either z or w) and r denotes the sample correlation between z and w . Assuming fitness residuals are normal, r' can be scaled to follow a student- t distribution

$$\sqrt{n-1} \left(\frac{r' - \rho}{\sqrt{1-\rho^2}} \right) \sim t_{n-1} \quad (29.32d)$$

Using this result, power calculations follow from standard approaches, wherein for a given strength of selection (scaled as ρ), sample size (n), and level of significance (α), one can compute the probability of rejecting the null hypothesis of $\rho = 0$ (see similar examples in LW Appendix 5).

As shown in Figure 29.9, sample size typically needs to be in the hundreds to have significant power of detecting even modest selection on a trait. With zero/one coded fitness data (such as viability), the residuals follow binomial (rather than normal) distributions, and simulations by Hersch and Phillips (2004) showed that using Equation 29.32d *overestimates* the power to detect a trait-fitness association in this case. Values of n obtained from Equation 29.32d should thus be regarded as *lower bounds*. Further, because of the higher sampling variances with estimates of z^2 , for a fixed value of n , the power to detect quadratic effects (such as γ) is expected to be much less than the power associated with a comparable value for a linear effect (β). Hence, if a large n is required to have any serious power to detect a linear effect, an even larger (and often *much* larger) value of n is required to detect a similar quadratic effect.

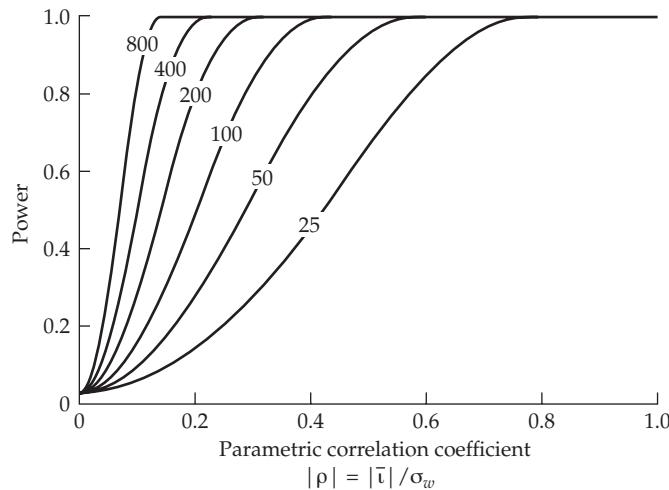

Figure 29.9 The power of a univariate regression to detect a directional selection gradient is a function of the correlation (ρ) between trait value and relative fitness, where $\rho = \bar{t}/\sigma_w = \beta \sigma_z/\sigma_w$. Power is plotted as a function of ρ with the curves for sample sizes starting at $n = 25$ and successively doubling until 800. Here power is the probability that the sample correlation is declared significantly different from zero using a test of significance of $\alpha = 0.05$. (After Hersch and Phillips 2004.)

Mean-standardized Gradients and Fitness Elasticities

Most traits of interest are scaled in the units of their measurement, which could be linear (lengths), areal (leaf surface), volumetric (mass), and even ordinal (traits such as shades of color). The evaluation of different traits across such a range of scales requires some sort of standardization to return a dimensionless quantity for comparison. Typically this is done by dividing a trait by its standard deviation (**variance-standardization**), or, less frequently, dividing it by its mean (**mean-standardization**). For example, Chapters 6 and 13 compared mean- and variance-standardization for the additive genetic variance and the selection response. As shown in Chapter 6, determining which standardization to use is not a trivial issue, as traits that are closely related to fitness have lower heritabilities (variance-standardized values) but higher coefficients of additive variance (mean-standardized values) relative to traits that are more distantly related to fitness.

This debate on the appropriate standardization also extends to selection gradients. Following Lande and Arnold (1983), much of the literature has reported variance-standardized gradients, $\beta_{sd} = \sigma_z \beta$ (also denoted as β_σ). There are, however, potential concerns with variance-standardization (Chapters 6 and 13). The genetic variance (which influences the total variance) is itself a product of past selection, implying that a trait with a history of strong selection (and hence a smaller value of σ_z^2 , due to selection reducing the level of genetic variation) may be perceived as being under stronger current selection than the same trait in a population with a history of weaker past selection (and hence a larger value of σ_z^2). Further, the nature of the trait (whether ordinal, dichotomous, or continuous) can result in dramatic differences in variance. Finally, variance-standardization does not naturally lead to an unambiguous definition of the relative strength of selection. While β_{sd} is the expected change in relative fitness induced by one standard-deviation change in z , whether this is strong or weak depends, in part, on whether the standing variance is large or small.

An alternative is mean-standardization,

$$\beta_\mu = \mu \beta \quad (29.33a)$$

an approach used as early as Johnson et al. (1955), and championed by Morgan and Schoen (1997), van Tienderen (2000), Hereford et al. (2004), and Matsumura et al. (2012) as superior to variance-standardization. The motivation for this scaling is that if β represents the change

in w from a unit change in z , then $\mu\beta$ represents the change in w for a change in z by an amount μ .

The relationship between the mean- and variance-standardizations is simply

$$\frac{\beta_\mu}{\mu} = \beta = \frac{\beta_{sd}}{\sigma}, \quad \text{hence} \quad \beta_\mu = \frac{\mu}{\sigma} \beta_{sd} \quad \text{and} \quad \beta_{sd} = \frac{\sigma}{\mu} \beta_\mu \quad (29.33b)$$

Mean-standardization offers three potential benefits, one obvious, the other two more subtle. First, it does not depend on the trait variance, and hence removes the influence that past selection (in shaping the current variance) has on the measure of current selection strength. Second, it provides a natural scale for the strength of selection, as $\beta_\mu = 1$ when the trait is fitness itself ($z = W$). To see this, first note that the relationship ($W = \bar{W} \cdot w$) between absolute (W) and relative (w) fitness implies, for $z = W$, that

$$\beta = \frac{\sigma(z, w)}{\sigma_z^2} = \frac{\sigma(W, w)}{\sigma^2(W)} = \frac{\bar{W}\sigma^2(w)}{\bar{W}^2\sigma^2(w)} = \frac{1}{\bar{W}} \quad (29.33c)$$

giving $\beta_\mu = \mu\beta = \bar{W}/\bar{W} = 1$. Mean-standardized gradients are also used to obtain the proportional selection response for a trait, with

$$\frac{R}{\mu_z} = \frac{\sigma_A^2}{\mu_z} \beta = \left(\frac{\sigma_A^2}{\mu_z^2} \right) \beta_u = I_A \beta_u \quad (29.33d)$$

where $I_A = (\sigma_A^2/\mu_z^2)$ is Hansen's (Hansen et al. 2003, 2011) metric of evolvability (the square of Houle's 1992 original definition); see Chapter 6.

A final advantage of mean-standardized gradients is that they measure the **elasticity of fitness** with respect to a trait, namely the proportional increase in fitness given a proportional increase in the trait (Morgan and Schoen 1997; van Tienderen 2000). Under the assumption that z is Gaussian distributed, Equation 29.20a implies that

$$\beta_u = \mu\beta = \mu \left(\frac{1}{\bar{W}} \frac{\partial \bar{W}}{\partial \mu} \right) = \left(\frac{\mu}{\partial \mu} \right) \left(\frac{\partial \bar{W}}{\bar{W}} \right) = \frac{\partial \ln(\bar{W})}{\partial \ln(\mu)} \quad (29.33e)$$

Comparison with Equation 29.4c shows that β_u is the elasticity of fitness (or more generally, of a fitness component) with respect to the trait. For example, if $\beta_\mu = 0.3$, increasing a trait value by μ increases fitness by 30%. Conversely, with variance-standardization, $\beta_{sd} = 0.3$ implies that increasing the trait value by one standard deviation results in a 30% increase in fitness. This latter value, however, is not an elasticity because it is not expressed as a function of the proportional change of the trait.

This interpretation of β_μ as an elasticity provides a natural connection between demography (the population growth rate, λ) and evolution (the rate of change in a trait, R). Because elasticities are both additive and also satisfy the chain rule of differentiation, the elasticity of a trait on the population growth rate (λ) can be computed as a function of the elasticity (e_i) of the i th (out of k) fitness component (W_i) of growth rate and the elasticity ($\beta_{\mu,i}$) of the trait on the i th fitness component, yielding

$$\frac{\partial \ln(\lambda)}{\partial \ln(\mu)} = \sum_{i=1}^k \left(\frac{\partial \ln(\lambda)}{\partial \ln(W_i)} \right) \left(\frac{\partial \ln(W_i)}{\partial \ln(\mu)} \right) = \sum_{i=1}^k e_i \beta_{\mu,i} \quad (29.33f)$$

Equation 29.33f, when paired with an appropriate path diagram connecting the trait to fitness components and also connecting those fitness components to λ , forms the basis of elasticity path analysis, which offers a very flexible approach for treating components of fitness (Chapter 30).

An example suggested by Hereford et al. (2004) illustrates this connection. In their meta-analysis, Hereford et al. found medians of the mean-standardized gradients, β_μ , over

their sample of traits on viability and fecundity of 0.57 and 0.23, respectively. Likewise, using an avian dataset, Sæther and Bakke (2000) found average elasticities of viability and fecundity of $e = \partial \ln(\lambda)/\partial \ln(W_i) = 0.6$ and 0.25, respectively, on population growth. These values showed that a proportional change in viability had a far larger ($0.6/0.25 = 2.4$ -fold) impact on the growth rate, λ , than did the same proportional change in fecundity.

Combining the median β_μ values for traits reported by Hereford et al. (2004) with the average elasticity values reported by Sæther and Bakke (2000), the elasticity of a trait on λ via viability selection is $0.6 \cdot 0.57 = 0.34$, while the elasticity through fecundity is $0.25 \cdot 0.23 = 0.06$, for a total elasticity of $0.34 + 0.06 = 0.40$, with the vast majority (86%) via its impact on viability. Hence, a doubling of the trait value results in a 40% increase in the growth rate, mostly through its impact on viability. This is not an isolated case. As summarized by Crone (2001), across a range of studies, adult viability usually had a much higher elasticity than fecundity. The exception was in **semelparous** plants (those with only a single episode of reproduction before death), where growth rate had the highest elasticity, followed by fecundity, and then adult viability. Hence, all else being equal, traits under viability selection likely have a larger impact on λ .

Despite their appeal, there are restrictions and caveats concerning mean-standardized gradients. First, they are only defined for traits where the origin on their measurement scale is not arbitrary. While many traits have a biologically motivated zero value (e.g., height, weight), this restriction excludes many interesting traits, such as seasonal timing (the origin of the calendar is arbitrary) and composite traits (e.g., principal components) (Kingsolver and Pfenning 2007). Second, there are delicate issues in the use of mean-standardization with dichotomous traits, such as the resistance fraction (f) and its complement, the susceptible fraction ($1 - f$). Because either fraction can be used as a measure of the strength of selection, they should both return the same standardized gradients, but the mean-standardized gradients for resistance and susceptibility are different unless $f = 1/2$ (Stinchcombe 2005). Finally, Kingsolver and Pfenning (2007) noted that traits with large β_μ values tend to have small coefficients of variation, a trend not expected if β_μ is a fair standardization.

MOVING AWAY FROM QUADRATIC FITNESS FUNCTIONS

Quadratic Surfaces Can Be Very Misleading

A potentially serious problem with quadratic regressions as estimators of $W(z)$ is that they allow for *only a single local maximum or minimum*. Fitness surfaces with multiple local maxima, or even sharp transitions, are thus poorly described by a quadratic. Figure 29.10A presents a particularly illustrative example, showing that a quadratic fit to a truncation-selection fitness function creates a spurious local minimum. Given this potential for a very misleading view of the fitness surface, why is there so much focus on quadratic regressions? There are two primary motivations. First, the quadratic is the simplest function that allows for curvature, and hence is the simplest estimate of any nonlinearity in the fitness surface. Second, and much more important, when the conditions for the breeder's equation hold (Chapters 6, 13, and 24), the sole measures of phenotypic change entering into the short-term selection response equations for mean (Equation 13.8c) and variance (Equation 16.7b) are the coefficients from the best linear (β from Equation 29.25b) and best quadratic (γ from Equation 29.29f) fit. Hence, even if the fitness surface is very poorly described by a quadratic, even to the point of being very misleading (Figure 29.10), one would still extract the coefficients for the response in the mean and variance by using the quadratic estimate. There is thus the potential for conflict in the use of quadratic regressions between ecologists (who wish to ascertain how traits influence fitness) and evolutionary biologists (who wish to examine how these traits might evolve). In reality, however, both viewpoints are correct. The more accurate the description of the fitness surface, the more ecological insight it provides into the trait, but this fitness surface also needs to be translated into the required parameters to predict the evolutionary dynamics of the trait.

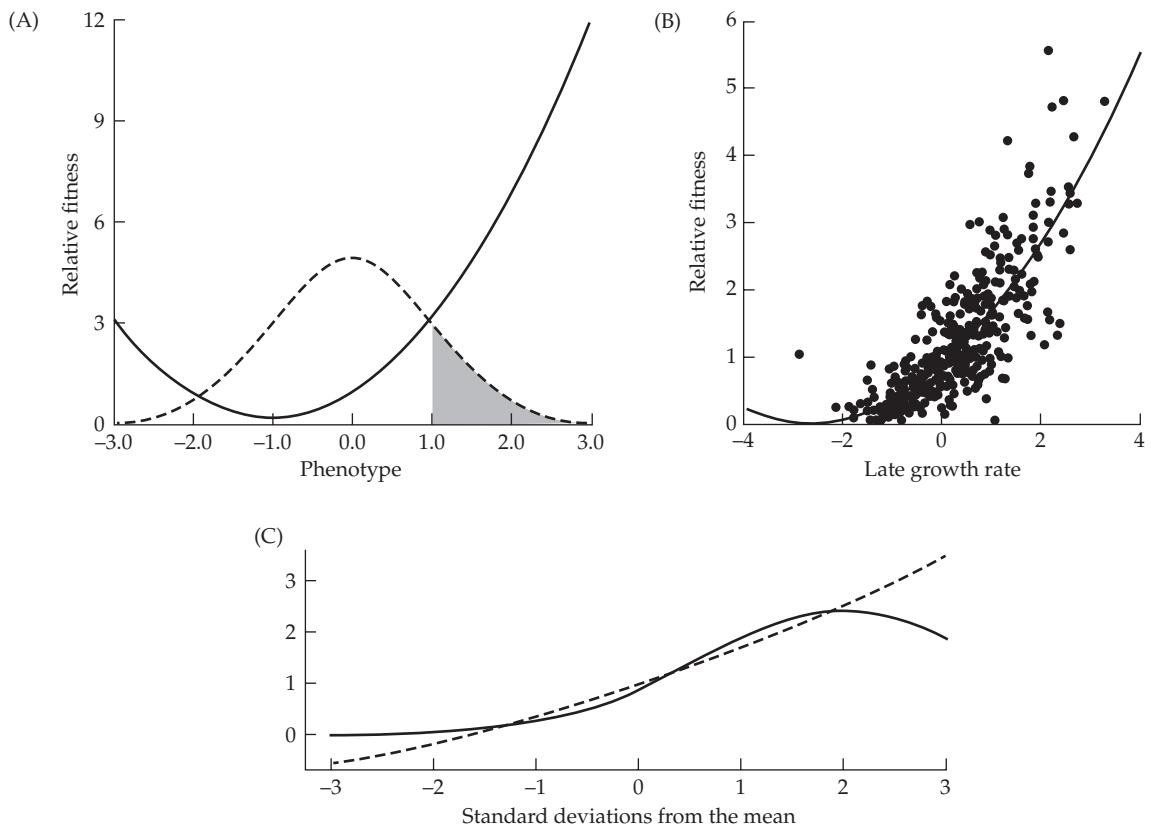

Figure 29.10 Examples of misleading approximations of $W(z)$ resulting from using a quadratic regression. **A:** A hypothetical example wherein phenotypes are normally distributed with only individuals exceeding one phenotypic standard deviation surviving (i.e., threshold selection). The best quadratic regression erroneously suggests the presence of disruptive selection (by introducing a false minimum), rather than the strict directional selection that is actually occurring. In contrast (not shown), the same logic shows that if individuals *above* 1.0 are culled, then the quadratic surface would indicate stabilizing selection by introducing a false maximum. (After Schlüter 1988.) **B:** Data from Mitchell-Olds and Bergelson (1990) on individual fitness as a function of late growth rate (z) for the annual plant *Impatiens capensis*. The data clearly depart from linearity, as they show curvature. The best-fitting quadratic (plotted) indicates a minimum in fitness (disruptive selection) around $z \simeq -2.4$. However, a better fit was given by a model of exponentially increasing fitness, with $w(z) + 0.5 = \exp(0.52 + 0.46 \cdot z - 0.002 \cdot z^2)$, suggesting that strict directional selection is acting on z , as this function monotonically increases over the character range being measured. (After Mitchell-Olds and Bergelson 1990.) **C:** When the optimal value under true stabilizing selection (solid curve; with the true $W(z)$ given by Equation 29.34a) is sufficiently above the current population mean, the best-fitting quadratic (dashed curve) has a positive curvature ($\gamma > 0$). Here the population mean is at zero, and the optimum is two standard deviations above zero. If the mean were two standard deviations above the optimum, the best-fitting quadratic would have a negative curvature ($\gamma < 0$). (After Geyer and Shaw 2008; Shaw and Geyer 2010.)

Gaussian and Exponential Fitness Functions

If our sole focus is in describing the fitness surface (as opposed to extracting components of selection response), then other parametric forms besides the simple quadratic could be considered. One obvious candidate is a Gaussian fitness function

$$W(z) = a \cdot \exp\left(-\frac{(z - \theta)^2}{\omega^2}\right) \quad (29.34a)$$

Weldon (1901), in one of the first studies of selection on a quantitative trait in nature,

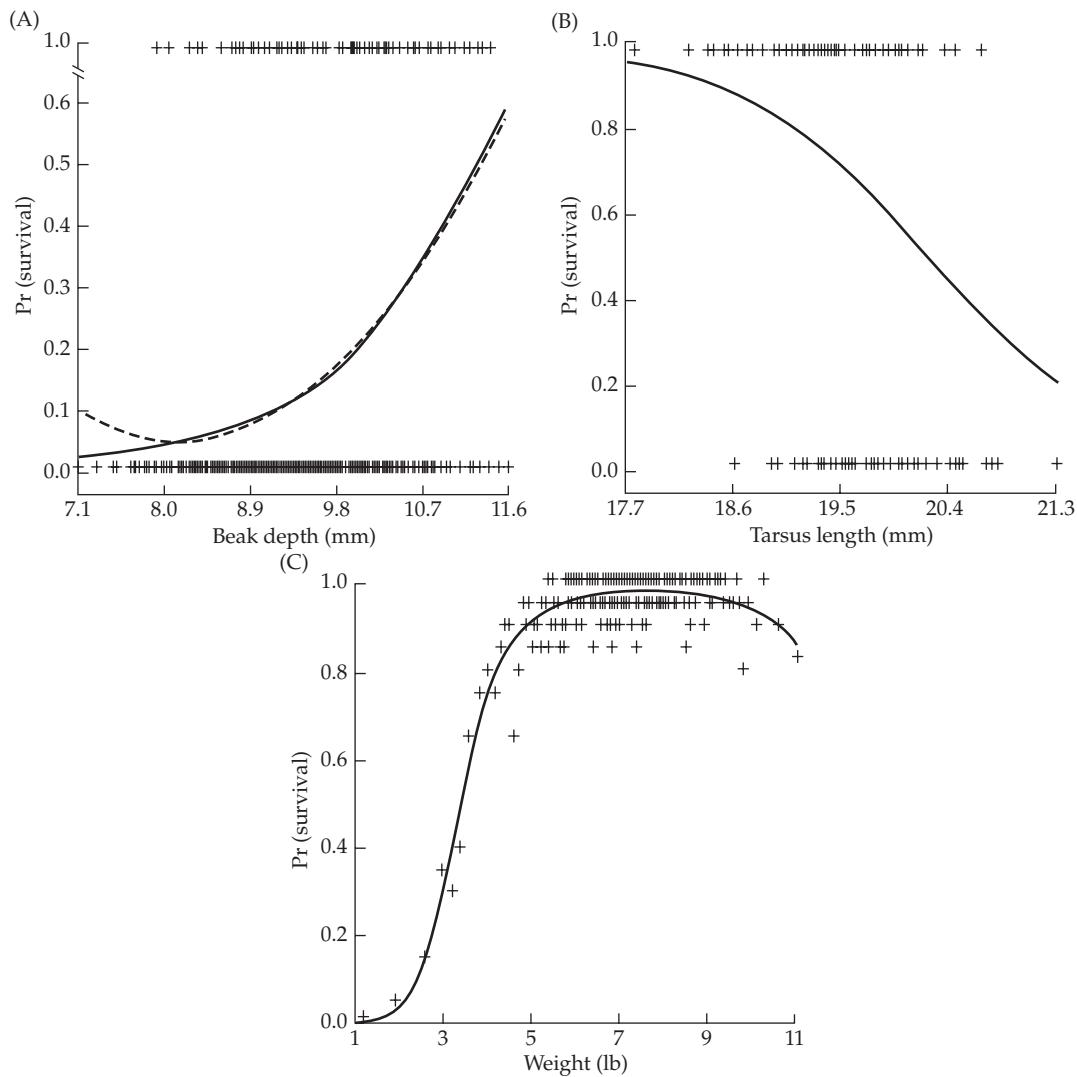

Figure 29.11 Examples of fitness surfaces generated using Schlüter's cubic-spline estimate. The actual fitness values for individuals are indicated by '+', and the solid curve indicates the cubic-spline estimate of $W(z)$. **A:** Probability of survival as a function of beak depth in Darwin's finch (*Geospiza fortis*). The dashed curve indicates the estimate of the surface by a quadratic regression, which generates a spurious minimum. **B:** Overwinter survival in juvenile female song sparrows (*Melospiza melodia*) as a function of tarsus length. **C:** Survival of male human infants as a function of birth weight. (After Schlüter 1988.)

remarked that the Gaussian seems to be a good description of the fitness function (in his case, crab survival as a function of size), and it was used by Cavalli-Sforza and Bodmer (1971) to model the relationship between human birth weight and survival observed by Karn and Penrose (1951).

To model strictly directional selection, the exponential function,

$$W(z) = a \cdot \exp(bz) \quad (29.34b)$$

can be used, while the more general function,

$$W(z) = c \cdot \exp(a + bz + cz^2) \quad (29.34c)$$

allows for both directional and stabilizing or disruptive selection (Mitchell-Olds and Bergelson 1990; see Figure 29.10B). If a trait is normally distributed before selection, it remains

normally distributed following selection when Equation 29.34c is the fitness function, of which Equations 29.34a and 29.34b are special cases (Felsenstein 1977).

Semiparametric Approaches: Schluter's Cubic-spline Estimate

In order to more reliably estimate the fitness function, Schluter (1988) developed a semiparametric method that makes no assumptions about the functional form of the fitness surface, but does require assumptions about the distribution of residuals. Schluter's approach fits the data with a series of **cubic splines** (a series of cubic polynomials that join smoothly together), and uses generalized cross-validation to generate a "best fit" criterion for model selection. In some sense, this is a nonparametric model, as it makes no assumptions about the functional form of the fitness surface. It is, however, parametric in the sense that model fitting requires assumptions about the distribution of the residuals as a function of phenotypic value, z . Schluter developed a program to estimate $W(z)$ when assuming either normal, binomial, or Poisson distributed residuals, using a resampling procedure to generate rough confidence intervals on estimates of $W(z)$. Examples of fitness surfaces that were estimated using this approach are given in Figure 29.11. When one of the classical examples of stabilizing selection, the data of Karn and Penrose (1951) relating survival of human infants to their birth weight, was reanalyzed using Schluter's method, the local maximum was not significant. Parametric tests of the significance of estimated local maxima or minima were discussed by Mitchell-Olds and Shaw (1987) for quadratic regressions, while nonparametric tests were discussed by Schluter (1988). Gimenez et al. (2006) extended Schluter's method to survival estimates based on capture-recapture data.

Janzen-Stein and Morrissey-Sakrejda Gradients: Calculating Average and Landscape Gradients Under General Fitness Functions

We have shown that when phenotypes are normally distributed before an episode of selection, $\beta = S/\sigma_z^2$ equals two different summary statistics of the geometry of selection,

$$\beta = \int \frac{\partial w(z)}{\partial z} p(z) dz = \frac{\partial \ln \bar{W}}{\partial \mu_z}$$

namely, the average selection gradient (the average slope of the individual fitness surface over the current distribution of phenotypes) and the landscape gradient (the gradient of log mean fitness with respect to the population mean). This relationship also holds for *any* phenotypic distribution when the individual fitness function is exactly a quadratic (Equations 29.30c and 29.30g). Outside of this special case for a quadratic $w(z)$ these equalities break down when the distribution of z is no longer normal distributed.

This raises the question of how to obtain these gradients when the trait does not follow a normal distribution and the individual fitness function is not a quadratic. For example, suppose the fitness surface is fitted by a nonquadratic function (such as Equations 29.34a or 29.34b) or by using Schluter's semiparametric regression. What should we take as the "gradient" of fitness in this case? The answer very much depends on the specific question that an investigator is asking. If one wishes to obtain a summary measure of the nature of selection, then the average gradients (the average slope or curvature; Equation 29.20b and 29.20c) might be a reasonable metric.

Janzen and Stein (1998) considered the case in which some general individual fitness surface, $w(z)$, was fit using n observations. Motivated by Equation 29.20b, they suggest using

$$\beta_{JS} = \int \frac{\partial w(z)}{\partial z} p(z) dz = E_z \left[\frac{\partial w(z)}{\partial z} \right] \simeq \frac{1}{n} \sum_{i=1}^n \frac{\partial w(z)}{\partial z} \Big|_{z=z_i} \quad (29.35a)$$

with the last step following by approximating the expectation by using the sampled values. We refer to this as a **Janzen-Stein selection gradient**. They used this approach to obtain a gradient when a logistic function is used to fit $w(z)$, where an explicit form of the required derivative is easily obtained. The same approach can be extended to the average

curvature of the individual fitness surface by recalling Equation 29.20c, which calculates the corresponding Janzen-Stein (quadratic) gradient as

$$\gamma_{JS} = \int \frac{\partial^2 w(z)}{\partial z^2} p(z) dz \simeq \frac{1}{n} \sum_{i=1}^n \frac{\partial^2 w(z)}{\partial z^2} \Big|_{z=z_i} \quad (29.35b)$$

When the fitness surface is complex (for example, a fine-meshed grid with individual fitness values for each coordinate, such as would be returned by a semiparametric regression), numerical methods can be used to compute the required partials for Equations 29.35a and 29.35b. When $\delta \simeq 0$,

$$\begin{aligned} \frac{\partial w(z)}{\partial z} \Big|_{z=z_i} &\simeq \frac{w(z_i + \delta/2) - w(z_i - \delta/2)}{\delta} \\ \frac{\partial^2 w(z)}{\partial z^2} \Big|_{z=z_i} &\simeq \frac{w(z_i - \delta) - 2w(z_i) + w(z_i + \delta)}{\delta} \end{aligned} \quad (29.35c)$$

While average gradients of the individual fitness function provide reasonable summary statistics for discussions about the nature of selection, if the concern is the *evolution* of these traits over time, then landscape gradients are required. This follows from our extensive discussion in Chapter 24 of selection response when normality no longer holds. The generalized Barton-Turelli selection response equations (Equation 24.26) for changes in the phenotypic moments after a generation of selection requires estimates of various partials of the landscape gradient with respect to the moments of the phenotypic distribution. If the underlying genetics are such that the distribution of breeding values is nearly normal, then (Equation 24.30a) the only measure of selection entering into the equation for the change in mean is the landscape gradient with respect to the population mean. If the distribution of breeding values shows skew and/or kurtosis (specifically, a nonzero value of the scaled kurtosis, $\kappa_4 = [\mu_{4,G} - 3\sigma_A^4]/\sigma_A^4$), then partials of the landscape gradient with respect to the phenotypic variance and skew are required to predict the change in mean.

The requirement of landscape gradients to predict selection response motivates the definition of the **Morrissey-Sakrejda selection gradient** (Morrissey and Sakrejda 2013, 2014; Morrissey 2014a). Following Janzen and Stein, they suggest that this gradient (for a given estimated fitness function) can also be computed numerically. Here

$$\beta_{MS} = \frac{\partial \ln \bar{W}}{\partial \mu_z} = \frac{1}{\bar{W}} \frac{\partial \bar{W}}{\partial \mu_z}, \quad \text{where } \bar{W} = \frac{1}{n} \sum_{i=1}^n W(z_i) \quad (29.35d)$$

A similar expression defines γ_{MS} . This approach works for general fitness surfaces, such as those estimated using a semiparametric regression, and nonnormal distributions.

MORE REALISTIC MODELS OF THE DISTRIBUTION OF FITNESS COMPONENTS

Placing the estimation of fitness components, total fitness, and fitness surfaces within a rigorous statistical framework requires more realistic models for the distribution of fitness residuals. We build toward this goal in two steps. First, we introduce a number of generalized linear models (a topic initially discussed in Chapter 14) that allow for more biologically realistic modeling of the distribution of fitness effects within a given episode of selection. We then turn to aster models that compute the much more complex distribution resulting from the compounding of component distributions over multiple episodes of selection.

Generalized Linear Models for Fitness Components

The data for total fitness are nonnegative integers, representing the number of offspring left by an individual. The components that make up total fitness are also integer data, and

fall into two broad distributional categories. We first consider **Bernoulli random variables** (fitness components have a value of 1 with probability p , else they have a value of 0), such as occurs with viability selection (alive or dead) and mating status (mated or not mated).

Translating Bernoulli components of fitness into a fitness surface requires a model of how p varies with trait value, z (or more generally, a set of trait values represented by the vector, \mathbf{z}). A natural choice is the **logistic regression** model (Janzen and Stein 1998), which was introduced in Chapter 14. Equation 14.10a presented its simplest version,

$$W(z) = p(z) = \Pr(\text{survival} | z) = \frac{\exp(a + bz)}{1 + \exp(a + bz)} = \frac{1}{1 + \exp(-[a + bz])} \quad (29.36a)$$

Equation 29.36a is a model of directional selection, as $W(z)$ increases toward one as z increases when $b > 0$. Likewise, $W(z)$ decreases toward zero as z increases when $b < 0$. As discussed in Chapter 14, a logistic regression is equivalent to modeling $p(z)$ using the **logit** function,

$$\text{logit}[p(z)] = \ln \left[\frac{p(z)}{1 - p(z)} \right] = \begin{cases} a + bz & (\text{univariate case}) \\ a + \sum_i b_i z_i = a + \mathbf{b}^T \mathbf{z} & (\text{multivariate case}) \end{cases} \quad (29.36b)$$

The upper righthand expression in Equation 29.36b corresponds to modeling the logit of p with a simple linear regression, while the lower expression is a more general linear model, which could include quadratic terms (e.g., $b_1 z + b_2 z^2$), which allows for the possibility of either concave or convex selection. Most generally, the righthand expressions in Equation 29.36b could be a full mixed model. For example, Coulson (2012), modeled the impact of size, z , on survival in Soay sheep by assuming that

$$\text{logit}[p(z, t)] = a + bz - \eta N(t) + r(t)$$

where the fixed effect (η) accounts for density-dependent survival ($N[t]$ is the population size at time t), and the random effect, $r(t)$, accounts for the environmental effect at time t .

Logistic regressions naturally accommodate the heteroscedastic nature of residuals for viability (and other Bernoulli random variables), and maximum likelihood (LW Appendix 3) can be used to estimate model parameters. Modifications of logistic regressions can also be used to estimate fitness using capture-recapture data (Kingsolver and Smith 1995). Capture-recapture models were reviewed by Lebreton et al. (1992), while the analysis of the targets of selection using capture-recapture data was further discussed by Conroy et al. (2002), Zabel et al. (2005), and Gimenez et al. (2006).

The logit function takes an unconstrained linear model (with potential values over $-\infty$ to ∞) and maps it into the constrained parameter space for p , namely, between zero and one. As mentioned in Chapter 14, this is the basic structure of **generalized linear models**: the conditional expectation of an observed value, y , given some underlying variable, z , can be expressed as $E(y | z) = g(z)$ for some monotonic function g , where some inverse transformation returns a linear model,

$$g^{-1}[E(y | z)] = z = \mu + \sum \beta_k x_{k,i}$$

The inverse function, g^{-1} , is called the **link function**, as it transforms the conditional expectation into a linear model.

The basic idea of such models is that some underlying (and unobserved) **latent variable**, z , is transformed into an observed variable, y . Such a model can be thought of as having three distinct scales (de Villemereuil et al. 2016): (i) an underlying **latent scale**, the value of z ; (ii) an **expected data scale**, $E(y | z) = g(z)$, which is the expected value of y for that value of z ; and (iii) an **observed data scale**, the actual observed value of y , which is a function of its expectation plus a residual error, where the latter need not be normal (and indeed, usually is not). This approach is called a **generalized linear model (GLM)** if the latent

variable, z , is modeled via a standard general linear model (involving only fixed effects), and a **generalized linear mixed model (GLMM)** if we model z as a mixed linear model (z is a mixture of both fixed and random effects; e.g., Coulson 2012). GLMs and GLMMs allow for fairly general error structures (e.g., Poisson, binomial, etc.) and are generally solved by either maximum-likelihood or Bayesian approaches (e.g., Hadfield 2010). GLMs and GLMMs were reviewed in detail by McCulloch et al. (2008) and Stroup (2012).

More general survival functions (beyond the simple logistic) can be found in the analysis of clinical trials (e.g., Klein and Moeschberger 1997; Lawless 2003) and time-to-failure analysis from industrial statistics (e.g., Kenett and Zacks 1998), both examples of **survival analysis**. Manly (1976) suggested the use of the **double exponential fitness function** for viability data, where

$$W(z) = \Pr(\text{survival} | z) = \exp(-\exp[a + bz]) \quad (29.37)$$

This is a special case of the classic **proportional-hazards model** (Cox 1972) for human clinical trials, wherein the probability of survival to time t is determined by a general risk for every individual in the population (specified by some monotonically nondecreasing function, $g(t)$, so that probability of survival declines with increasing values of t), and a specific (proportional) risk for the particular phenotype z , which yields

$$W(z, t) = \Pr(\text{survival} | z, t) = \exp(-\exp[ag(t) + bz]) \quad (29.38a)$$

One choice is $g(t) = \ln(t)$, giving the general risk as $\exp(-\exp[ag(t)]) = \exp(-\lambda t)$, namely the exponential distribution (a constant, i.e., age-independent, risk), weighted by the risk for phenotype z ,

$$W(z, t) = \exp(-[\lambda t] \cdot \exp[bz]) \quad (29.38b)$$

If survival at stage j is measured, the proportional-hazards model can be written as

$$W(z, j) = \Pr(\text{survival} | z, j) = \exp(-\exp[h_j + bz]) \quad (29.38c)$$

One advantage of using proportional-hazards models (due to the memoryless feature of the exponential distribution) is that they can allow for certain types of missing, or **censored**, data (Little and Rubin 2002), such as the last time a marked individual was recovered.

Given that an individual has survived and mated, the second broad class of probability models for fitness components involves discrete counting distributions, which range over $0, 1, 2, \dots$, such as number of mates or number of offspring per mating. One candidate distribution is the Poisson (Equation 14.16), which is solely a function of its mean value, θ . As with Bernoulli data, we need a model for how θ varies as a function of the trait value z , in which case the probability of j offspring (or j mates, or j of some other fitness component) is

$$\Pr(W = j | z) = e^{-\theta(z)} \frac{\theta(z)^j}{j!} \quad (29.39a)$$

From Equation 14.17b, the log-linear model is a candidate for translating z into a mean for the Poisson, where

$$\ln[\theta(z)] = a + bz \quad (29.39b)$$

Because $\theta(z)$ is constrained to be nonnegative, Equation 29.39b takes an unconstrained linear model and maps it into the range $(0, \infty)$, corresponding to the allowable range of means for a Poisson. More generally, for n traits we can use the log-linear model,

$$\ln[\theta(z)] = a + \sum_i^n b_i z_i = a + \mathbf{b}^T \mathbf{z} \quad (29.39c)$$

which again can include quadratic terms (e.g., $a + b_1 z + b_2 z^2$) and hence model concave or convex selection.

One limitation of the Poisson is that its mean equals its variance, whereas fitness data are often **overdispersed**, with the variance exceeding the mean (often, but not always, caused by an excess of zero values). In overdispersed settings, an alternative candidate model is the **negative binomial distribution**. This models the total number of successes (y) that occur before r failures for independent trials with a success probability of p ,

$$\Pr(y = j | r, p) = \frac{(j + r - 1)!}{j! (r - 1)!} p^j (1 - p)^r \quad \text{for } j = 0, 1, \dots \quad (29.40a)$$

If a random variable, y , follows a negative-binomial distribution, denoted by $y \sim NB(r, p)$, then its mean and variance are

$$\mu_y = \frac{pr}{1 - p} \quad \text{and} \quad \sigma_y^2 = \frac{pr}{(1 - p)^2}. \quad \text{Hence} \quad \frac{\sigma_y^2}{\mu_y} = \frac{1}{1 - p} > 1 \quad (29.40b)$$

showing that the variance can exceed the mean by an arbitrary amount. Because of this feature, the negative-binomial is often used in place of a Poisson to allow for overdispersion (Wilson et al. 2005b; Yang et al. 2009). One approach for modeling fitness data using this distribution is to assume a constant r value for all trait values (estimated from the data), and then model $p(z)$ using the logit function (Equation 29.36b). The negative binomial is the sum of r geometric random variables, and hence is the discrete counterpart of the gamma distribution (which is the sum of r exponential random variables; Appendix 2).

Two other approaches for building discrete counting distributions for fitness components deal with the often problematic issue of handling an excess of zero values (Martin et al. 2005). The first is to use a **zero-truncated distribution**, whose values are *conditional* on being nonzero (i.e., they ignore zero values entirely). If we let $\phi(j | z) = \Pr(W = j | z)$ denote a discrete counting distribution (such as a Poisson, binomial, or negative binomial), then its zero-truncated version is given by

$$\Pr(W = j | z) = \frac{\phi(j | z)}{1 - \phi(0 | z)} \quad \text{for } j \geq 1 \quad (29.41a)$$

where j equals number of offspring, mates, flower heads, and so forth. For example, the zero-truncated Poisson is

$$\Pr[W = j | \theta(z)] = \frac{\theta(z)^j e^{-\theta(z)} / j!}{1 - e^{-\theta(z)}} = \frac{e^{-\theta(z)}}{1 - e^{-\theta(z)}} \cdot \frac{\theta(z)^j}{j!} \quad \text{for } j \geq 1 \quad (29.41b)$$

As above, the trait-specific mean $\theta(z)$ can be modeled as a log-linear model (Equations 29.39b and 29.39c). This can be generalized to a **k-truncated distribution**, wherein the first k states (i.e., 0 to a value of $k - 1$) are ignored

$$\Pr(W = j | z) = \frac{\phi(j | z)}{1 - \sum_{i=0}^{k-1} \phi(i | z)} \quad \text{for } j \geq k \quad (29.41c)$$

and which occasionally appears in the selection literature (Shaw et al. 2008).

The other approach is to construct a **zero-inflated distribution**, which includes an additional point mass, $1 - q(z)$, at zero,

$$\Pr(W = j | z) = \begin{cases} 1 - q(z) + q(z)\phi(0 | z) & \text{for } j = 0 \\ q(z)\phi(j | z) & \text{for } j \geq 1 \end{cases} \quad (29.42)$$

where (as above) $\phi(j | z) = \Pr(W = j | z)$ is a discrete counting distribution and $q(z)$ is the probability that the observation given z is *not* zero-inflated. As above, we can model $q(z)$ using the logit function (Equation 29.36b). Alternatively, one can model the zero-inflated

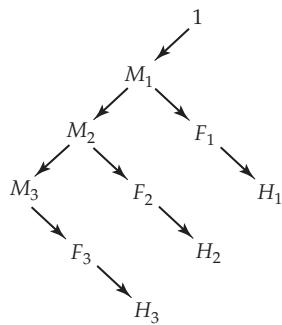

Figure 29.12 A life-history graph of potential fitness components in the aster *Echinacea angustifolia*. The distribution of lifetime fitness starts by considering the discrete number of offspring left by a single individual (the 1 at the upper right starting the graph). First, this individual must survive to year one (M_1), in which case it may flower (F_1), and if it flowers, it has some (discrete) number (H_1) of flower heads (taken as the surrogate for fitness). The same pattern continues (providing it survives) over years two and three, with lifetime fitness given by $H_1 + H_2 + H_3$. A life history can be constructed as a forest graph, as there are no loops and each node has only one predecessor. Further, if the value of a predecessor is zero, then all descendant values from that predecessor are also zero. For example, if an individual fails to survive to year two (M_2 is zero), then H_2 and H_3 are zero. If F_1 is zero, then H_1 is zero, but this (by itself) tells us nothing about H_2 or H_3 , as they are not descendants of F_1 . This graphical representation allows very complex life histories to be accurately modeled. (After Geyer et al. 2007.)

distribution as an **atom** (probability mass) at zero and a zero-truncated distribution if not zero.

Aster Models: Modeling the Distribution of Total Fitness

While the above section presented more realistic distributions for a given *component* of fitness, the distribution of *lifetime* fitness is much more complex, compounding a series of Bernoulli (viability, mating, etc.) and discrete counting distributions (number of mates, number of offspring, etc.). The resulting distribution incorporating all of these episodes has an excess of zero values and does not fit any standard distribution. Ideally, one would like an approach that allows an investigator to specify the distribution of each of the components and then arrive at the correct distribution of total fitness.

An example of this problem is presented in Figure 29.12, which shows the life history of the purple coneflower (*Echinacea angustifolia*) in the family Asteraceae (Geyer et al. 2007). A single individual may survive year one (M_1), in which case it may flower (F_1), in which case it has some discrete flower head–count status (H_1), with this pattern continuing in years two and three (assuming survival). Lifetime flower head production ($\sum H_i$) is used as the surrogate for total fitness. Even this fairly simple life history has a complex, very nonstandard, distribution for total fitness. One can model the M_i and F_i values as Bernoulli random variables, and the H_i values as zero-truncated Poissons (because we are conditioning on them flowering). Equivalently, conditioned on survival ($M_i = 1$), flower head status H_i could be directly modeled as a zero-inflated Poisson.

Motivated by the problem posed by Figure 29.12, Geyer et al. (2007; 2013; Shaw et al. 2008; Geyer 2010; Geyer and Shaw 2010a, 2010b) developed an approach they called **aster models** (a homage to the initial aster study) as a very flexible framework for modeling the distribution of total lifetime fitness given a life-history graph. As Geyer noted, the term aster models is far catchier than “forest graph exponential family conditional or unconditional canonical statistic models.” Aster models start with a life-history graph (a **forest graph**, as there are no loops and each node has only one predecessor), and assume that the distribution to the next step of the graph (a fitness component) is a member of the exponential family (which includes Bernoulli, binomial, Poisson, and negative binomial distributions, as well

as their truncated versions).

Shaw et al. (2008) noted that simple aster models correspond to previous methods of analysis. The simplest life-history graph is $1 \rightarrow X$. If X is normally distributed, this is a standard linear model (such as Lande-Arnold regression). If X is Bernoulli, this is a logistic regression (Equation 29.36), while if X is Poisson, this is the log-linear model (Equation 29.39c). The graph is $1 \rightarrow X \rightarrow Y$, where X is Bernoulli and Y is either a zero-truncated Poisson or a zero-truncated negative-binomial correspond to the zero-inflated versions of these distributions (Equation 29.42). Finally, the graph $1 \rightarrow X_1 \rightarrow X_2 \rightarrow \dots \rightarrow X_n$ (where all the X_i are Bernoulli) corresponds to survival analysis. The power of aster models is that they use the specific life-history details of the organism of interest and reasonable candidate distributions for each fitness component to build up a proper distribution of lifetime fitness.

By modeling the parameter values for each fitness component distribution as functions of trait value z (e.g., Equations 29.36b and 29.39c), aster models can be used to construct fitness surfaces using the correct residual structure. This can be done using Geyer's R package `aster2`. We return to aster models and fitness surfaces in Chapter 30.

THE IMPORTANCE OF EXPERIMENTAL MANIPULATION

Several authors have stressed that regression approaches should be viewed as only the *preliminary step* in any analysis of the actual agents of selection, treating any suggested traits under selection as candidates to be further tested by experimental manipulation (Mitchell-Olds and Shaw 1987, 1990; Schlüter 1988; Wade and Kalisz 1990; Kingsolver and Pfenning 2007). Further, as Example 29.1 highlights, the role of the **invisible fraction** (selection on a trait before it is expressed) is generally only accessible by direct manipulative experiments (Hadfield 2008). Recall that in Example 29.1, the very strong selection on the invisible fraction (here, viability selection on time to flowering) would have been missed if not for transplant experiments with known flower-size genotypes. A second interesting example is the work of Sinervo and McAdam (2008) on clutch size in side-blotched lizards (*Uta stansburiana*). Through the use of both hormonal control and surgical reduction in the number of ovaries, they showed a viability cost to increased clutch size that occurs before clutch size is expressed.

One can envision two (not mutually exclusive) experimental approaches for assessing trait-fitness relationships: **environmental manipulation** and **phenotypic manipulation**. The idea of assessing fitnesses in manipulated environments (be they physical or biotic alterations) traces back to the first attempts to measure natural selection on quantitative traits. Weldon (1895, 1899) observed that the frontal-length to carapace-length ratio in the European green crab (*Carcinus maenas*) declined over a five-year period in Plymouth Sound. Noting that a breakwater in the harbor had recently been completed, he hypothesized that increased silt accumulation might be a selective agent behind this change. To test this, he exposed crabs to silt conditions similar to that expected in Plymouth, and found that the survivors in this laboratory setting had reduced frontal length. He hypothesized that narrow frontal length had an impact on filtering out sediments.

A more recent example where the biotic, rather than physical, environment was altered involves the work of Breden and Wade (1989), who observed a positive relationship between group size and fitness in the imported willow leaf beetle. However, when predators were excluded, there was no such relationship, so that β is correlated with the environment (presence or absence of predators). Wade and Kalisz (1990) suggested computing fitness regressions in several different environments, and looking for correlations between β (and/or γ) and environmental features (Figure 29.13). Such correlations suggest specific environmental features for candidates as causal agents of selection.

Under phenotypic manipulation, the investigator artificially modifies the value of the focal trait in individuals and then assesses the fitness consequences in nature (e.g., Sinervo and Basolo 1996; Travis and Reznick 1998). A classic example of this approach is the work of Andersson (1982), which examined the impact of tail length in male mating success in a

Kenyan population of long-tailed widowbirds (*Euplectes progne*). Males with experimentally elongated tails showed greater mating success than males with normal or shortened tails. Further, shortened tails had no impact on the ability of males to control territories, indicating that female choice, rather than male-male competition, was the selective force acting on tail length.

One caveat about using artificial manipulations is that because they may produce variants far outside the normal range of the distribution of z , estimates of β and γ may be correspondingly spurious (Arnold 1988). Conversely, it has been argued that many traits may be near their optima and hence show a limited range of variation relative to the selective forces faced during their evolution. Given this potentially limited range of phenotypes, Lexer et al. (2003) suggested that experimental hybridization with closely related species (which is often easily to accomplish in plants) may provide important insight into the nature of selection. However, hybrids can have a number of significant fitness consequences outside the impact of specific traits on fitness, and hence caution is in order when using this approach.

Example 29.11. Grether (1996) examined male mating success and survival in a California population of the rubyspot damselfly (*Hetaerina americana*). Mature males of this species have a red spot at the base of their wings, and Grether was interested in whether variation in the size of this spot influences sexual and/or natural selection. Three fitness components were measured: reproductive life span (a measure of survival selection), mating rate (a measure of sexual selection), and lifetime mating success (a combination of both survival and sexual selection). All three showed significant selection gradients with red spot size, but not with body size. Thus, the Lande-Arnold regression suggested that larger spot size is favored by both sexual (mating rate) and natural (reproductive life span) selection. As a test of this, Grether examined these components in three additional groups: an “enlarged” group where red ink was used to increase spot size, a “sham” group where the same area was filled with clear ink, and an unmanipulated group. Mating success (mates per day) was significantly greater in the enlarged group, while unchanged in the sham versus control groups. Thus, experimental manipulation of this trait confirmed the role of red spot size in sexual selection. Surprisingly, males with enlarged spots had mortality rates that were 23% higher than the controls, while the sham and control groups showed no differences. Thus, contrary to what the fitness regression suggests, direct manipulation shows that increasing spot size decreases survival. Unmeasured traits (or other factors) generated an apparently strong positive selection gradient of survival on spot size that was not verified by phenotypic manipulation.

Performance and Eco-evolutionary Surfaces

The ultimate aim of detecting selection on a trait is not just to understand its nature (directional, convex, concave), but ideally its ecological *causes*. Phenotypic manipulation can verify that a trait is under selection, but may offer little direct insight into the forces underlying that selection. Functional morphology may offer increased insight, by considering the impact that a trait (or suite of traits) has on one (or more) composite **performance traits** that directly influence fitness (such as running, flying, or swimming speed; seed dispersal; or predator avoidance). The idea is that the performance value (h), not the trait value (z), is the direct target of selection, giving the causal (path) diagram as $z \rightarrow h \rightarrow w$, with more ecological insight garnered by considering the nature of selection acting on h . In exactly the same fashion that we constructed an individual fitness surface for the trait using regressions, Arnold (1983b, 2003) suggested the use of **performance surfaces**. Here linear or quadratic regressions are used to predict a performance value, h , given the observed traits,

$$h = a + \sum_i b_i z_i + \sum_j \sum_k c_{jk} z_j z_k + \epsilon \quad (29.43)$$

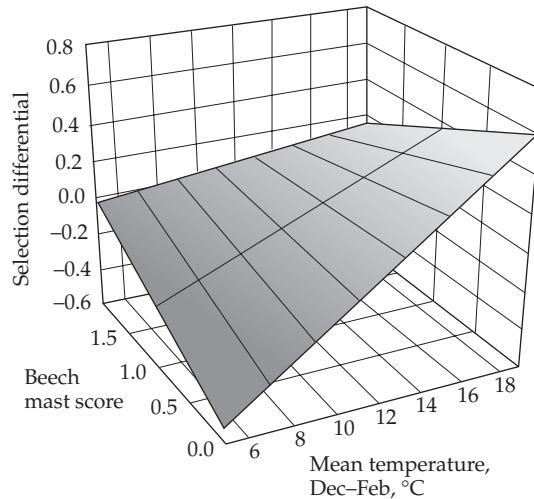

Figure 29.13 The eco-evolutionary surface for selection on fledging weight in great tits (*Parus major*), based on data from Wytham Woods, Oxford, England. The fitted surface plots the selection differential, S , for fledging weight as a function of biotic (food) and abiotic (temperature) variables. The abiotic variable was the average December to February temperature, the biotic variable the amount of beech tree (*Fagus sylvatica*) nuts, given by the mast score. (After MacColl 2011.)

Arnold suggested that performance surfaces can offer important insight, potentially bridging a conceptual gap between trait and fitness values through a functional intermediate that is more biologically interpretable (also see Geber and Griffen 2003 for a plant perspective). By analogy with Equation 29.29b, the regression coefficients (b_i and c_{jk}) in Equation 29.43 are often referred to as **performance gradients**.

Performance is occasionally used as a direct proxy for fitness (one measures performance, rather than directly measuring fitness), and the performance gradients subsequently taken as proxies for fitness gradients. Franklin and Morrissey (2017) cautioned that the conditions under which performance gradients (coefficients of z in the h on z regression) correspond to selection gradients (coefficients of z in the w on z regression) are very narrow. Specifically, the regression of fitness on the performance score (h) must be both linear and with an intercept of zero.

A complementary approach is that of MacColl (2011), who suggested that ecological insight can be gleaned by regressing selection differentials or gradients on potential biotic or abiotic factors, generating an **eco-evolutionary surface** (Figure 29.13), and thus generalizing the suggestion of Wade and Kalisz (1990). The idea is that one has trait-fitness data over a series of years along with candidate biotic and abiotic factors, fitting the regression

$$\beta = a + b_1 f_1 + b_2 f_2 + \cdots + b_k f_k + \epsilon \quad (29.44)$$

where f_i represent environmental and biotic values. This is a modification of the **factor regression** approach used by plant breeders to decompose $G \times E$ into sensitivities to specific environmental components (e.g., Baril 1992; Baril et al. 1995; Epinat-Le Signor 2001). Equation 29.44 generates a surface that attempts to predict trait selection as a function of ecological variables (regressing the selection gradient or differential for a trait as a function of ecological factors, as opposed to a fitness surfaces, which regresses fitness on trait values).

MacColl (2011) gave an example of selection on fledging weight in great tits (*Parus major*) as a function of December to February temperatures and the amount of nuts (the mast score) produced by beech trees (*Fagus sylvatica*). As shown in Figure 29.13, the resulting graph suggests selection for lower weight ($S < 0$) when food is scarce and temperatures are low, but selection for higher weight ($S > 0$) when temperatures are high. As with a

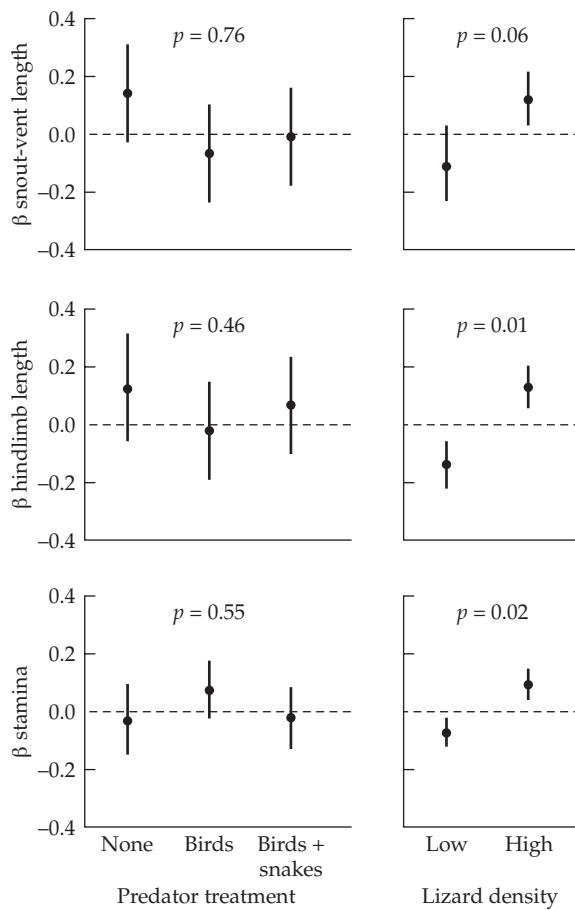

Figure 29.14 The impact of environmental manipulation of agents of possible selection on *Anolis* lizards in the Caribbean. The presence or absence of predators did not change the selection gradients on three traits (snout-vent length, limb length, running stamina), while lizard density had a significant impact ($p \leq 0.05$). See Example 29.12 for more details. (After Calsbeek and Cox 2010.)

fitness-trait regression, this approach is most appropriate when used to suggest hypotheses to be tested by manipulative experiments.

Example 29.12. Example 29.11 highlighted one type of manipulation: artificially changing trait values and examining the resulting impact on fitness. An alternative is to manipulate the *environment* and examine the impact on selection for particular traits, accomplishing experimentally what Equation 29.44 attempts to do statistically. A classic example of this is the work of Calsbeek and Cox (2010), on populations of the brown anole lizard (*Anolis sagrei*) on very small, environmentally manipulated, islands in the Caribbean. Some islands had no bird or snake predators, some had only bird predators, and some both birds and snakes. The presence of predators increased mortality, but did not significantly change the selection gradients on body size (snout-vent length), limb length, or running stamina (Figure 29.14). Conversely, altering the island lizard density resulted in significant differences in all three gradients (Figure 29.14), demonstrating that competition (or some other density-related effect, such as pathogen transmission) was much more important than predation as agents of selection on these traits.

30

Measuring Multivariate Selection

We have found that there are fundamental differences between the surviving birds and those eliminated, and we conclude that the birds which survived survived because they possessed certain structural characters, and that the birds which perished perished not through accident, but because they did not possess certain structural characters which would have enabled them to withstand the severity of the test imposed by nature; they were eliminated because they were unfit. Bumpus (1899)

While we have previously hinted at some of the features of multivariate selection (Chapters 13 and 20), we now start our formal discussion of selection on a vector of traits. As in Chapter 29, we distinguish between *selection*, the within-generation change in the (fitness-weighted) distribution of trait values and the *response to selection*, how the distribution of trait values changes across generations. *Phenotypic* correlations between traits within an individual influence within-generation changes, while *genetic* correlations (correlations among the breeding values for different traits within an individual) influence the between-generation response (Chapter 13). In particular, when a suite of traits is phenotypically correlated, simply observing the within-generation change in their means or variances is *not* sufficient to determine which ones are under selection.

To assess which traits are under selection, one must remove the effects of phenotypic correlations to separate **direct** selection from **correlated** selection. This is done by using partial regressions (linear for changes in the means and quadratic for changes in variances and covariances), and much of our focus here is on such fitness-trait regressions. Essentially all of the measures of phenotypic selection discussed here are multivariate extensions of the univariate measures introduced in Chapter 29. As these expressions are presented in terms of matrices and vectors, we rely rather heavily in places on matrix machinery (such as eigenvalues and eigenvectors, canonical decompositions, and, in a few places, matrix calculus). Appendix 5 discusses the mathematics of treating matrices as geometric objects, while Appendix 6 provides a brief refresher of important concepts and tools from the calculus of matrices (such as multidimensional derivatives and Taylor series).

The structure of this chapter is as follows: We first introduce the multivariate versions of selection differentials and gradients and their properties. Next, the geometry of quadratic regressions is examined in some detail, followed by discussions of multivariate nonparametric regressions and the strength of selection in natural populations. We conclude with some comments on unmeasured characters, the use of path analysis as an alternative (and often complementary) approach to the analysis of selection, and measures of multilevel selection.

As was the case for Chapter 29, much of the discussion here centers around the landmark paper of Lande and Arnold (1983) and the very long shadow it has cast for the past three decades in the phenotypic selection literature. There is a healthy debate as to the robustness of conclusions from this approach, especially in terms of measures of nonlinear selection. A second concern is that the ordinary least-squares (OLS) solutions of the Lande-Arnold regression assume that fitness residuals are normally distributed and homoscedastic, which is clearly incorrect. We introduced these issues in a univariate setting in Chapter 29, and here we continue their discussion in the multivariate setting.

SELECTION ON MULTIVARIATE PHENOTYPES: DIFFERENTIALS AND GRADIENTS

Chapter 29 described a variety of measures of univariate selection, with an emphasis on approximating the individual fitness function. In order to extend these methods to a vector

of characters, we need to account for phenotypic correlations. To do so, we follow the multiple regression approach of Lande and Arnold (1983), which was initially suggested by Pearson (1903). The phenotype of an individual is now a vector, $\mathbf{z} = (z_1, z_2, \dots, z_n)^T$, of n character values. Suppose we denote the mean vector and covariance matrix of \mathbf{z} before selection by $\boldsymbol{\mu}$ and \mathbf{P} , respectively, and by $\boldsymbol{\mu}^*$ and \mathbf{P}^* after selection (but before reproduction). As an aside, we use this phrase *before reproduction*, which often appears in the literature. This does not mean that reproductive aspects of fitness are ignored; rather, it simply means that we ignore any complications arising from genetic transmission to the next generation. Formally, this means that the fitness-weight distribution of the parents (which reflects reproductive success; Chapter 29) is taken as the distribution after selection (as opposed to the trait distribution seen in their offspring, which confounds selection with the cross-generational transmission). To avoid additional complications, we examine only a single episode of selection. Partitions over multiple episodes follow as fairly straightforward extensions of the univariate partitions discussed in Chapter 29 (Arnold and Wade 1984a; Wade and Kalisz 1989; McGlothlin 2010).

Changes in the Mean Vector: The Directional Selection Differential Vector, \mathbf{S}

The multivariate extension of the **directional selection differential** is the vector

$$\mathbf{S} = \boldsymbol{\mu}^* - \boldsymbol{\mu}$$

whose i th element is $S_i = \mu_i^* - \mu_i$, which is the differential for character z_i . (The fastidious reader might object to the nonstandard use of a capital bold letter, as opposed to the more standard bold lowercase letter, for a vector, but univariate selection theory uses S for the selection differential, and we keep that notation here.) As with the univariate case, the Robertson-Price identity (Equation 6.10) holds, with $\mathbf{S} = \sigma(\mathbf{z}, w)$, meaning that the elements of \mathbf{S} represent the covariance between character value and relative fitness, $S_i = \sigma(z_i, w)$. This immediately implies (from Equation 29.6b) that the opportunity for selection, I (which is the population variance, σ_w^2 , in relative fitness), bounds the range of S_i , and

$$\frac{|S_i|}{\sigma_{z_i}} \leq \sqrt{I} \quad (30.1a)$$

and

$$|\bar{s}_i| \leq \sigma_w \quad (30.1b)$$

Both show that selection intensity, $\bar{s}_i = S_i/\sigma_{z_i}$, for any trait (with $\sigma_{z_i}^2$ being the phenotypic variance of trait i) is bounded by the standard deviation of fitness.

As illustrated in Figure 30.1, \mathbf{S} confounds the **direct effects** of selection on a focal trait with the **indirect effects** from selection on phenotypically correlated characters. Suppose character 1 is under direct selection to increase in value while character 2 is not directly selected. If z_1 and z_2 are uncorrelated, there is no within-generation change in μ_2 (the mean of z_2). However, if z_1 and z_2 are positively correlated, because individuals with large values of z_1 also tend to have large values of z_2 , there will be a within-generation increase in μ_2 ($S_2 > 0$). Conversely, if z_1 and z_2 are negatively correlated, selection to increase z_1 will result in a within-generation decrease in μ_2 ($S_2 < 0$). Hence, a character not under selection can still experience a within-generation change resulting from selection on a phenotypically correlated trait (**indirect selection** or **correlated selection**). Fortunately, the **directional selection gradient**, $\boldsymbol{\beta} = \mathbf{P}^{-1}\mathbf{S}$, accounts for indirect selection resulting from phenotypic correlations (among the *measured* traits in the study), providing a less biased picture of the nature of directional selection acting on the component traits comprising \mathbf{z} .

The Directional Selection Gradient Vector, $\boldsymbol{\beta}$

As was discussed briefly in Chapters 13 and 20, $\boldsymbol{\beta}$, removes the effects of phenotypic correlations (among the set of traits being considered) because it is a vector of partial regression

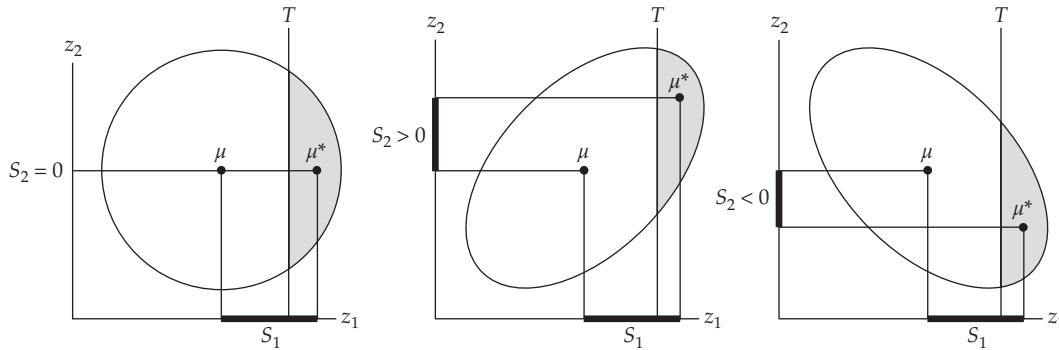

Figure 30.1 Selection on a character can result in a within-generation change in the mean of other phenotypically correlated characters that are not themselves under direct selection. Suppose we assume that character 1 is under simple truncation selection, so only individuals with values of $z_1 > T$ reproduce. There is no *direct* selection on trait 2. Here μ and μ^* are the population mean vector before and after selection, respectively. **Left:** When z_1 and z_2 are uncorrelated, $S_2 = 0$. **Center:** When z_1 and z_2 are positively correlated, $S_2 > 0$. **Right:** When z_1 and z_2 are negatively correlated, $S_2 < 0$.

coefficients. From multiple regression theory (LW Chapter 8), the vector of partial regression coefficients for predicting the value of w , given a vector of observations \mathbf{z} , is $\mathbf{P}^{-1}\boldsymbol{\sigma}(\mathbf{z}, w)$, where \mathbf{P} is the covariance matrix of \mathbf{z} and $\boldsymbol{\sigma}(\mathbf{z}, w)$ is the vector of covariances between the elements of \mathbf{z} and fitness, with an i th element of $\boldsymbol{\sigma}(z_i, w)$. Because $\mathbf{S} = \boldsymbol{\sigma}(\mathbf{z}, w)$, it immediately follows that

$$\mathbf{P}^{-1}\boldsymbol{\sigma}(\mathbf{z}, w) = \mathbf{P}^{-1}\mathbf{S} = \boldsymbol{\beta} \quad (30.2a)$$

is the vector of partial regression coefficients for the linear regression of relative fitness, w , on phenotypic value, \mathbf{z} , namely,

$$w(\mathbf{z}) = 1 + \sum_{j=1}^n \beta_j(z_j - \mu_j) + e = 1 + \boldsymbol{\beta}^T(\mathbf{z} - \boldsymbol{\mu}) + e \quad (30.2b)$$

Recalling the fact (LW Chapters 3 and 8) that the regression must pass through the means of both w and \mathbf{z} (1 and $\boldsymbol{\mu}$, respectively), allows us to remove the intercept constant, a , in the regression. We could equivalently write Equation 30.2b as $w(\mathbf{z}) = a + \boldsymbol{\beta}^T\mathbf{z} + e$, where $a = 1 - \boldsymbol{\beta}^T\boldsymbol{\mu}$.

The partial regression coefficient, β_j , represents the change in w from a one-unit increase in z_j while holding all the other characters constant. It is important to note, however, that $\boldsymbol{\beta}$ accounts for the effects of phenotypic correlations only among the *measured* set of characters that comprise the elements of \mathbf{z} . Among the members of this set, a character under no directional selection has a value of $\beta_j = 0$.

Because $\mathbf{S} = \mathbf{P}\boldsymbol{\beta}$, we have

$$S_i = \sum_{j=1}^n \beta_j P_{ij} = \beta_i P_{ii} + \sum_{j \neq i} \beta_j P_{ij} \quad (30.3)$$

which illustrates that the directional selection differential for trait i confounds direct selection on that character (β_i) with indirect contributions due to selection on phenotypically correlated characters ($\beta_j P_{ij} \neq 0$). These contributions are given, respectively, by the first and second terms in Equation 30.3.

Operationally, fitness regressions are usually computed using **standardized variables**,

$$z_{sd,i} = \frac{z_i - \mu_i}{\sigma_i} \quad (30.4a)$$

with $z_{sd,i}$ having a mean of zero and unit variance (this is often denoted by z'_i in the literature). As mentioned in Chapter 29, one could also mean-standardize (z_i/μ_i) , but when the term *standardized variable* is used in the evolutionary and ecological literature, it usually implies Equation 30.4a. The selection differential of the standardized variable is simply the selection intensity \bar{t} (Equation 13.6a), as

$$S_{sd,i} = \sigma(z_{sd,i}, w) = \sigma(z_i/\sigma_i, w) = \frac{\sigma(z_i, w)}{\sigma_i} = \frac{S_i}{\sigma_i} = \bar{t}_i$$

The standardization given by Equation 30.4 can be expressed in matrix form as

$$\mathbf{z}_{sd} = \mathbf{D}^{-1}(\mathbf{z} - \boldsymbol{\mu}) \quad (30.4b)$$

where \mathbf{D} is the diagonal matrix

$$\mathbf{D} = \begin{pmatrix} \sigma_1 & 0 & \cdots & 0 \\ 0 & \sigma_2 & \cdots & 0 \\ \vdots & & \ddots & \vdots \\ 0 & 0 & \cdots & \sigma_n \end{pmatrix} \quad (30.4c)$$

Equations 30.4b and 30.4c imply that the phenotypic covariance matrix (\mathbf{P}_{sd}) for the standardized variables is simply the matrix of all pairwise correlations. Following our notation from Chapter 29, we denote selection gradients using variance-standardized variables by $\beta_{sd,i}$, although they are often denoted by β'_i in the literature. When expressed with standardized variables, Equation 30.2b becomes

$$w(\mathbf{z}_{sd}) = 1 + \beta_{sd}^T \mathbf{z}_{sd} + e, \quad \text{where } \beta_{sd} = \mathbf{P}_{sd}^{-1} \mathbf{S}_{sd}$$

Here $\beta_{sd,i}$ is the expected change in relative fitness given a change of one standard deviation in trait z_i when all of the other *measured* trait values (i.e., the elements of \mathbf{z}) are held constant.

The total strength of directional selection on the set of measured characters is a quantity of interest, and is given by the norm of β , where (Equation A5.1a)

$$\|\beta\| = \sqrt{\beta^T \beta} = \sqrt{\sum \beta_i^2}$$

Morrissey (2014b) noted that $E[\|\hat{\beta}\|] \geq \|\beta\|$, as the values of β_i are measured with error, and such error carries over into the norm. Suppose k independent traits are measured, where $\hat{\beta}_i \sim N(\beta, \sigma^2)$, so that each β_i is independent and identically distributed, with sampling error σ^2 . In this case, $E[\|\hat{\beta}\|] = \sqrt{k(\beta + \sigma^2)} > \|\beta\| = \sqrt{k\beta}$. Given that the standard error of an estimate of β is often of the same order as the estimate itself (Morrissey 2014b), the total strength of selection can be considerably overestimated by $\|\hat{\beta}\|$.

We also remark in passing that the Henshaw-Zemel (2017) distributional selection differential (a nonparametric measure of the total shift in a distribution following selection; Equation 29.15a) can be generalized into a multivariate version that also partitions trait selection into direct and indirect effects; see their paper for details.

Example 30.1. The original application of the Lande-Arnold regression was on a population of one-spotted stink bugs (*Euschistus variolarius*), collected along the shore of Lake Michigan after a storm (Lande and Arnold 1983), an insect equivalent of the classic Bumpus (1899) study. Of the 94 individuals collected (legend has it that some were deposited into an open adult beverage container, in a truly selfless act of science), 39 were alive. All individuals were measured for four characters: head (Hd) and thorax (Tx) width and scutellum (Sc) and forewing (Fw) length. The data were then logarithmically transformed to more closely approximate

normality, and the resulting log-transformed variables were variance-standardized. Selection differentials were calculated as the difference between the trait means among those bugs that survived and the total sample (dead or alive). Because these selection differentials were scaled in standard deviations, they correspond to selection intensities (\bar{i} ; Equation 13.6a). The resulting vector of standardized selection differentials and correlation matrix were

$$\mathbf{S}_{sd} = \begin{pmatrix} \bar{i}_{Hd} \\ \bar{i}_{Tx} \\ \bar{i}_{Sc} \\ \bar{i}_{Fw} \end{pmatrix} = \begin{pmatrix} -0.11 \\ -0.06 \\ -0.28^* \\ -0.43^{**} \end{pmatrix} \quad \mathbf{P}_{sd} = \begin{pmatrix} 1.00 & 0.72 & 0.50 & 0.60 \\ 0.72 & 1.00 & 0.59 & 0.71 \\ 0.50 & 0.59 & 1.00 & 0.62 \\ 0.60 & 0.71 & 0.62 & 1.00 \end{pmatrix}$$

where * and ** denote 5% and 1% significance for the elements in \mathbf{S}_{sd} . Hence,

$$\boldsymbol{\beta}_{sd} = (\mathbf{P}_{sd})^{-1} \mathbf{S}_{sd} = \begin{pmatrix} 1.00 & 0.72 & 0.50 & 0.60 \\ 0.72 & 1.00 & 0.59 & 0.71 \\ 0.50 & 0.59 & 1.00 & 0.62 \\ 0.60 & 0.71 & 0.62 & 1.00 \end{pmatrix}^{-1} \begin{pmatrix} -0.11 \\ -0.06 \\ -0.28 \\ -0.43 \end{pmatrix} = \begin{pmatrix} 0.02 \\ 0.53^{**} \\ -0.16 \\ -0.72^{**} \end{pmatrix}$$

The selection differentials for scutellum and wing length were both significantly different from zero, while the only significant gradients were for thorax and wing length. Hence, while the within-generation change in thorax length was negative (but not significantly different from zero), in reality there was strong direct selection to *increase* thorax length. An increase of one standard deviation in thorax length increases relative fitness by $\beta_{sd} = 0.53$ (i.e., 53%), while an increase of one standard deviation in wing length reduces fitness by 72%.

Directional Gradients, Fitness Surface Geometry, and Selection Response

Consider a scalar-valued function, $f(\mathbf{x})$, whose argument is a vector, $\mathbf{x} = (x_1, \dots, x_n)^T$. Recall from vector calculus (Appendix 6) that the **gradient vector**, $\nabla_{\mathbf{x}} f(\mathbf{x})$, of f with respect to \mathbf{x} is defined as

$$\nabla_{\mathbf{x}} f(\mathbf{x}) = \begin{pmatrix} \partial f / \partial x_1 \\ \partial f / \partial x_2 \\ \vdots \\ \partial f / \partial x_n \end{pmatrix}$$

namely, the vector of each partial of f with respect to x_i , for $1 \leq i \leq n$. Further, recall that the gradient vector of a multivariate function points in the direction of change that will give the greatest (local) increase in f .

When phenotypes are multivariate normal, $\boldsymbol{\beta} = \mathbf{P}^{-1} \mathbf{S}$ provides a convenient descriptor of the geometries, measured by gradients, of both the individual fitness surface, $w(\mathbf{z})$, and the mean population landscape, \bar{W} . Let us consider the landscape first. If we assume the \mathbf{z} is multivariate normal (MVN), Example A6.3 shows that

$$\boldsymbol{\beta} = \nabla_{\boldsymbol{\mu}} [\ln \bar{W}(\boldsymbol{\mu})] = \bar{W}^{-1} \cdot \nabla_{\boldsymbol{\mu}} [\bar{W}(\boldsymbol{\mu})] \quad (30.5a)$$

which holds provided the fitnesses are frequency-independent (Lande 1976, 1979a). In this case, $\boldsymbol{\beta}$ is the gradient of *mean population* fitness with respect to the mean vector, $\boldsymbol{\mu}$, namely, the direction of steepest local increase in \bar{W} . Hence, given the current population mean, \bar{W} increases most rapidly when the change in the vector of means ($\Delta\boldsymbol{\mu}$) is in the direction given by $\boldsymbol{\beta}$. If the fitnesses are frequency-dependent (individual fitnesses change as the population mean changes, so that $\nabla_{\boldsymbol{\mu}} [w(\mathbf{z})] \neq 0$), then provided \mathbf{z} is multivariate-normally distributed, Example A6.3 further shows that

$$\boldsymbol{\beta} = \nabla_{\boldsymbol{\mu}} [\ln \bar{W}(\boldsymbol{\mu})] + \int \nabla_{\boldsymbol{\mu}} [w(\mathbf{z})] \varphi(\mathbf{z}) d\mathbf{z} \quad (30.5b)$$

The integral in this expression accounts for the effects of frequency-dependence (the change in the *individual fitness* surface with respect to changes in the mean, μ) and φ is the MVN density function (Lande 1976). The vector β does not point in the direction of steepest increase in \bar{W} unless the second integral is zero.

Equation 30.5a shows the connection between the fitness *landscape* (the mean fitness surface) and β when \mathbf{z} is MVN. A similar connection with β occurs (when \mathbf{z} is also MVN) with the *individual fitness* surface. Here β as the average gradient of individual relative fitnesses (over the population distribution of phenotypes),

$$\beta = E_{\mathbf{z}} \left[\nabla_{\mathbf{z}} [w(\mathbf{z})] \right] = \int \nabla_{\mathbf{z}} [w(\mathbf{z})] \varphi(\mathbf{z}) d\mathbf{z} \quad (30.6)$$

which holds provided $\mathbf{z} \sim \text{MVN}$ (Lande and Arnold 1983). To see this, we use integration by parts to yield

$$\int_{\mathbf{a}}^{\mathbf{b}} \nabla_{\mathbf{z}} [w(\mathbf{z})] \varphi(\mathbf{z}) d\mathbf{z} = w(\mathbf{z}) \varphi(\mathbf{z}) \Big|_{\mathbf{a}}^{\mathbf{b}} - \int_{\mathbf{a}}^{\mathbf{b}} \nabla_{\mathbf{z}} [\varphi(\mathbf{z})] w(\mathbf{z}) d\mathbf{z}$$

If we take the limit as $\mathbf{a} \rightarrow -\infty$ and $\mathbf{b} \rightarrow \infty$, the first term on the righthand side vanishes as $\varphi(\mathbf{z}) \rightarrow 0$ when $\mathbf{z} \rightarrow \pm \infty$. If $\mathbf{z} \sim \text{MVN}(\mu, \mathbf{P})$, then Equation A6.2a gives $\nabla_{\mathbf{z}} [\varphi(\mathbf{z})] = -\varphi(\mathbf{z}) \mathbf{P}^{-1} (\mathbf{z} - \mu)$, implying

$$\begin{aligned} \int \nabla_{\mathbf{z}} [w(\mathbf{z})] \varphi(\mathbf{z}) d\mathbf{z} &= - \int \nabla_{\mathbf{z}} [\varphi(\mathbf{z})] w(\mathbf{z}) d\mathbf{z} = \int w(\mathbf{z}) \varphi(\mathbf{z}) \mathbf{P}^{-1} (\mathbf{z} - \mu) d\mathbf{z} \\ &= \mathbf{P}^{-1} \left(\int \mathbf{z} w(\mathbf{z}) \varphi(\mathbf{z}) d\mathbf{z} - \mu \int w(\mathbf{z}) \varphi(\mathbf{z}) d\mathbf{z} \right) \\ &= \mathbf{P}^{-1} (\mu^* - \mu) = \mathbf{P}^{-1} \mathbf{S} = \beta \end{aligned}$$

The first integral in the second line corresponds to the mean trait value weighted by relative fitness (μ^*), while the second integral is the average value of relative fitness (1). Note from this derivation that Equation 30.6 holds regardless of whether fitness is frequency-dependent or -independent. This follows because the gradient was taken with respect to \mathbf{z} , rather than with respect to the vector of means, μ .

Finally, while our focus has been on the role that β plays in measuring phenotypic selection, β also plays an important role in the response to selection. If we can assume that the breeder's equation holds, it is the only measure of phenotypic selection required to predict the response in the means, as the vector, \mathbf{R} , of response (changes in means) is calculated by $\mathbf{R} = \mathbf{G}\beta$ (Equation 13.26a). Cheverud (1984b) made the important point that although it is often assumed that a set of phenotypically correlated traits responds to selection in a coordinated fashion, this is not necessarily the case. Because β removes the effects of phenotypic correlations, phenotypic characters will only respond as a group if they are all under direct selection or if they are *genetically* correlated, a point discussed in detail in Volume 3.

Changes in the Covariance Matrix: The Quadratic Selection Differential Matrix, C

Motivated by the univariate case wherein $C = \sigma[w, (z - \mu)(z - \mu)]$, the multivariate **quadratic selection differential** is defined as the square ($n \times n$) matrix, \mathbf{C} , whose elements are the covariances between all pairs of quadratic deviations, $(z_i - \mu_i)(z_j - \mu_j)$, and relative fitness, w , namely,

$$C_{ij} = \sigma[w, (z_i - \mu_i)(z_j - \mu_j)] \quad (30.7a)$$

As derived in Example 30.2, Lande and Arnold (1983) showed that

$$\mathbf{C} = \sigma[w, (\mathbf{z} - \mu)(\mathbf{z} - \mu)^T] = \mathbf{P}^* - \mathbf{P} + \mathbf{S} \mathbf{S}^T \quad (30.7b)$$

where \mathbf{P} and \mathbf{P}^* are, respectively, the phenotypic covariance matrices before- and after-selection. If no quadratic selection is acting, the covariance between each quadratic deviation and fitness is zero, and with $\mathbf{C} = \mathbf{0}$. In this case, Equation 30.7b returns the within-generation change in \mathbf{P} resulting from selection as

$$P_{ij}^* - P_{ij} = -S_i S_j \quad (30.7c)$$

This demonstrates that the $S_i S_j$ term corrects C_{ij} for the change in covariance caused by directional selection alone. This expression is the multivariate extension of the condition $\sigma^2(z^*) - \sigma^2(z) = P^* - P = -S^2$ for a single trait (Equation 29.16a); the latter expression follows as a special case ($i = j$) for Equation 30.7c.

Example 30.2. We wish to show that $\mathbf{P}^* - \mathbf{P} = \boldsymbol{\sigma}[w(\mathbf{z}), (\mathbf{z} - \boldsymbol{\mu})(\mathbf{z} - \boldsymbol{\mu})^T] - \mathbf{S} \mathbf{S}^T$, which implies Equation 30.7b. From the definition of the variance-covariance matrix,

$$\mathbf{P} = E[(\mathbf{z} - \boldsymbol{\mu})(\mathbf{z} - \boldsymbol{\mu})^T] = \int (\mathbf{z} - \boldsymbol{\mu})(\mathbf{z} - \boldsymbol{\mu})^T p(\mathbf{z}) d\mathbf{z} \quad (30.8a)$$

$$\mathbf{P}^* = E[(\mathbf{z}^* - \boldsymbol{\mu}^*)(\mathbf{z}^* - \boldsymbol{\mu}^*)^T] = \int (\mathbf{z}^* - \boldsymbol{\mu}^*)(\mathbf{z}^* - \boldsymbol{\mu}^*)^T p^*(\mathbf{z}) d\mathbf{z} \quad (30.8b)$$

where $p^*(\mathbf{z}) = w(\mathbf{z}) p(\mathbf{z})$ is the distribution of \mathbf{z} after selection (but before reproduction). If we note that $\boldsymbol{\mu}^* = \boldsymbol{\mu} + \mathbf{S}$, the integrated expression in Equation 30.8b can be written as

$$\begin{aligned} (\mathbf{z} - \boldsymbol{\mu}^*)(\mathbf{z} - \boldsymbol{\mu}^*)^T &= (\mathbf{z} - \boldsymbol{\mu} - \mathbf{S})(\mathbf{z} - \boldsymbol{\mu} - \mathbf{S})^T \\ &= (\mathbf{z} - \boldsymbol{\mu} - \mathbf{S})([\mathbf{z} - \boldsymbol{\mu}]^T - \mathbf{S}^T) \\ &= (\mathbf{z} - \boldsymbol{\mu})(\mathbf{z} - \boldsymbol{\mu})^T - (\mathbf{z} - \boldsymbol{\mu})\mathbf{S}^T - \mathbf{S}(\mathbf{z} - \boldsymbol{\mu})^T + \mathbf{S}\mathbf{S}^T \end{aligned} \quad (30.8c)$$

Because $\int \mathbf{z} p^*(\mathbf{z}) d\mathbf{z} = \boldsymbol{\mu}^*$ and $\int p^*(\mathbf{z}) d\mathbf{z} = 1$, then

$$\int (\mathbf{z} - \boldsymbol{\mu}) \mathbf{S}^T p^*(\mathbf{z}) d\mathbf{z} = \int [\mathbf{z} p^*(\mathbf{z})] \mathbf{S}^T d\mathbf{z} - \boldsymbol{\mu} \mathbf{S}^T \int p^*(\mathbf{z}) d\mathbf{z} = (\boldsymbol{\mu}^* - \boldsymbol{\mu}) \mathbf{S}^T = \mathbf{S} \mathbf{S}^T$$

$$\int \mathbf{S}(\mathbf{z} - \boldsymbol{\mu})^T p^*(\mathbf{z}) d\mathbf{z} = \mathbf{S}(\boldsymbol{\mu}^*)^T - \mathbf{S}\boldsymbol{\mu}^T = \mathbf{S}(\boldsymbol{\mu}^* - \boldsymbol{\mu})^T = \mathbf{S} \mathbf{S}^T$$

$$\int \mathbf{S} \mathbf{S}^T p^*(\mathbf{z}) d\mathbf{z} = \mathbf{S} \mathbf{S}^T$$

Substituting these results into Equation 30.8b yields

$$\begin{aligned} \mathbf{P}^* &= \int (\mathbf{z} - \boldsymbol{\mu})(\mathbf{z} - \boldsymbol{\mu})^T w(\mathbf{z}) p(\mathbf{z}) d\mathbf{z} - \mathbf{S} \mathbf{S}^T - \mathbf{S} \mathbf{S}^T + \mathbf{S} \mathbf{S}^T \\ &= E[w(\mathbf{z}) \cdot (\mathbf{z} - \boldsymbol{\mu})(\mathbf{z} - \boldsymbol{\mu})^T] - \mathbf{S} \mathbf{S}^T \end{aligned} \quad (30.8d)$$

Because $E[w(\mathbf{z})] = 1$, we can write $\mathbf{P} = E[w(\mathbf{z})] \cdot \mathbf{P}$. Using the definition of \mathbf{P} ,

$$\begin{aligned} \mathbf{P}^* - \mathbf{P} &= E[w(\mathbf{z}) \cdot (\mathbf{z} - \boldsymbol{\mu})(\mathbf{z} - \boldsymbol{\mu})^T] - \mathbf{S} \mathbf{S}^T - E[w(\mathbf{z})] \cdot E[(\mathbf{z} - \boldsymbol{\mu})(\mathbf{z} - \boldsymbol{\mu})^T] \\ &= \boldsymbol{\sigma}[w(\mathbf{z}), (\mathbf{z} - \boldsymbol{\mu})(\mathbf{z} - \boldsymbol{\mu})^T] - \mathbf{S} \mathbf{S}^T \end{aligned} \quad (30.8e)$$

with the last equality following from the definition of a covariance, $\sigma(x, y) = E(x \cdot y) - E(x)E(y)$.

As was the case for \mathbf{S} , the fact that C_{ij} is a covariance immediately allows us to bound its range using the opportunity for selection (Chapter 29). Because $\sigma^2(x, y) \leq \sigma^2(x)\sigma^2(y)$,

$$C_{ij}^2 \leq \sigma^2(w)\sigma^2[(z_i - \mu_i)(z_j - \mu_j)] = I\sigma^2[(z_i - \mu_i)(z_j - \mu_j)] \quad (30.9a)$$

When z_i and z_j are bivariate-normal, then (Kendall and Stuart 1983),

$$\sigma^2[(z_i - \mu_i)(z_j - \mu_j)] = P_{ij}^2 + P_{ii}P_{jj} = P_{ij}^2(1 + \rho_{ij}^{-2}) \quad (30.9b)$$

where ρ_{ij} is the phenotypic covariance between z_i and z_j . Hence, for Gaussian-distributed phenotypes,

$$\left| \frac{C_{ij}}{P_{ij}} \right| \leq \sqrt{I} \sqrt{1 + \rho_{ij}^{-2}} \quad (30.10)$$

which is a variant of the original bound based on I , as suggested by Arnold (1986). Note that when $i = j$, $\rho_{ii} = 1$, and we recover Equation 29.18c.

The Quadratic Selection Gradient Matrix, γ

Like the directional selection differential vector, \mathbf{S} , the quadratic selection differential, \mathbf{C} , confounds the effects of direct selection with selection on phenotypically correlated characters. As was the case with \mathbf{S} , these indirect effects can also be removed by a regression. Consider the quadratic regression of relative fitness as a function of phenotypic value,

$$w(\mathbf{z}) = a + \sum_{j=1}^n b_j z_j + \frac{1}{2} \sum_{j=1}^n \sum_{k=1}^n \gamma_{jk} (z_j - \mu_j)(z_k - \mu_k) \quad (30.11a)$$

$$= a + \mathbf{b}^T \mathbf{z} + \frac{1}{2} (\mathbf{z} - \boldsymbol{\mu})^T \boldsymbol{\gamma} (\mathbf{z} - \boldsymbol{\mu}) \quad (30.11b)$$

Using multiple regression theory, Lande and Arnold (1983) showed that when $\mathbf{z} \sim \text{MVN}$, the matrix, $\boldsymbol{\gamma}$, of quadratic partial regression coefficients is given by

$$\boldsymbol{\gamma} = \mathbf{P}^{-1} \boldsymbol{\sigma} [w, (\mathbf{z} - \boldsymbol{\mu})(\mathbf{z} - \boldsymbol{\mu})^T] \mathbf{P}^{-1} = \mathbf{P}^{-1} \mathbf{C} \mathbf{P}^{-1} \quad (30.12)$$

This is the **quadratic selection gradient**, and (like β) it removes the effects of phenotypic correlations (among the *measured* traits), thus providing a more accurate picture of how selection is operating on the multivariate phenotype.

As we saw in the univariate case (Chapter 29), the vector of linear coefficients (\mathbf{b}) for the quadratic regression need not equal the vector of partial regression coefficients ($\boldsymbol{\beta}$) that is obtained by assuming only a *linear* regression (Equation 30.2b). Equation 29.28a showed (for the univariate case) that if the phenotypic distribution is skewed, the linear term (b) in the quadratic regression is a function of both S and C , while the linear term in a linear regression (β) is only a function of S . When phenotypes are multivariate normal, the skew is zero, and $\mathbf{b} = \boldsymbol{\beta}$ (Lande and Arnold 1983), which recovers the multivariate version of the Pearson-Lande-Arnold regression,

$$w(\mathbf{z}) = a + \boldsymbol{\beta}^T \mathbf{z} + \frac{1}{2} (\mathbf{z} - \boldsymbol{\mu})^T \boldsymbol{\gamma} (\mathbf{z} - \boldsymbol{\mu}) \quad (30.13a)$$

As with linear regression, one typically standardizes the trait values (Equation 30.4b), in which case Equation 30.13a can be written more compactly as

$$w(\mathbf{z}) = a + \boldsymbol{\beta}_{sd}^T \mathbf{z}_{sd} + \frac{1}{2} \mathbf{z}_{sd}^T \boldsymbol{\gamma}_{sd} \mathbf{z}_{sd} \quad (30.13b)$$

Because the elements, γ_{ij} , of the matrix $\boldsymbol{\gamma}$ (or its standarized counterpart, $\boldsymbol{\gamma}_{sd}$) are partial regression coefficients, they predict the change in expected fitness caused by changing the associated quadratic deviation while holding all other variables constant. Increasing

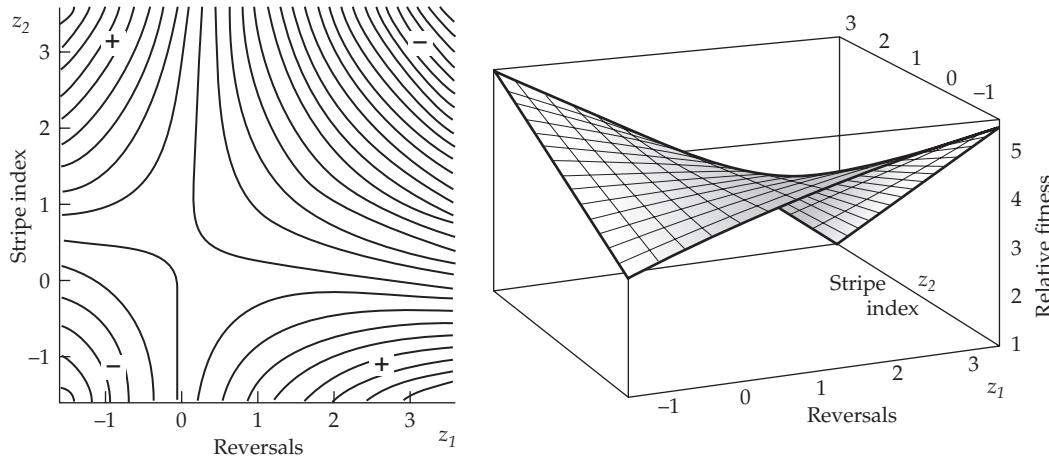

Figure 30.2 The fitness surface (measured as one-year survivorship) for number of reversals (z_1) and body stripe index (z_2) in the garter snake *Thamnophis ordinoides*. There is a significant correlational gradient between these two characters, and all other directional and quadratic gradients are nonsignificant. **Left:** A plot of contours of equal fitness, with peaks represented by + and valleys by -, shows that the best-fitting quadratic fitness surface has a saddle point. **Right:** Three-dimensional representation of the best-fitting quadratic fitness surface. As will be discussed shortly, the eigenvalues of the γ matrix can be used to clarify the geometry of the associated quadratic fitness surface. Here, the eigenvalues of γ are 0.256 and -0.290 , indicating roughly equal amounts of convex selection along one canonical axis (given by the index $0.77 \cdot z_1 - 0.64 \cdot z_2$) and concave selection along the other ($0.64 \cdot z_1 + 0.77 \cdot z_2$). (Based on data from Brodie 1992.)

the value of $(z_j - \mu_j)(z_k - \mu_k)$ by one unit in such a way as to hold all other variables and all other pairwise combinations of characters constant is expected to change relative fitness by γ_{jk} for $j \neq k$ and by $\gamma_{jj}/2$ if $j = k$ (the difference arises because $\gamma_{jk} = \gamma_{kj}$, so γ_{jk} appears twice in the regression unless $j = k$). The coefficients of γ thus describe the nature of selection on *quadratic* deviations from the mean for both single characters and pairwise combinations of characters. A value of $\gamma_{ii} < 0$ implies that fitness decreases as z_i moves away (in either direction) from its phenotypic mean. As was discussed in Chapter 29, this is a necessary, *but not sufficient*, condition for ensuring stabilizing selection on character i . As a result, the terms **concave selection** or **concave fitness surface** are often used to indicate this situation. The term *stabilizing selection* is restricted to situations where the fitness surface is concave *and* the population distribution is under a peak in the fitness surface. Similarly, $\gamma_{ii} > 0$ implies that fitness increases as i moves away from its mean (**convex selection** or **convex fitness surface**), which is again a necessary, but not sufficient condition, for disruptive selection. Turning to combinations of characters, nonzero values of γ_{jk} ($j \neq k$) suggest the presence of **correlational selection**, with $\gamma_{jk} > 0$ suggesting selection for a positive phenotypic correlation between characters j and k , and $\gamma_{jk} < 0$ suggesting selection for a negative phenotypic correlation between those characters.. Although it appear to be straightforward to infer the overall nature of selection by looking at the various pairwise values of γ_{ij} , this can result in an extremely *misleading picture* about the geometry of the fitness surface (e.g., Figure 30.3). We will discuss this problem and its solution shortly.

Finally, as we did for directional selection differentials, S (Equation 30.3), we can partition changes in the quadratic selection differential, C , into direct effects and indirect effects resulting from selection on phenotypically correlated traits. Solving for C by post- and pre-multiplying γ (Equation 30.12) by P gives $C = P \gamma P$, which yields

$$C_{ij} = \sum_{k=1}^n \sum_{\ell=1}^n \gamma_{k\ell} P_{ik} P_{\ell j} \quad (30.14)$$

showing that within-generation changes in phenotypic covariance between traits i and j , as measured by C_{ij} , are influenced by quadratic selection ($\gamma_{k\ell} \neq 0$) on pairs of characters, k and ℓ , that are correlated with i and j , specifically, when the product $P_{ik} P_{\ell j} \neq 0$.

Example 30.3. Brodie (1992) examined one-year survivorship in an Oregon population of garter snakes (*Thamnophis ordinoides*). Over a three-year period, 646 snakes were marked, 101 of which were eventually recaptured. Four morphological and behavioral characters were measured: overall stripedness of the body-color pattern (stripes), sprint speed, distance moved until an antipredator display was performed, and number of reversals of direction during flight from predators (reversals). None of the values of β_i or γ_{ii} were significant. However, there was a significant quadratic association between striping pattern and number of reversals, with $\gamma_{ij} = -0.268 \pm 0.097$ (confidence intervals were generated using the delete-one jackknife method of Mitchell-Olds 1989). As shown in Figure 30.2, the best-fitting quadratic regression of individual fitness has a saddle point, which means that concave selection (negative fitness surface curvature) occurs along one direction and convex selection (positive fitness surface curvature) occurs along the other. Brodie suggested a biological explanation for selection favoring a negative correlation between these two characters. When the body pattern is banded, blotched, or spotted, the detection of movement by visual predators is enhanced. In such individuals, frequent reversals can disrupt a visual search. Conversely, the presence of body stripes makes it difficult for predators to judge the speed of the snake, so frequent reversals (and hence additional movement for predators to perceive) would be disadvantageous.

Quadratic Gradients, Fitness Surface Geometry, and Selection Response

As was the case for β , when phenotypes are multivariate normal, γ also describes geometric features of both the individual fitness surface and the mean population fitness landscape. It provides a measure of the average curvature of the individual fitness surface, as

$$\gamma = \int \mathbf{H}_{\mathbf{z}}[w(\mathbf{z})] \varphi(\mathbf{z}) d\mathbf{z} \quad (30.15a)$$

where $\mathbf{H}_{\mathbf{z}}[f]$ denotes the Hessian matrix of f with respect to \mathbf{z} (the matrix of all second partial derivatives; where $H_{ij} = \partial^2 f / \partial z_i \partial z_j$) and is a multivariate measure of the quadratic (local) curvature of a function (Appendix A6). This result, due to Lande and Arnold (1983) can be obtained by an integration-by-parts argument similar to that used to obtain Equation 30.6, and holds for both frequency-dependent and frequency-independent fitnesses.

When fitnesses are frequency-independent (again provided $\mathbf{z} \sim \text{MVN}$), γ also provides a description of the curvature of the mean fitness landscape, with

$$\mathbf{H}_{\boldsymbol{\mu}}[\ln \bar{W}(\boldsymbol{\mu})] = \boldsymbol{\gamma} - \boldsymbol{\beta}\boldsymbol{\beta}^T \quad (30.15b)$$

This result is due to Lande (cited in Phillips and Arnold 1989), and it indicates that there are two sources for curvature in the mean fitness landscape: $-\boldsymbol{\beta}\boldsymbol{\beta}^T$ from directional selection and $\boldsymbol{\gamma}$ from quadratic selection.

Finally, when the breeder's equation holds, $\boldsymbol{\gamma}$ and $\boldsymbol{\beta}$ are sufficient to describe how phenotypic selection alters the additive-genetic covariance matrix. As we show in Volume 3, the additive-genetic covariance matrix, \mathbf{G}^* , following selection (but before reproduction) is calculated by

$$\mathbf{G}^* = \mathbf{G} (\boldsymbol{\gamma} - \boldsymbol{\beta}\boldsymbol{\beta}^T) \mathbf{G} + \mathbf{G} \quad (30.16)$$

Fitness Surface Curvature and Within-generation Changes in Variances and Covariances

Equations 30.15–30.16 provide some insight into the connection between within-generation changes in phenotypic and genetic variances and the curvature of the fitness surface. To

see such connections, we ignore the complications introduced by either phenotypic or genetic correlations. First, consider the within-generation change in the phenotypic variance. Equations 30.7b and 30.14 imply that

$$C_{ii} = \sigma^2(z_i^*) - \sigma^2(z_i) + S_i^2 = \gamma_{ii} P_{ii}^2 = \gamma_{ii} \sigma^4(z_i) \quad (30.17a)$$

Hence, the within-generation change (denoted by $\delta[x]$) in the phenotypic variance for trait i is

$$\delta [\sigma^2(z_i)] = \gamma_{ii} P_{ii}^2 - S_i^2 \quad (30.17b)$$

Thus, concave selection ($\gamma_{ii} < 0$) reduces the phenotypic variance of a trait, while convex selection ($\gamma_{ii} > 0$) increases it. The net effect of directional selection ($S_i \neq 0$) is to always reduce the variance, which means that undetected directional selection (i.e., S was not measured) can mask the effects of convex selection (e.g., Example 29.10) and enhance the effects of concave selection. Likewise, from Equation 30.16 (and assuming there are no genetic correlations), the within-generation change in the additive variance is

$$\delta [\sigma^2(A_i)] = (\gamma_{ii} - \beta_i^2) \sigma^4(A_i) \quad (30.17c)$$

As with the phenotypic variance, both concave and directional selection reduce the additive variance, while convex selection increases it (Chapter 16). Note that Equation 30.17c (as well as Equation 30.16) is the *within-generation* change in the additive genetic variance. Recombination and segregation in the selected individuals will change the additive variance in the offspring generation by reducing the disequilibrium generated by selection and by adding segregation variance (Chapters 16 and 24).

What about the effect of correlational selection ($\gamma_{ij} \neq 0$)? Again, assuming all correlations (genetic and phenotypic) are (initially) zero, Equation 30.16 yields

$$C_{ij} = \sigma(z_i^*, z_j^*) - \sigma(z_i, z_j) + S_i S_j = 2\gamma_{ij} P_{ii} P_{jj} \quad (30.18a)$$

and the within-generation change in the phenotypic covariance becomes

$$\delta [\sigma(z_i, z_j)] = 2\gamma_{ij} P_{ii} P_{jj} - S_i S_j \quad (30.18b)$$

Positive values of γ_{ij} increase the phenotypic correlation, while negative values reduce it. Note that directional selection does not have a uniform effect: if both i and j are selected in the same direction, this decreases the phenotypic correlation, while if they are selected in opposite directions, this increases the correlation. Assuming no (initial) genetic correlations, Equation 30.16 gives the (within-generation) change in the genetic covariance as

$$\delta [\sigma(A_i, A_j)] = (2\gamma_{ij} - \beta_i \beta_j) \sigma^2(A_i) \sigma^2(A_j) \quad (30.18c)$$

Under the infinitesimal model, this change in the genetic covariance is due entirely to disequilibrium, which (for unlinked loci) is reduced by half in the offspring (Chapters 16 and 24).

The major features of linear and quadratic differentials and gradients discussed here are summarized in Table 30.1. Excellent overviews were also provided by Brodie et al. (1995) and Arnold et al. (2001).

MULTIDIMENSIONAL QUADRATIC FITNESS REGRESSIONS

As noted for univariate cases, approximating the individual fitness function by a quadratic can give a very distorted view of the true fitness surface (Figure 29.10). We expect this distortion to be even greater in a multivariate setting. With this caveat in mind, quadratic fitness surfaces are still quite useful. One advantage is that a quadratic is the simplest surface allowing for curvature. Further, when phenotypes are normally distributed, the coefficients

Table 30.1 Analogous features of directional and quadratic differentials and gradients. Details are in the text.

Changes in Means (Directional Selection)	Changes in Covariances (Quadratic Selection)
Differentials measure the covariance between relative fitness and phenotype	
$S_i = \sigma [w, z_i]$	$C_{ij} = \sigma [w, (z_i - \mu_i)(z_j - \mu_j)]$
The opportunity for selection bounds the differential	
$\frac{ S_i }{\sigma(z_i)} \leq \sqrt{I}$ for any distribution of \mathbf{z}	$\left \frac{C_{ij}}{P_{ij}} \right \leq \sqrt{I} \sqrt{1 + \rho_{ij}^{-2}}$ if $\mathbf{z} \sim \text{MVN}$
Differentials confound direct and indirect selection	
$\mathbf{S} = \boldsymbol{\mu}^* - \boldsymbol{\mu} = \mathbf{P}\boldsymbol{\beta}$ $S_i = \sum_{j=1}^n \beta_j P_{ij}$	$\mathbf{C} = \mathbf{P}^* - \mathbf{P} + \mathbf{S}\mathbf{S}^T = \mathbf{P}\boldsymbol{\gamma}\mathbf{P}$ $C_{ij} = \sum_{k=1}^n \sum_{\ell=1}^n \gamma_{k\ell} P_{ik} P_{\ell j}$
Gradients measure the amount of direct selection	
$\boldsymbol{\beta} = \mathbf{P}^{-1}\mathbf{S}$	$\boldsymbol{\gamma} = \mathbf{P}^{-1}\mathbf{C}\mathbf{P}^{-1}$
Gradients describe the slope and curvature of the log mean fitness landscape, provided $\mathbf{z} \sim \text{MVN}$ and fitnesses are frequency-independent	
$\beta_i = \frac{\partial \ln \bar{W}(\boldsymbol{\mu})}{\partial \mu_i}$	$\gamma_{ij} = \frac{\partial^2 \ln \bar{W}(\boldsymbol{\mu})}{\partial \mu_i \partial \mu_j} + \beta_i \beta_j$
Gradients describe the average slope and average curvature of the individual fitness surface, provided $\mathbf{z} \sim \text{MVN}$	
$\beta_i = \int \frac{\partial w(\mathbf{z})}{\partial z_i} \varphi(\mathbf{z}) d\mathbf{z}$	$\gamma_{ij} = \int \frac{\partial^2 w(\mathbf{z})}{\partial z_i \partial z_j} \varphi(\mathbf{z}) d\mathbf{z}$
Gradients appear as coefficients in fitness regressions	
$w(\mathbf{z}) = 1 + \sum \beta_j (z_j - \mu_j)$	$w(\mathbf{z}) = a + \sum b_j (z_j - \mu_j) + \frac{1}{2} \sum_{j,k} \gamma_{jk} (z_j - \mu_j)(z_k - \mu_k)$
$w(\mathbf{z}) = 1 + \boldsymbol{\beta}^T(\mathbf{z} - \boldsymbol{\mu})$	$w(\mathbf{z}) = a + \mathbf{b}^T(\mathbf{z} - \boldsymbol{\mu}) + \frac{1}{2} (\mathbf{z} - \boldsymbol{\mu})^T \boldsymbol{\gamma} (\mathbf{z} - \boldsymbol{\mu})$
$w(\mathbf{z}) = 1 + \boldsymbol{\beta}_{sd}^T \mathbf{z}_{sd}$	$w(\mathbf{z}) = a + \mathbf{b}_{sd}^T \mathbf{z}_{sd} + \frac{1}{2} \mathbf{z}_{sd}^T \boldsymbol{\gamma}_{sd} \mathbf{z}_{sd}$
$\boldsymbol{\beta}$ = slope of the best linear fit	$\boldsymbol{\gamma}$ = the quadratic coefficient of the best quadratic fit. $\mathbf{b} = \boldsymbol{\beta}$ when $\mathbf{z} \sim \text{MVN}$
Gradients appear as coefficients in evolutionary equations when $(\mathbf{z}, \mathbf{g}) \sim \text{MVN}$	
$\Delta \boldsymbol{\mu} = \mathbf{G}\boldsymbol{\beta}$	$\mathbf{G}^* - \mathbf{G} = \mathbf{G} \left(\boldsymbol{\gamma} - \boldsymbol{\beta} \boldsymbol{\beta}^T \right) \mathbf{G}$

in the quadratic regression also appear as the coefficients of equations for predicting evolutionary change (Table 30.1). We will briefly review some statistical issues of fitting such regressions before examining the geometry of multivariate quadratic regressions.

Estimation, Hypothesis Testing, and Confidence Intervals

Even if we can assume that a best-fitting quadratic is a reasonable approximation of the individual fitness surface, we are still faced with a number of statistical issues. For k traits,

the full quadratic regression (Equation 30.13) involves $k(k+3)/2$ parameters: $k(k+1)/2$ from γ ($k\gamma_{ii}$ and $k[k-1]/2$ symmetric γ_{ij} terms) and k from β . With 5, 10, and 25 characters, this corresponds to 20, 65, and 350 parameters, respectively. Hence, the number of observations should be $n \gg k(k+3)/2$ (ideally, by at least an order of magnitude) in order to estimate these parameters with any precision. Unless we test for, and confirm, trait multivariate normality (Appendix 5), β must be estimated from the best *linear* multiple regression, as the vector of linear slopes in a *quadratic* regression need not equal β . Further, while the literature suggests that the estimate for γ is obtained from the best quadratic regression (Equation 30.13), Equation 29.28b showed that this estimate is biased by the presence of skew. Following Equation 29.29e, a strictly quadratic regression (i.e., with no linear terms),

$$w = a + \frac{1}{2} \mathbf{z}_{sd}^T \boldsymbol{\gamma}_{sd} \mathbf{z}_{sd} + e$$

is not biased by skew, but is still a biased estimator for γ if the multivariate pattern of kurtosis differs from that for a multivariate normal (Equation 29.29f).

A second problem is **multicollinearity**—if many of the characters being measured are highly correlated, the phenotypic covariance matrix can be nearly singular, so even small errors in estimating P result in large differences in P^{-1} . This, in turn, results in a very large sampling variance for the estimates of β and γ (which translates into their instability). A quick check for multicollinearity is to regress each trait on all the others. Subtracting the resulting model R^2 from 1.0 determines the **tolerance**, with very high R^2 or low tolerances indicating that multicollinearity is likely to be an issue. One possible solution is to use principal components (Appendix 5) to extract a subset of the characters (measured as PCs; namely, specific linear combinations of the characters) that explains most of the phenotypic variance of P . Fitness regressions using the first few PCs as the characters can then be computed (Lande and Arnold 1983). This approach also reduces the problem of the number of parameters to estimate, but it risks the real possibility of removing the most important characters. Past strong selection may have eroded away much of the variation (Chapters 5, 16, 25, and 26), resulting in such traits being either excluded in a PC set or spread (with weak effects) over several indices of current traits. A further complication is that PCs—weighted indices of trait values—are often difficult to interpret biologically. While the first PC of P for morphological characters generally corresponds to a general measure of size (but see Somers 1986), the others are typically much more problematic to interpret. Finally, using PCs can spread the effects of direct selection on one character over several PCs, further complicating interpretation. While using the PCs of the phenotypic covariance matrix, P , can be problematic, we will show that the PCs associated with the matrix of quadratic selection gradients, γ , can provide considerable insight into the nature of selection.

A variety of additional concerns regarding fitness regressions were discussed in Chapter 29. Briefly, residuals of fitness regressions are expected by their nature to be poorly behaved, so using standard methods of confidence intervals on regression coefficients is often not appropriate. Mitchell-Olds and Shaw (1987) and Mitchell-Olds (1989) suggested using the delete-one jackknife method for approximating confidence intervals for coefficients in quadratic regressions when the residuals are not normal. Likewise, the discussions of randomization tests and cross-validation procedures in Chapter 29 extend to multivariate regressions in a straightforward manner. Multivariate tests of the presence of a single mode in the fitness surface were discussed by Mitchell-Olds and Shaw (1987), and we will introduce the Box-Hunter confidence volume for the stationary point on a quadratic fitness surface shortly (after first introducing some required matrix machinery).

Regression Packages and Coefficients of γ

The coefficients of the elements of γ have a form that may be different from the output of a quadratic regression package. Suppose we have two variables with a mean of zero. Under a Lande-Arnold regression, the quadratic contribution to fitness, w , is

$$\left(\frac{\gamma_{11}}{2} z_1 \right) + \left(\frac{\gamma_{22}}{2} z_2 \right) + (\gamma_{12} \cdot z_1 \cdot z_2)$$

However, many regression packages output the quadratic coefficients as

$$(b_{11} \cdot z_1) + (b_{22} \cdot z_2) + (b_{12} \cdot z_1 \cdot z_2)$$

In such cases, $\gamma_{ii}/2 = b_{ii}$, or $\gamma_{ii} = 2b_{ii}$, while $\gamma_{ij} = b_{ij}$ for $i \neq j$. Failure to make this correction results in the reported γ_{ii} coefficients being only half their true value, thus *underestimating* the strength of quadratic selection on z_i (Lande and Arnold 1983; Stinchcombe et al. 2008). Just how widespread this mistake is in the literature remains unclear, but it may be the rule rather than the exception (at least for papers published before 2008). Indeed, Stinchcombe et al. found that almost 80% of the 33 studies they examined made this error.

Geometric Aspects

Despite their apparent simplicity, multivariate quadratic fitness regressions have a rather rich geometric structure. By adjusting the character values to give them a mean of zero, the general quadratic fitness regression can be written as

$$w(\mathbf{z}) = a + \sum_{i=1}^n b_i z_i + \frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n \gamma_{ij} z_i z_j = a + \mathbf{b}^T \mathbf{z} + \frac{1}{2} \mathbf{z}^T \boldsymbol{\gamma} \mathbf{z} \quad (30.19)$$

If $\mathbf{z} \sim \text{MVN}$, then $\mathbf{b} = \beta$ (the vector of coefficients of the best *linear* fit). Note that if we regard Equation 30.19 as a second-order Taylor series approximation (Equation A6.7) of $w(z)$, then \mathbf{b} and $\boldsymbol{\gamma}$ can be interpreted as the gradient and Hessian, respectively, of individual fitness evaluated at the population mean (here $\mu = \mathbf{0}$ by construction). Even though a quadratic is the simplest curved surface, its geometry can still be difficult to visualize (Phillips and Arnold 1989; Brodie et al. 1995). The key is that the nature of curvature of Equation 30.19 is determined by the eigenvalues of the $\boldsymbol{\gamma}$ matrix.

We start our exploration of this geometry by considering the gradient of this best-fitting quadratic fitness surface. Applying Equations A6.1b and A6.1c to Equation 30.19 yields

$$\nabla_{\mathbf{z}}[w(\mathbf{z})] = \mathbf{b} + \boldsymbol{\gamma} \mathbf{z} \quad (30.20a)$$

Hence, the direction of steepest ascent on the fitness surface (the direction in which to move in phenotype space to maximally increase local individual fitness) around \mathbf{z} is the vector $\mathbf{b} + \boldsymbol{\gamma} \mathbf{z}$. If the true individual fitness surface is indeed a quadratic, the average gradient of individual fitness taken over the distribution of phenotypes is

$$\int \nabla_{\mathbf{z}}[w(\mathbf{z})] p(\mathbf{z}) d\mathbf{z} = \mathbf{b} \int p(\mathbf{z}) d\mathbf{z} + \boldsymbol{\gamma} \int \mathbf{z} p(\mathbf{z}) d\mathbf{z} = \mathbf{b} \quad (30.20b)$$

as the last integral is μ (which is zero by construction). Hence, if the true fitness function is quadratic, the average gradient of individual fitness is given by \mathbf{b} , independent of the distribution of \mathbf{z} .

Solving for $\nabla_{\mathbf{z}}[w(\mathbf{z})] = \mathbf{0}$, shows that a point, \mathbf{z}_0 , that satisfies $\boldsymbol{\gamma} \mathbf{z}_0 = -\mathbf{b}$ is a candidate for a local extremum (also called a **stationary point**, as the gradient is zero). When $\boldsymbol{\gamma}$ is nonsingular,

$$\mathbf{z}_0 = -\boldsymbol{\gamma}^{-1} \mathbf{b} \quad (30.21a)$$

is the unique stationary point of this quadratic surface. Substituting into Equation 30.19, the expected individual fitness at this point is

$$w_0 = a + \frac{1}{2} \mathbf{b}^T \mathbf{z}_0 \quad (30.21b)$$

as obtained by Phillips and Arnold (1989). Because $\partial^2 w(\mathbf{z}) / \partial z_i \partial z_j = \gamma_{ij}$, the Hessian of $w(\mathbf{z})$ is just $\boldsymbol{\gamma}$. Thus, \mathbf{z}_0 is a local minimum if $\boldsymbol{\gamma}$ is **positive-definite** (all eigenvalues are positive),

a local maximum if γ is **negative-definite** (all eigenvalues are negative), or a saddle point if the eigenvalues differ in sign (see Equation A6.8b).

If γ is singular (i.e., it has at least one zero eigenvalue), then there is no unique stationary point. An example of this is seen in Figure 30.3B, where there is a ridge (rather than a single point) of phenotypic values having the highest fitness value. The consequence of a zero eigenvalue is that the fitness surface has no curvature along the axis that is defined by the associated eigenvector. If γ has k zero eigenvalues, then the fitness surface has no curvature along k dimensions. The remaining fitness space showing curvature has a single stationary point, which is given by Equation 30.21a for γ and b when reduced to the $n - k$ dimensions showing curvature.

A Brief Digression: Orthonormal and Diagonalized Matrices

We need some additional machinery on the geometry of matrices (from Appendix 5) to further our discussion of the geometry of the quadratic fitness surface. Matrix transformations (multiplying a vector by a matrix) consist of two basic operations: **rotations** (changes in the direction of the vector) and **scalings** (changes in its length). A transformation can be partitioned into these two basic operations by using **orthonormal** matrices. If we write a square matrix as $\mathbf{U} = (\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_n)$, where each \mathbf{u}_i is an n -dimensional column vector, \mathbf{U} is said to be orthonormal if

$$\mathbf{u}_i^T \mathbf{u}_j = \begin{cases} 1 & \text{if } i = j \\ 0 & \text{if } i \neq j \end{cases}$$

In other words, each column of \mathbf{U} is independent from every other column and has unit length. Matrices with this property are also referred to as **unitary** and satisfy $\mathbf{U}^T = \mathbf{U}^{-1}$, so

$$\mathbf{U}^T \mathbf{U} = \mathbf{U} \mathbf{U}^T = \mathbf{I} \quad (30.22)$$

The transformation induced by an orthonormal matrix has a very simple geometric interpretation in that it is a **rigid rotation** of the original coordinate system—all axes of the original coordinates are simply rotated by the same angle to create the new coordinate system (Appendix 5). The angle between any two vectors remains unchanged following their transformation by the same orthonormal matrix. If the angle between the vectors \mathbf{x}_1 and \mathbf{x}_2 is θ , then the angle between the transformed vectors $\mathbf{y}_1 = \mathbf{U}\mathbf{x}_1$ and $\mathbf{y}_2 = \mathbf{U}\mathbf{x}_2$ is also θ (Equation A5.5d).

A symmetric matrix \mathbf{A} (such as a variance-covariance matrix) can be **diagonalized** as

$$\mathbf{A} = \mathbf{U} \Lambda \mathbf{U}^T \quad (30.23)$$

where Λ is a diagonal matrix and \mathbf{U} is an orthonormal matrix ($\mathbf{U}^{-1} = \mathbf{U}^T$). If λ_i and \mathbf{e}_i , respectively, denote the i th eigenvalue and its associated unit-length eigenvector of \mathbf{A} , then

$$\Lambda = \text{diag}(\lambda_1, \lambda_2, \dots, \lambda_n) = \begin{pmatrix} \lambda_1 & 0 & \cdots & 0 \\ 0 & \lambda_2 & \cdots & 0 \\ \vdots & & \ddots & \vdots \\ 0 & \cdots & \cdots & \lambda_n \end{pmatrix} \quad (30.24a)$$

and

$$\mathbf{U} = (\mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_n) \quad (30.24b)$$

Geometrically, \mathbf{U} describes a rigid rotation of the original coordinate system while Λ shows the amounts that unit lengths in the original coordinate system are scaled in the transformed system. Using the unitary property of \mathbf{U} , premultiplying \mathbf{A} by \mathbf{U}^T and then postmultiplying by \mathbf{U} results in a diagonal matrix whose elements are the eigenvalues of \mathbf{A} ,

$$\begin{aligned} \mathbf{U}^T \mathbf{A} \mathbf{U} &= \mathbf{U}^T (\mathbf{U} \Lambda \mathbf{U}^T) \mathbf{U} = (\mathbf{U}^T \mathbf{U}) \Lambda (\mathbf{U}^T \mathbf{U}) \\ &= \Lambda \end{aligned} \quad (30.25)$$

The effect of using such a transformation is that (on this new scale) we remove all cross-product terms in a quadratic product (i.e., the $z_i z_j$ terms for $i \neq j$ in Equation 30.19 are absent). Put another way, *on this new scale, there is no correlational selection*, as $\gamma_{ij} = 0$ for $i \neq j$. A few very useful results immediately follow from Equation 30.25. For $\mathbf{A}^{1/2}$ and \mathbf{A}^{-1} , the \mathbf{U} matrix is unchanged, while the diagonal elements in the associated Λ matrix are given by the square root or inverse, respectively. Thus, \mathbf{A} , $\mathbf{A}^{1/2}$, and \mathbf{A}^{-1} (provided the latter exists; i.e., no there are zero eigenvalues) all have the same eigenvectors and their eigenvalues are related as λ_i , $\lambda_i^{1/2}$, and λ_i^{-1} , respectively.

Example 30.4. Consider selection acting on two characters, z_1 and z_2 . Suppose we find that $\gamma_{11} = -2$ and $\gamma_{22} = -1$, suggesting that the individual fitness surface has negative curvature in both z_1 and z_2 . At first glance the picture this evokes is stabilizing selection on both z_1 and z_2 , with the stabilizing selection surface perhaps rotated due to selection for correlations between z_1 and z_2 . The first caveat, as mentioned in Chapter 29, is that negative curvature (concavity), by itself, does not imply a local maximum. Even if γ is negative definite (all $\lambda_i < 0$; Appendix 5), the location, \mathbf{z}_0 , of the maximum in the quadratic surface may be *outside* of the observed range of population values and hence not currently applicable to the population being studied. A much more subtle point is that, as Figure 30.3 shows, the nature of the fitness surface is very much dependent on the amount of selection for correlations between z_1 and z_2 . Figure 30.3 considers the surfaces associated with the same values for γ_{11} and γ_{22} , but three different values of γ_{12} under the assumption that $\mathbf{b} = 0$. Note that although in all three cases, $\gamma_{12} > 0$ (i.e., selection favors increased correlations between the phenotypic values of z_1 and z_2), the fitness surfaces are *qualitatively very different*. When $\gamma_{12} = 0.25$, the individual fitness surface indeed shows stabilizing selection in both characters. For $\gamma_{12} = \sqrt{2} \simeq 1.42$, the fitness surface has a ridge in one direction, with stabilizing selection in the other. When $\gamma_{12} = 4$, the fitness surface is a saddle, with convex selection along one axis and concave selection along the other. An especially troubling point is that if the standard error of γ_{12} is sufficiently large, we will not be able to distinguish between these very different types of selection even if we could show that $\gamma_{11}, \gamma_{22} < 0$, and $\gamma_{12} > 0$.

Canonical Transformation of γ

While the curvature of a quadratic fitness surface is completely determined by γ , it is easy to be misled about the actual nature of the fitness surface if one attempts to infer its multivariate structure from a simple inspection of the diagonal elements of γ . As Figure 30.3 shows, even for two characters, visualizing the individual fitness surface is not trivial and can easily be extremely misleading. The problem is that the cross-product terms (γ_{ij} for $i \neq j$) make the quadratic form difficult to interpret geometrically. Removing these terms by a change of variables, so that the axes of new variables coincide with the axes of symmetry of the quadratic form (its **canonical axes**), greatly facilitates visualization of the fitness surface.

Motivated by this observation, Phillips and Arnold (1989) suggested using two slightly different versions of the canonical transformation of γ to clarify the geometric structure of the best fitting quadratic fitness surface. Applying Equation 30.25, if we consider the matrix, \mathbf{U} , whose columns are the eigenvectors of γ , then the transformation $\mathbf{y} = \mathbf{U}^T \mathbf{z}$ (and hence $\mathbf{z} = \mathbf{U}\mathbf{y}$, because $\mathbf{U}^{-1} = \mathbf{U}^T$ as \mathbf{U} is orthonormal) removes all the cross-product terms in the quadratic form, and returns

$$\begin{aligned} w(\mathbf{z}) &= a + \mathbf{b}^T \mathbf{U} \mathbf{y} + \frac{1}{2} (\mathbf{U} \mathbf{y})^T \gamma (\mathbf{U} \mathbf{y}) = a + \mathbf{b}^T \mathbf{U} \mathbf{y} + \frac{1}{2} \mathbf{y}^T (\mathbf{U}^T \gamma \mathbf{U}) \mathbf{y} \\ &= a + \mathbf{b}^T \mathbf{U} \mathbf{y} + \frac{1}{2} \mathbf{y}^T \Lambda \mathbf{y} = a + \sum_{i=1}^n \theta_i y_i + \frac{1}{2} \sum_{i=1}^n \lambda_i y_i^2 \end{aligned} \quad (30.26)$$

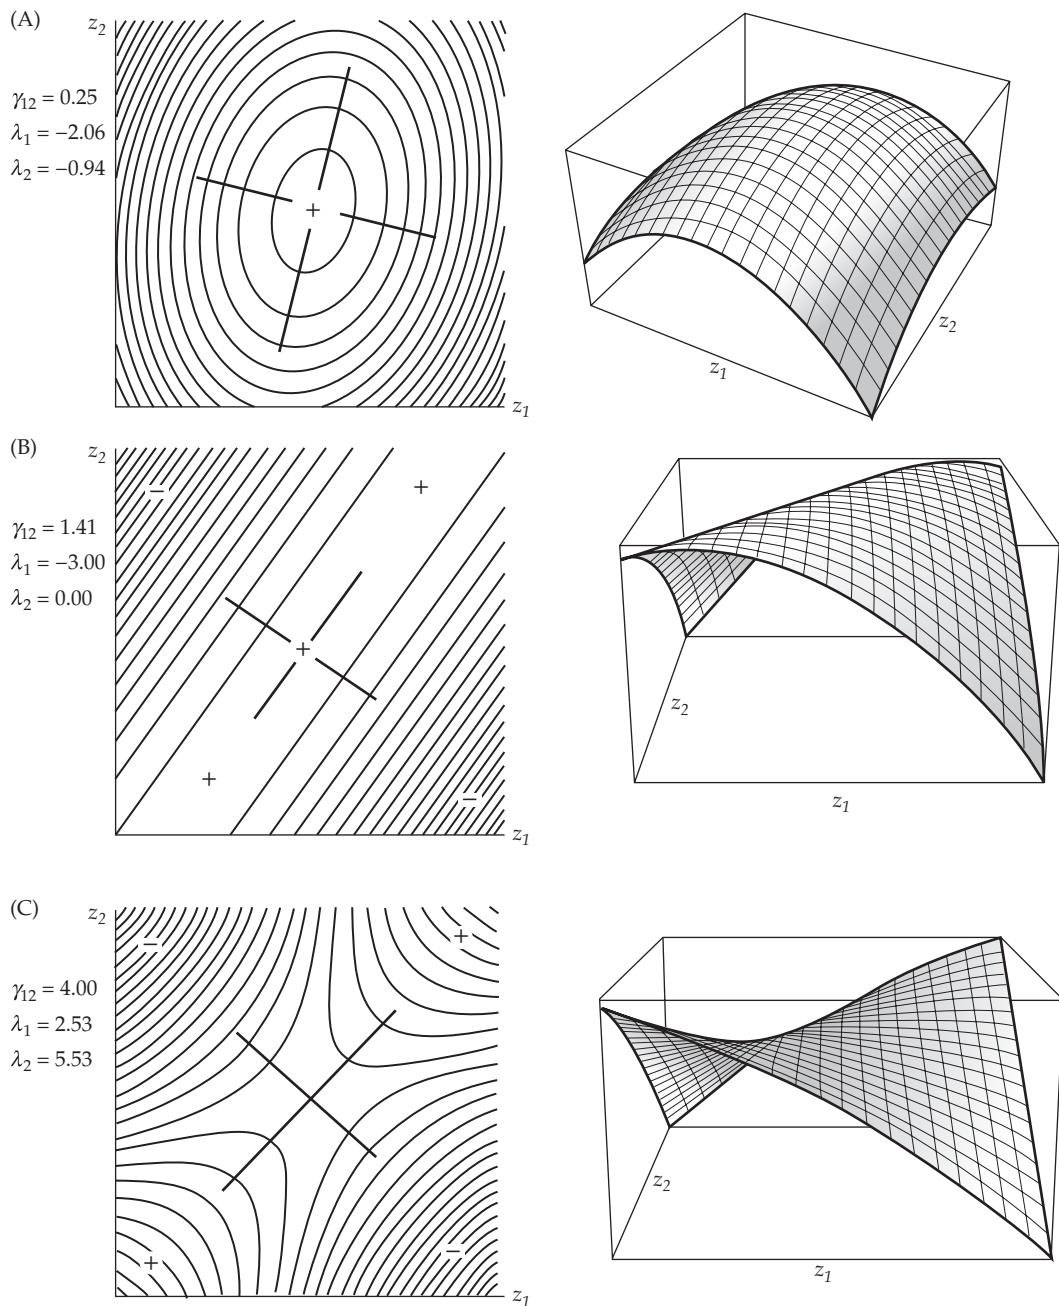

Figure 30.3 Three quadratic fitness surfaces, in all of which $\gamma_{11} = -2$, $\gamma_{22} = -1$, and $\mathbf{b} = 0$. On the left are fitness contour plots, with peaks represented by + and valleys by -. **Axes of symmetry** of the surface (the canonical, major, or principal axes of γ ; Equation 30.24b) are denoted by the thick lines. These axes correspond to the eigenvectors of γ (with their corresponding eigenvalues, λ_1 and λ_2 , also shown in the figure). On the right are three-dimensional plots of individual fitness as a function of the phenotypic values of the characters z_1 and z_2 . **A:** $\gamma_{12} = 0.25$. This corresponds to stabilizing selection on both characters, with fitness falling off more rapidly (as indicated by the shorter distance between contour lines) along the z_1 axis than along the z_2 axis. **B:** Here $\gamma_{12} = \sqrt{2} \simeq 1.41$, in which case γ is singular (as $\lambda_2 = 0$). The resulting fitness surface shows a ridge in one direction (\mathbf{e}_2 , the eigenvector corresponding to $\lambda_2 = 0$) and strong stabilizing selection in the orthogonal direction (given by \mathbf{e}_1). **C:** When $\gamma_{12} = 4$, the fitness surface shows a saddle point, and there is concave selection along one of the canonical axes of the fitness surface (\mathbf{e}_2 , corresponding to $\lambda_2 = -5.53$) and convex selection along the other (\mathbf{e}_1 , corresponding to $\lambda_1 = 2.53$).

where $\theta_i = \mathbf{e}_i^T \mathbf{b}$ and $y_i = \mathbf{e}_i^T \mathbf{z}$, with λ_i and \mathbf{e}_i , respectively, representing the eigenvalues and associated unit eigenvectors of γ . Alternatively, if a stationary point, \mathbf{z}_0 , exists (e.g., γ is nonsingular, all $\lambda_i \neq 0$), the change of variables, $\mathbf{y} = \mathbf{U}^T(\mathbf{z} - \mathbf{z}_0)$, further removes all linear terms (Box and Draper 1987), so

$$w(\mathbf{z}) = w_0 + \frac{1}{2} \mathbf{y}^T \boldsymbol{\Lambda} \mathbf{y} = w_0 + \frac{1}{2} \sum_{i=1}^n \lambda_i y_i^2 \quad (30.27)$$

where $y_i = \mathbf{e}_i^T(\mathbf{z} - \mathbf{z}_0)$ and w_0 is shown by Equation 30.21b. Equation 30.26 is called the **A canonical form** and Equation 30.27, the **B canonical form** (Box and Draper 1987). Both forms represent a rotation of the original axis to the new set of coordinates (the canonical axes of γ) that align them with axes of symmetry of the original quadratic surface. The B canonical form further shifts the origin to the stationary point, \mathbf{z}_0 . Because the contribution to individual fitness from $\mathbf{b}^T \mathbf{z}$ is a hyperplane, its effect is to tilt the fitness surface. The B canonical form effectively levels this tilting, thus allowing us to focus entirely on the curvature (quadratic) aspects of the fitness surface.

The orientation (the **principal, or major, axes**) of the quadratic surface is determined by the eigenvectors $(\mathbf{e}_1, \dots, \mathbf{e}_n)$ of γ , while the eigenvalues $(\lambda_1, \dots, \lambda_n)$ of γ determine the nature and amount of curvature of the surface along each canonical axis. Along the axis defined by $y_i = \mathbf{e}_i^T \mathbf{z}$, the individual fitness function has positive curvature (is convex) if $\lambda_i > 0$. It has negative curvature (is concave) if $\lambda_i < 0$, and no curvature (is a plane) if $\lambda_i = 0$. The amount of curvature is indicated by the magnitude of λ_i ; the larger $|\lambda_i|$, the more extreme the curvature. An alternative way to envision the canonical transformation is that the original vector, \mathbf{z} , of n characters is transformed into a vector, \mathbf{y} , of n independent selection indices (Simms 1990). Directional selection on the index, y_i , is measured by θ_i , while quadratic selection on y_i is measured by λ_i .

Returning to Figure 30.3, we see that the axes of symmetry of the quadratic surface are the canonical axes of γ . For $\gamma_{12} = 0.25$ (Figure 30.3A), $\lambda_1 = -2.06$ and $\lambda_2 = -0.94$, and so the fitness surface is concave along each canonical axis, with more extreme curvature along the y_1 axis. When $\gamma = \sqrt{2}$ (Figure 30.3B), one eigenvalue is zero while the other is -3 , so the surface shows no curvature along one axis (it is a plane) but is strongly concave along the other. Finally, when $\gamma_{12} = 4$ (Figure 30.3C), the two eigenvalues differ in sign, as they are -5.53 and 2.53 . This generates a saddle point, with a surface that is concave along one axis and convex along with other, and here with the concave curvature being more the extreme.

From Equation 30.26, we can see that the fitness change along a particular axis (\mathbf{e}_i) is $\theta_i y_i + (\lambda_i/2) y_i^2$. If $|\theta_i| \gg |\lambda_i| > 0$, the curvature of the fitness surface along this axis is dominated by the effects of linear (as opposed to quadratic) selection for modest values of $y_i = \mathbf{e}_i^T \mathbf{z}$. If $\lambda_i = 0$, the fitness surface along y_i has no curvature, so the fitness surface is a ridge along this axis. If $\theta_i > 0$, this is a rising ridge (fitness increases as y_i increases), whereas it is a falling ridge (fitness decreases as y_i increases) if $\theta_i < 0$, and it is flat if $\theta_i = 0$. Even if γ is not singular, it may be nearly so, with some of the eigenvalues being very close to zero. In this case, the fitness surface shows little curvature along the axes given by the eigenvectors associated with these nearly zero eigenvalues. Further issues relating to the visualization of multivariate fitness surfaces are discussed in Phillips and Arnold (1989), while Box and Draper (1987) review the statistical foundations of this approach.

Example 30.5. Consider the first two scenarios depicted in Figures 30.3A and 30.3B. The resulting γ and the component matrices for its diagonalization (which are easily obtained using the `eigen` function in R) are as follows:

$$\gamma_1 = \begin{pmatrix} -2 & 0.25 \\ 0.25 & -1 \end{pmatrix}, \quad \mathbf{U}_1 = \begin{pmatrix} 0.230 & 0.973 \\ 0.973 & -0.230 \end{pmatrix}, \quad \boldsymbol{\Lambda}_1 = \begin{pmatrix} -2.06 & 0 \\ 0 & -0.94 \end{pmatrix}$$

and

$$\gamma_2 = \begin{pmatrix} -2 & 1.41 \\ 1.41 & -1 \end{pmatrix}, \quad \mathbf{U}_2 = \begin{pmatrix} 0.577 & 0.816 \\ 0.816 & -0.577 \end{pmatrix}, \quad \mathbf{A}_2 = \begin{pmatrix} 0 & 0 \\ 0 & -3.00 \end{pmatrix}$$

Because $\mathbf{U} = (\mathbf{e}_1 \ \mathbf{e}_2)$, the transformed variables, $y_i = \mathbf{e}_i^T \mathbf{z}$, for γ_1 (for Figure 30.3A) are

$$y_1 = \mathbf{e}_1^T \mathbf{z} = 0.230 \cdot z_1 + 0.973 \cdot z_2, \quad y_2 = \mathbf{e}_2^T \mathbf{z} = 0.973 \cdot z_1 - 0.230 \cdot z_2$$

where the quadratic term now becomes

$$\frac{1}{2} (-2.06 y_1^2 - 0.94 y_2^2) = -1.03y_1^2 - 0.47y_2^2$$

For γ_2 (Figure 30.3B), there is a zero eigenvalue, corresponding to no curvature. This occurs in the direction of $y_1 = \mathbf{e}_1^T \mathbf{z} = 0.577 \cdot z_1 + 0.816 \cdot z_2$ (where \mathbf{e}_1 is the eigenvector associated with the zero eigenvalue), while the curvature in the direction of $y_2 = \mathbf{e}_2^T \mathbf{z} = 0.816 \cdot z_1 - 0.577 \cdot z_2$ is given by $-(3.00/2)y_2^2$.

Are Traits Based on Canonical Axes Meaningful?

While there clearly are significant benefits from using the canonical rotation of γ to infer those trait combinations that are under the strongest quadratic selection, this approach has also sparked a lively debate in the literature. Blows (2007a, 2007b) championed it as providing considerable insight into the nature of selection, while Conner (2007) suggested that “these advantages are usually outweighed by the disadvantage that the results are not very biologically interpretable,” a point echoed by Hunt et al. (2007a). Basically, the concern these authors expressed parallels issues about the use of principal components: even though a specific combination of traits may account for most of the variation, their biological interpretation may be convoluted (at best). This argument raises two questions: What are the true targets of selection, and what is a trait?

The power of quantitative genetics is that *anything* we can measure can be regarded as a trait, no matter how strange or seemingly biologically unreasonable it may be. Clearly, ecologists and evolutionary biologists working on specific traits (such as clutch size or body weight) bring a wealth of empirical knowledge about these traits when considering possible targets of selection. In this sense, field biologists regard many traits as natural objects. While most would agree that some are (e.g., clutch size), other traits (such as body shape) are more problematic, as they can be defined and measured in a myriad of different ways. At a deeper level, it is the nature of the question that usually determines whether a biologist regards a particular trait as a natural object. Even when considering the same general features, a developmental biologist’s view of natural traits may be quite different from an ecologist’s view, and in turn both views may be different from those of an evolutionary biologist.

Thus, when a trait is not regarded as a natural object, but rather is some weighted combination of values of natural objects, biologists may feel that much of their intuitive and empirical knowledge about the individual components is diffused over some seemingly arbitrary combination of their values. This is not an unreasonable view. However, selection is not reasonable in that it does not care about how traits are defined; it simply acts on particular multivariate phenotypes. When selection is acting on a complex structure in a medium- or high-dimensional space, simply examining the fitness of projections from this space onto some subset of lower-dimensional traits can be extremely misleading (Walsh 2007; Blows and Walsh 2009). From the perspective of selection, the natural objects are the linear combinations of trait values that comprise the canonical axes of γ .

It is this connection with the axes of natural selection that imposes a very real difference between concerns about the interpretation of PCs for a phenotypic covariance matrix and the major axes of γ . The latter defines a real object of ecological importance, namely how

selection views the traits under selection, while the former define axes of existing variation, which may (or may be) be attributable to selection. Using PCs from the phenotypic covariance matrix to define new traits can diffuse a true target of selection, as the PCs are used simply to deal with phenotypic correlations. In contrast, the canonical axes of γ specifically *highlight* the targets of selection. As Sewall Wright (1935b) insightfully noted: “It is the harmonious adjustment of all of the characteristics of the organism that is the object of selection, not the separate metrical ‘characters.’”

Strength of Selection: γ_{ii} Versus λ

Recall from Equation 30.11a that $(\gamma_{ii}/2)(z_i - \mu_i)^2$ is the contribution toward relative fitness, w , from squared deviations of trait i from its mean. It is therefore natural to assume that if $\gamma_{ii} < 0$ (concave selection), this implies at least the potential of stabilizing selection on trait i . Figure 30.3 showed that using only the diagonal elements of γ can potentially give a very misleading picture of the nature of quadratic selection. However, the eigenvalues (λ) of γ provide a more exact description of the true nature of selection. Blows and Brooks (2003) stressed this point, and noted in an analysis of 19 studies that $|\gamma_{ii}|_{max} < |\lambda|_{max}$. Thus, studies that report weak values for quadratic selection are potentially biased if they use γ_{ii} values, rather than the full geometry of γ , as described by its eigenvalues. A further point (mentioned above) is that many published studies report only half the true value for λ_{ii} due to incorrect translation of the coefficient of the quadratic regression.

Blows and Brooks (2003) noted several advantages of focusing on estimation of the λ_i versus estimation of all of the γ_{ij} , noting that there are n eigenvalues, and $n(n + 1)/2$ elements in γ . Further, given that many eigenvalues may be close to zero, a **subspace** of γ , such as the space spanned by the first few principal (i.e., canonical) components of γ may essentially capture all of the relevant information on the quadratic fitness surface. Following Simms (1990) and Simms and Rausher (1993), Blows and Brooks suggested that estimation and hypothesis testing can occur if we first obtain the eigenvectors of γ , and then use them to generate the transformed variables $y = U^T z$ in the quadratic regression given by Equation 30.26. This approach is often referred to as a **double regression**, as one first uses the eigenvectors of γ to generate y and then fits a quadratic regression of w using y . The quadratic terms in the regression correspond to the eigenvalues of γ (Equation 30.26), and confidence intervals and significance levels can be conducted within the standard GLM framework (LW Chapter 8). Bisgaard and Ankenman (1996) provided a formal statistical framework for generating standard errors for the estimated λ_i when using this procedure. However, Reynolds et al. (2010) noted that the initial transformation (to generate y) biases tests of significance of the λ_i , and they suggested a permutation method to obtain correct type-I error rates.

Kruuk and Garant (2007) noted that the **Mercer-Mercer theorem** (2000) states that the magnitude of the largest eigenvalue of γ is as least as great as the largest magnitude of the diagonal elements of γ . Thus, it is “algebraically inevitable” that at least one combination of traits will show stronger quadratic selection than any of the original traits (provided all values of $\gamma_{ii} \neq 0$). Nevertheless, the biological issue here is whether λ_i is *significantly* greater than γ_{ii} (as opposed to only being slightly larger). Reynolds et al. (2010) found higher power for detecting curvature (nonzero eigenvalues of γ) using canonical analysis than when testing each value of γ_{ii} separately.

Example 30.6. Brooks and Endler (2001) examined four color traits in male guppies associated with sexual selection. The estimated γ matrix was

$$\gamma = \begin{pmatrix} 0.032 & -0.016 & -0.028 & 0.103 \\ -0.016 & 0.0001 & 0.066 & -0.131 \\ -0.028 & 0.066 & -0.022 & -0.099 \\ 0.103 & -0.131 & -0.099 & 0.060 \end{pmatrix}$$

The diagonal elements suggest evidence for weak convex selection ($\gamma_{44} = 0.060, \gamma_{11} = 0.032$) and some evidence for very weak concave selection ($\gamma_{33} = -0.022$). However, the eigenvalues of γ are 0.262, 0.012, -0.077, and -0.123. Of these eigenvalues, only the leading one (0.262) is significantly different from zero, with an amount of convex selection over four times that suggested from the largest γ_{ii} value (0.060). The take-home message is that simply relying upon a visual inspection of the diagonal elements of γ can depict a very misleading view of the nature of selection.

Significance and Confidence Regions for a Stationary Point

Recall from Equation 30.21a that when γ is nonsingular (i.e., it contains no zero eigenvalues), then $\mathbf{z}_0 = -\gamma^{-1}\mathbf{b}$ is the unique extremum (stationary point) in the quadratic regression. If γ contains k zero eigenvalues, there is no curvature along the trait combinations given by the k associated eigenvectors (the fitness surface is a k -dimensional hyperplane along these directions), while there is curvature (and a unique stationary point) in the remaining fitness space. As mentioned, this stationary value is a maximum if all of the eigenvalues are negative (and hence a test for significance for a maximum is that all of the eigenvalues should be significantly less than zero). Likewise, it is a local minimum if all the eigenvalues are positive (which can also be tested in the same manner). If γ contains both (significant) positive and negative eigenvalues, then \mathbf{z}_0 is a saddle point. Thus, tests for maxima or minima are straightforward. But what about the confidence region (or more correctly, a confidence *volume*) for the location of the stationary point?

A classical result for a quadratic regression is the **Box-Hunter confidence region**. Suppose we let $\mathbf{d}_{\mathbf{z}}$ denote the gradient vector of the best quadratic regression of w on \mathbf{z} , which (Equation 30.20a) is calculated by

$$\mathbf{d}_{\mathbf{z}} = \nabla_{\mathbf{z}}[w(\mathbf{z})] = \mathbf{b} + \gamma \mathbf{z}$$

Suppose there are k traits and n observations, and the residuals to the quadratic regression are independent and homoscedastic normal variables (as mentioned, for fitness data, this assumption is usually problematic). Box and Hunter (1954) showed that a $100(1 - \alpha)\%$ confidence volume is given by those vectors \mathbf{z} that satisfy the quadratic inequality

$$\mathbf{d}_{\mathbf{z}}^T \mathbf{V}^{-1} \mathbf{d}_{\mathbf{z}} = (\mathbf{b} + \gamma \mathbf{z})^T \mathbf{V}^{-1} (\mathbf{b} + \gamma \mathbf{z}) \leq k F_{1-\alpha, k, n-p} \quad (30.28)$$

where F is the $(1 - \alpha)$ value for an F distribution with k and $n - p$ degrees of freedom ($p = k(k+3)/2$ is the total number of estimated regression coefficients) and \mathbf{V} is an estimate of the covariance matrix for $\mathbf{d}_{\mathbf{z}}$. Values of \mathbf{z} that satisfy Equation 30.28 are within the confidence volume for the stationary point. See Del Castillo and Cahya (2001) and Peterson et al. (2002) for further discussion and developments. It is critical to stress that these methods all make the strong assumption that fitness residuals are normally distributed, which typically fails. We strongly favor using aster models (Chapter 29), which correctly model the fitness distribution and for which Geyer and Shaw (2010a) developed likelihood-based approaches for hypothesis testing and confidence intervals.

Using Aster Models to Estimate Fitness Surfaces

Most of the approaches presented in this chapter (and in much of Chapter 29) make normality assumptions, which come in two different flavors: first, the assumed multivariate normality (MVN) of the distribution of *trait values*, \mathbf{z} ; and second, the assumed MVN for the distribution of *residuals in the fitness regression*, $\mathbf{e} = w(\mathbf{z}) - \hat{w}(\mathbf{z})$. We address these in turn.

As summarized in Table 30.1, when $\mathbf{z} \sim \text{MVN}$, a variety of results hold that relate β and γ to measures of the geometries of the individual fitness surface and the mean fitness landscape. Further, as with the univariate case, for β and γ to equal, respectively, the linear and quadratic coefficients in a quadratic fitness regression also requires \mathbf{z} to be MVN (lack of skew and the kurtosis of a normal, see Equations 29.28a and 29.28b).

Perhaps the more critical normality assumption involves the distributional behavior of the *fitness residuals*. As mentioned in Chapter 29, the assumption that $\mathbf{z} \sim \text{MVN}$ is *not* required to fit a regression, although when \mathbf{z} is MVN, one can then equate estimated regression coefficients with the properties just mentioned. However, the assumption of multivariate normality of the fitness residuals is required, either directly (for hypotheses testing and constructing confidence intervals) or indirectly (the OLS assumption of homoscedastic residues is satisfied when residuals are MVN). Unfortunately, as mentioned in Chapter 29, most biologically realistic models for fitness components generate residuals that are both heteroscedastic and nonnormal.

As introduced in Chapter 29, Aster models (Geyer et al. 2007; Geyer and Shaw 2008, 2010a, 2010b; Shaw et al. 2008; Geyer 2010; Shaw and Geyer 2010) allow for a very wide range of distributional assumptions for the fitness-component residuals, and allow one to build up the distribution of total fitness by convoluting distributions across selection episodes. By fully, and correctly, accounting for the residual error structure, Aster models are far more statistically rigorous than Lande-Arnold estimation and can result in less bias when estimating the fitness surface. For example, in a simulated two-trait dataset fit by Shaw and Geyer (2010), Aster models correctly detected multivariate stabilizing selection (two negative eigenvalues for γ), while a Lande-Arnold regression of the same dataset suggested a saddle point (one positive and one negative eigenvalue). An OLS regression assumes that each value is equally weighted (the homoscedastic residual assumption), but when observations vary in their quality (such as heteroscedastic fitness residuals), weighting them properly (as done in Aster models) reduces bias.

While Aster models accommodate complex residual structures, they are not a panacea when it comes to estimating nonlinear fitness surfaces. In the fitness-estimation literature, *nonlinear* is often taken as synonymous with *quadratic*, but we have seen how misleading quadratic approximations can be (Figure 29.10). While the link functions used by the GLMs of an Aster model (transforming some underlying linear model into the expected data scale; Chapter 29) can induce nonlinearities (curvature), the transformation is also monotonic (Geyer et al 2007; Geyer 2010, Shaw and Geyer 2010). Hence, while nonlinearities may be introduced, additional peaks are not. In their current form, Aster models assume a quadratic geometry (at most, a single extremum) when the underlying input is a quadratic function of trait values. Hence, many of the issues involved in estimating a fitness landscape by assuming a quadratic geometry remain when using the current Aster framework.

MULTIVARIATE SEMIPARAMETRIC FITNESS SURFACE ESTIMATION

As discussed in Chapter 29, using the best-fitting univariate quadratic can result in a very misleading picture when there are multiple peaks or sharp thresholds (such as truncation selection) in the individual fitness surface. This also holds in multivariate space, and hence regressions predicting fitness given a vector \mathbf{z} of traits that are nonparametric (free of any assumed functional form) certainly have some advantages. Because some assumption about the residual structure is typically needed to fit such regressions, they are formally called **semiparametric**, but we will still refer to them as nonparametric owing to the minimal number of assumptions they involve concerning about the functional form of $w(z)$.

Despite the advantage of having a minimal number of assumptions, these estimators also have significant disadvantages. We have already seen the difficulty in visualizing the multivariate fitness surface when only a simple quadratic function is assumed, but in this case the eigenvalues of γ provide significant help in interpretation. However, with general nonparametric methods, there is no corresponding metric for the fitness surface geometry, and thus one must resort to actual visualization of the fitness surface. This requires an examination of successive pairwise cross-sections of the fitness surface (projections onto two of the axes of the fitness function), generating a series of 3-D surfaces (one fitness axis and two trait axes; see Figure 30.4). Further, because these methods typically first construct new axes (linear combinations of the traits; e.g., $x_1 = \mathbf{a}_1^T \mathbf{z}$, $x_2 = \mathbf{a}_2^T \mathbf{z}$), and then use them to construct the

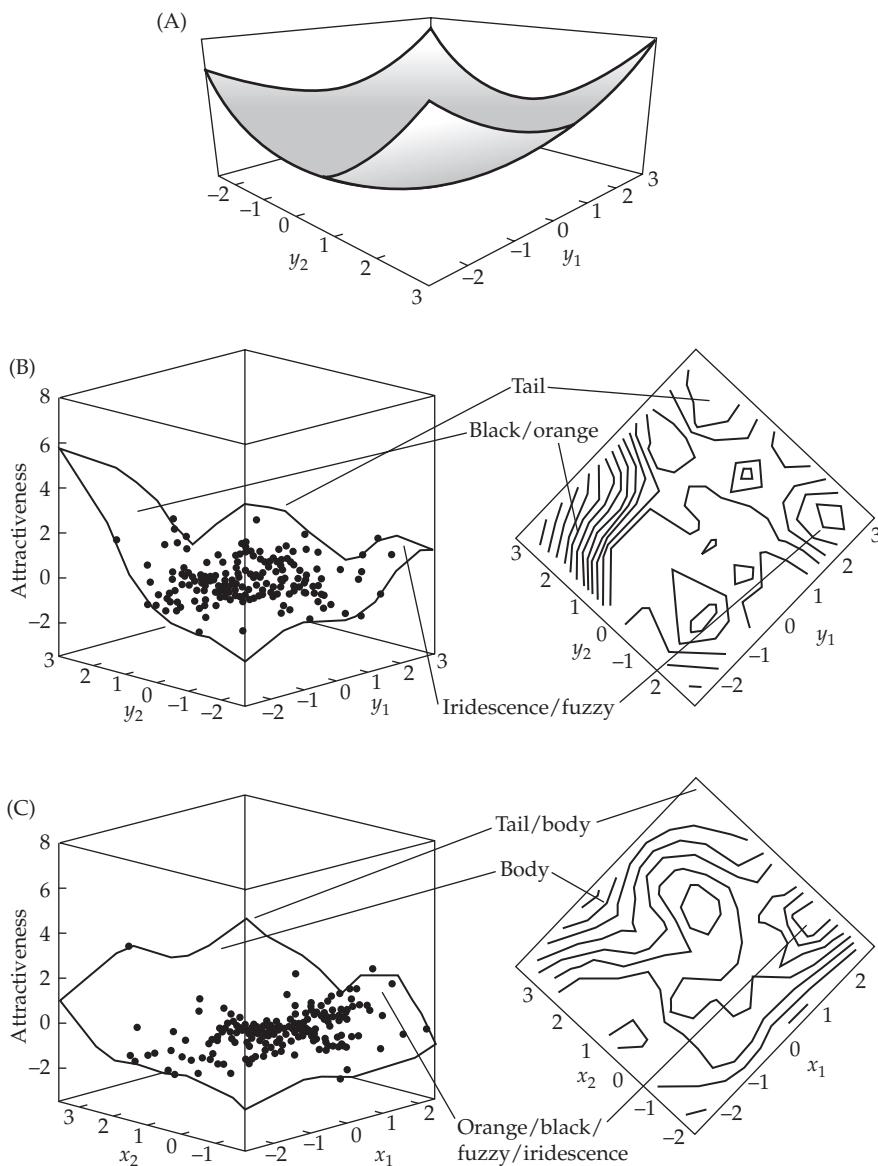

Figure 30.4 Visualization of the fitness surface for male attractiveness to female guppies as a function of color and size traits (for details see Example 30.7). **A:** The best-fitting quadratic regression. **B:** A thin-plate spline estimate of the fitness surface, using the axes given from the best quadratic regression ($y_i = \mathbf{e}_i^T \mathbf{z}$; Equation 30.26). **C:** The surface generated from projection-pursuit regressions (PPR) using the first two PPR axes ($x_i = \mathbf{a}_i^T \mathbf{z}$; Equation 30.29). While the thin-plate spline and PPR fitness surfaces look visually similar, it is important to recall that the trait loadings on their axes are different (see Example 30.7). The contour plots show the trait combinations that correspond to the different peaks. (After Blows et al. 2003.)

fitness surface, they display the pattern of selection on a series of composite traits, and not the actual traits themselves. This can make interpretation of the nature of selection on specific traits or combinations of traits problematic at best. Finally, the results from a nonparametric regression do not immediately provide coefficients to predict the response to selection, while (under normality assumptions) these follow automatically with a quadratic regression. Given these complementary strengths and weaknesses, researchers should use *both* quadratic and nonparametric regressions in the analysis of their selection data.

Projection-pursuit Regression and Thin-plate Splines

Schluter and Nychka (1994) extended Schluter's (1988) cubic spline univariate regressions (Chapter 29) to a vector of traits by using **projection-pursuit regression** (PPR; Friedman and Stuetzle 1981). The basic idea behind PPR is to approximate some complex function, $f(\mathbf{z})$, with a series of **projection vectors**, \mathbf{a}_i , and associated **ridge functions**, f_i ,

$$\begin{aligned} f(\mathbf{z}) &\simeq f_1(\mathbf{a}_1^T \mathbf{z}) + f_2(\mathbf{a}_2^T \mathbf{z}) + \cdots + f_k(\mathbf{a}_k^T \mathbf{z}) \\ &= f_1(x_1) + f_2(x_2) + \cdots + f_k(x_k) \end{aligned} \quad (30.29)$$

Solutions require two numerically intensive steps: estimation of the best-fitting projection vectors ($\mathbf{a}_1, \dots, \mathbf{a}_k$), and then estimation of their associated ridge functions (Schluter and Nychka used cubic splines for the latter). Thus, one chooses optimality and smoothing criteria and then obtains the first projection vector while fitting a cubic spline to the data along this projection. One then moves on to fitting the second projection vector, and so on. The assumption is that a rather low-dimensional space captures most of the structure of the fitness surface, so the first few projection vectors are sufficient to approximate individual fitness. As with the eigenvectors of γ in a quadratic regression, the projection vectors (\mathbf{a}_i) are those trait combinations (indices of trait values) that experience the strongest nonlinear selection. Visualization of the resulting complex surface is attempted by considering the pairwise projections on the first few projection vectors (Example 30.7 and Figure 30.4).

It is important to note that the projection vectors for a PPR do not necessarily correspond to the canonical axis of the γ matrix from a quadratic regression (Example 30.7). They do, however, correspond to the trait combinations under the strongest selection, but without the assumption of a quadratic fitness surface. As such, they represent a more general, and potentially natural, geometry for the axes of selection (Morrissey 2014b).

Another nonparametric approach is **thin-plate splines**, which are the two dimensional analog of univariate cubic splines. Using a projection onto two trait axes, thin-plate splines can be used to find the best-fitting 3-D surface on this reduced set of axes, thus employing another approach for visualizing complex surfaces.

The importance of allowing for more general fitness functions is highlighted by the work of Martin and Wainwright (2013), who examined fitness surfaces for a nascent adaptive radiation in a Bahamian clade of pupfish in the genus *Cyprinodon*. Using thin-plate splines, they found a fitness surface with multiple peaks, which corresponded to the morphology of existing populations in this radiation. Fitting the same data with a quadratic regression would have only resulted in a single peak (at most), which would have completely obscured important biological conclusions.

Example 30.7. Following up on the study of male color traits in guppies described in Example 30.6, Blows et al. (2003) examined six traits (two morphological and four color) for their role in female attractiveness. Both quadratic and projection-pursuit regressions were used to examine nonlinear selection on these traits. The trait loadings for the first two major axes of the quadratic regression of fitness on trait value (the eigenvectors \mathbf{e}_1 and \mathbf{e}_2 , corresponding to the two leading eigenvectors of γ) and the first two projection vectors (\mathbf{a}_1 and \mathbf{a}_2) from projection-pursuit regression were as follows:

Trait	\mathbf{e}_1	\mathbf{e}_2	\mathbf{a}_1	\mathbf{a}_2
Body area	-0.065	0.157	0.185	0.551
Tail area	0.663	0.635	0.331	0.087
Black area	-0.245	0.645	0.430	-0.182
Fuzzy area	0.372	-0.173	0.101	-0.286
Iridescent area	0.436	-0.134	0.569	-0.757
Orange area	-0.411	0.333	0.581	-0.016

Note that these two sets of projection vectors from the different regressions are rather distinct. If we apply Equation A5.2b, the angle between \mathbf{e}_1 and \mathbf{a}_1 will be 88° , while the

angle between \mathbf{e}_2 and \mathbf{a}_2 will be 87.5° . Thus, the major axes of the fitness surface are different (here, they are essentially orthogonal) if one uses a quadratic approximation as opposed to a projection-pursuit regression approximation. As Figure 30.4A shows, the best-fitting quadratic regression using \mathbf{e}_1 and \mathbf{e}_2 (where $y_1 = \mathbf{e}_1^T \mathbf{z}$ and $y_2 = \mathbf{e}_2^T \mathbf{z}$ are the trait values on this fitness surface for an individual with a trait vector, \mathbf{z}) shows disruptive selection, with fitness rising in all directions from a central minimum. If one uses these axes but then fits the data using thin-plate splines, the result is a rather different-looking fitness function (Figure 30.4B), but one that also shows multiple peaks corresponding to different combinations of the traits that females find attractive. When projection-pursuit regression is used (Figure 30.4C), the fitness surface (in rough appearance) is similar to that for thin-plate splines using the quadratic axes ($\mathbf{e}_1, \mathbf{e}_2$). However, because the values for the two sets of axes ($x_1 = \mathbf{a}_1^T \mathbf{z}, x_2 = \mathbf{a}_2^T \mathbf{z}$ versus $y_1 = \mathbf{e}_1^T \mathbf{z}, y_2 = \mathbf{e}_2^T \mathbf{z}$) are rather different, this superficial visual appearance must be mapped into trait values (as indicated in Figure 30.4). Again, the result is that the fitness surface has multiple peaks.

Gradients for General Fitness Surfaces

Table 30.1 shows that when \mathbf{z} is multivariate-normal, Lande-Arnold gradients describe the average geometry of an individual fitness surface and are the sole measure of selection in response equations (provided breeding values are Gaussian). When \mathbf{z} is not multivariate normal, these features do not necessarily hold. We addressed the issue of how univariate generalized gradients are computed in such settings (and what they imply) in Chapter 29, and these same concepts easily extend to multivariate settings. Janzen-Stein gradients (Equations 29.35a and 29.35b) measure the average geometry of the individual fitness surface. Suppose we let $\mathbf{z}_i, \dots, \mathbf{z}_n$ denote the n vectors of phenotypic observations. For trait i ,

$$\beta_{JS,i} = E_{\mathbf{z}_i} \left[\frac{\partial w(\mathbf{z})}{\partial z_i} \right] \simeq \frac{1}{n} \sum_{j=1}^n \frac{\partial w(\mathbf{z})}{\partial z_i} \Big|_{\mathbf{z}=\mathbf{z}_j} \quad (30.30a)$$

namely, the average value (over the n data vectors, $\mathbf{z}_1, \dots, \mathbf{z}_n$) of the gradient with respect to the focal trait.

Morrissey-Sakrejda gradients (Equation 29.35d) are calculated based on the partials of the mean fitness landscape. Fitness-landscape partials are critical because these are what quantifies the nature of phenotypic selection in both the multivariate response equations when the distribution of breeding values is multivariate normal (Table 30.1) and also in the more general Barton-Turelli expression (Equation 24.26) for when normality is not assumed. The Morrissey-Sakrejda gradient for trait i is

$$\beta_{MS,i} = \frac{1}{\bar{W}} \frac{\partial \bar{W}}{\partial \bar{z}_i}, \quad \text{where} \quad \bar{W} = \frac{1}{n} \sum_{j=1}^n W(\mathbf{z}_j) \quad (30.30b)$$

where, as above, there are n data vectors, with $W(\mathbf{z}_j)$ denoting the fitness associated with data vector \mathbf{z}_j . As in Chapter 29, these expressions apply to general fitness functions (such as those generated by PPR), and the required derivatives can be obtained numerically.

Calsbeek's Tensor Approach for Detecting Variation in Fitness Surfaces

When dealing with quadratic fitness surfaces, it is straightforward to test whether the regression coefficients vary among estimates from different temporal or spatial samples. How can this be accomplished when the fitness surface is generated by PPR, thin-plate splines, or some other semiparametric regression? Further, how does one best combine fitness surface estimates from a series of locations or times to display both an average fitness surface and also some measure of variability over samples?

A clever solution to both of these problems using **tensors** was suggested by Calsbeek (2012). The powerful tensor machinery, which is well known to physicists, has only been sporadically applied to quantitative-genetic problems (Rice 2002a, 2004b; Hine et al. 2009;

Aguirre et al. 2104). A matrix is a type of tensor with a table of items indexed by two subscripts. Now imagine a series of matrices stacked on top of each other to form a cube (think of a 3D chess board). This is a third-order tensor and is indexed by (i, j, k) (i.e., i for the i th matrix in the stack, whose elements are indexed by (j, k) , so that the entry $(2, 4, 5)$ in this tensor (stack of matrices) is the value in row 4, column 5, of the second matrix in the stack. The analysis of fitness functions that may vary over time or space proceeds by considering each fitness-function estimate (corresponding to a specific location or time) as one of the matrices in the total stack of such matrices over all of the locations or times.

Calsbeek's analysis (for two traits) proceeds by constructing a suitable mesh (neither too fine nor too coarse) for the two trait values, say 50 equally spaced increments on both axes, giving a 50×50 matrix. The entry in $(i, 5, 7)$ is the estimated fitness from a semiparametric regression for sample i for the value in axis one corresponding to row five and the value in axis two corresponding to column seven. The stacked series of such estimates forms the tensor. Calsbeek computed several measures of dispersion and variation among the different matrices representing fitness surfaces from different samples. Just as one can decompose a matrix into a series of approximations (e.g., PC1, PC2, etc.) that represent major axes of variation, one can also decompose a tensor into a series of matrices presenting major lower-order dimensions of variation. The first such matrix (the tensor generalization of the PC1 vector) represents the average fitness surface over the sample. Parametric bootstrapping can be used for approximate hypothesis testing, such as for determining the significance of between-sample differences in some component of the fitness surface. See Calsbeek (2012) for details on both of these procedures.

Model Selection

Given the plethora of choices for modeling fitness surfaces (which traits to include, what method to use, what type of function to fit, etc.), a few comments on the delicate issue of **model selection** are in order (see Burham and Anderson 2002 for a complete treatment). If one has a candidate set of models, which should be used? If the models are *nested* (with one being a subset of the other), then standard likelihood-ratio tests can be used choose between them (LW Appendix 4). However, most models are not nested. In such cases, various informal statistics are used to compare models, and we focus on two, the AIC and BIC metrics. For both of these metrics, a smaller value means it is a better model. We stress that while both metrics are fully grounded in theoretical principles (Burham and Anderson 2004), comparing values for two different models is largely ad hoc in that there is no formal test for significance (i.e., no formal criterion for determining when one model is clearly better than the other).

The idea behind both metrics (as in a likelihood-ratio test) is reward goodness of fit (i.e., smaller values of $-2 \ln[L]$ imply better fits, where L is the model likelihood), but also to penalize for the number of model parameters, k . One of the widely used model-comparison metrics is the **Akaike information criterion** (1973),

$$\text{AIC} = -2 \ln(L) + 2k$$

which was adjusted for the sample size, n , by Sugiura (1978),

$$\text{AIC}_c = -2 \ln(L) + 2k + \frac{2k(k+1)}{n-k-1} = -2 \ln(L) + \frac{2kn}{n-k-1}$$

The latter was briefly introduced (Equation 12.25a) in Example 12.5. AIC_c should be used in place of AIC unless $n/k > 40$ (Burham and Anderson 2004).

The other widely used metric is the **Bayes information criterion**,

$$\text{BIC} = -2 \ln(L) + \ln(n)k$$

which was introduced by Schwarz (1978), and thus is also known as the **Schwarz criterion**. While AIC and BIC are often used interchangeably, they are actually designed for slightly

different purposes. When one of the models being compared is the true model, then BIC picks this model with a probability approaching one in large samples. Conversely, AIC considers the situation where *none* of the candidate models may be correct and then tries to pick among the best of these. As noted by Shaw and Geyer (2010), if one is just considering a few traits, BIC should be used, but with a large number of traits AIC (or AIC_c) is a better choice. Investigators often report both, as the two metrics often rank models differently.

THE STRENGTH AND PATTERN OF SELECTION IN NATURAL POPULATIONS

Just how strong is selection in natural populations? When phrased in this way, the question is ambiguous, as it is not clear if the focus is on individual variance in fitness or direct selection on particular traits. One can observe a very high variance in individual fitness, and hence much *potential* for phenotypic selection, but if all variation in fitness is random (character-independent), then (in the extreme) there will be no phenotypic selection. In focusing on the strength of selection for particular *traits*, Darwin (1859) felt that characters change very slowly, and hence selection on them is weak. Conversely, there are classical examples (e.g., insecticide resistance and industrial melanism) of rapid responses, and hence presumably strong selection, although such cases are often the result of sudden shifts in the environment (such as anthropogenic changes), and how representative they are remains unclear.

Attempts at measuring selection on quantitative traits in nature trace back to Bumpus (1899) and Weldon (1901). The classical book by Endler (1986), which was one of the first attempts to summarize the average strength of selection, found that strong selection “is not rare and may even be common,” a conclusion that (at the time) was surprising to many. In 2001, Kingsolver and colleagues (Hoekstra et al. 2001; Kingsolver et al. 2001) started to harvest of the rich literature of Lande-Arnold fitness estimates that had been accumulating for almost two decades, and reached the conclusion that the average strength of selection was modest. As detailed shortly, these papers generated much discussion, with some proponents claiming they supported weak to modest selection and others claiming that they supported strong selection.

Meta-analysis

As reviewed in Appendix 4, **meta-analysis** is the field of statistics that deals with the analysis of trends over a large number of experiments (Hunter and Schmidt 2005; Borenstein et al. 2009a; Cooper et al. 2009; Harrison 2011; Koricheva et al. 2013). **Informal**, or **narrative**, **meta-analyses** are by far the most common approach in evolutionary biology. Here, one verbally summarizes the result of a number of studies. This is the type of analysis used by most of the early summaries of strengths of selection in the wild. However, by using the approaches in Appendix 4, one can combine *p* values over a number of experiments to reach a more global conclusion. While such global *p* values, and other summary statistics (such as empirical distributions by general trait type, and estimates of mean, or absolute, values), can appear in narrative meta-analyses, a **formal meta-analysis** is a much more effective way to use the data (Appendix 4).

Unfortunately, conducting a formal meta-analysis requires something that is very often lacking in published results, namely, *standard errors of estimates*. As detailed in Appendix 4, when standard errors are available, a meta-analysis can be placed into a very powerful fixed-effects or mixed-model framework that allows for a more rigorous, and detailed, analysis of the published data. In part, the focus on narrative approaches arises, not from a lack of statistical expertise from the authors of the meta-analyses, but rather from a lack of full transparency in the published literature, such as a failure to report (at a minimum) standard errors or (more ideally) making the entire dataset available for future analysis. In the words of Kingsolver et al. (2012), “we believe our general understanding of patterns of selection is most limited by lack of access to individual-level data (i.e., data on trait values and fitness measures for each individual) of most studies.”

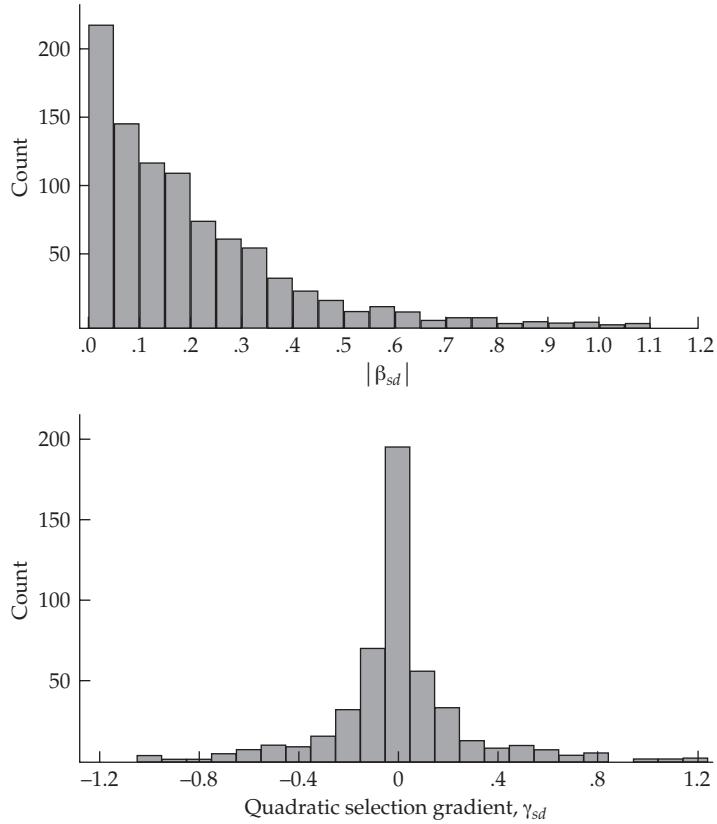

Figure 30.5 Summary of estimates of variance-standardized directional and quadratic gradients for natural populations. The data are from Kingsolver et al. (2001). **Top:** Plot of roughly 1000 estimated directional selection gradients in natural populations, with the median value of $|\beta_{sd}|$ being 0.16. The distribution of $|\beta_{sd}|$ was not significantly different from an exponential. **Bottom:** Plot of roughly 470 estimates of γ_{sd} from natural populations. The median value of $|\gamma_{sd}|$ was 0.10.

Kingsolver's Analysis

In a series of landmark papers, Kingsolver and colleagues (Hoekstra et al. 2001; Kingsolver et al. 2001) performed an informal meta-analysis on estimates of β and γ from 63 studies of natural populations published between 1984 and 1997. Their resulting frequency distributions of variance-standardized gradients ($\beta_{sd} = \sigma_z\beta$ and $\gamma_{sd} = \sigma_z^2\gamma$) are shown in Figure 30.5. These earlier findings have been updated using much larger datasets, but the basic conclusions from the initial 2001 papers remain the same, with narrative analyses by Geber and Griffen (2003), Kingsolver and Pfenning (2007), Cox and Calsbeek (2009), Siepielski et al. (2009, 2011, 2013), and Kingsolver and Diamond (2011) and more formal (mixed-model) analyses by Kingsolver et al. (2012), Morrissey and Hadfield (2012), and Morrissey (2016).

Kingsolver's initial analysis noted several trends. First, the distribution of absolute values of the variance-standardized directional selection gradients (β_{sd}) closely followed an exponential distribution, with a median (50% value) of 0.16. A β_{sd} of 0.16 implies that a change of one standard deviation in the trait changes relative fitness by 16%. Based on this observation, Kingsolver suggested that most directional selection in nature is fairly weak, although (as a result of the long tail of the exponential), there are a few large estimates (10% of estimates exceeded 0.5). Caution, however, is required with this initial estimate. It is well known that estimates of the expected absolute value, $|x|$, of a random variable, x , are inflated by sampling error (Equation A4.38a; Hereford et al. 2004; Morrissey 2016). For example, if

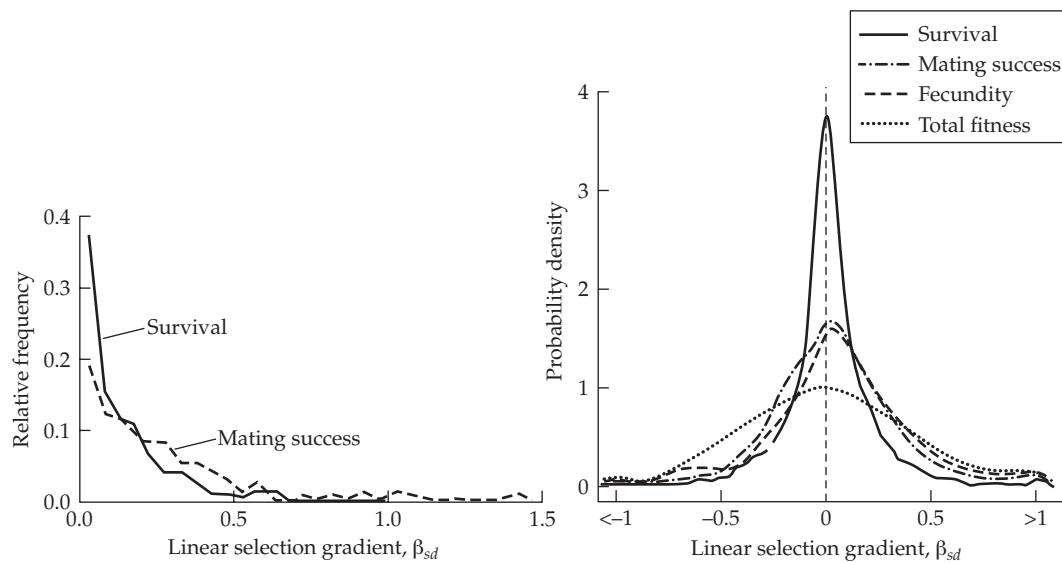

Figure 30.6 Distribution of variance-standardized directional selection gradients over different fitness components. **Left:** The distribution of $|\beta_{sd}|$ for both sexual and natural selection in the Kingsolver 2001 dataset. These gradients were measured by mating success and viability, respectively. The median value for viability was 0.153, but 0.250 for mating success. (After Hoekstra et al. 2001.) **Right:** Updated estimates of selection gradient using a larger dataset, showing the distribution of β_{sd} for traits influencing survival, mating success, fecundity, and total fitness. The latter three show a broader distribution of effects relative to survival. (After Kingsolver and Diamond 2011.)

$x \sim N(0, \sigma_x^2)$, then $E[|x|] = \sigma_x \sqrt{2/\pi}$ (Equation A4.37a), while if σ_e^2 is the error associated with estimating x using a sample value, \hat{x} , then $E[|\hat{x}|] = \sqrt{\sigma_x^2 + \sigma_e^2} \sqrt{2/\pi} > E[|x|]$. Hence, the average true strength of directional selection, $E[|\beta|]$, is less than the estimated strength, $E[|\hat{\beta}|]$. Indeed, Morrissey (2016) suggested that the initial Kingsolver value was roughly a twofold overestimate.

Two additional sources of bias can result in a further overestimation of the average strength of β , both of which are related to low power: Beavis effects (the overestimation of true effect size when using only values that are declared to be significant) and **publication bias** (the failure to publish nonsignificant results). Together, all these sources of bias strengthen the claim of weak selection. Consistent with this suggestion, most of the larger estimates of $|\beta_{sd}|$ occur in studies with small sample sizes, with most estimates below 0.1 occurring when the sample size was 1000 or greater. Hence, it is possible that some of the large β_{sd} values are simply a consequence of the larger estimation variance in smaller sample (the Beavis effect was discussed in LW Chapter 14 in the context of QTL mapping).

The discussion of β was focused on absolute values because their sign is likely to vary when considering a large set of traits and (without reference to a specific trait) the sign is usually not particularly relevant. Such is not the case with γ_{ii} , whose sign has an unambiguous meaning. Specifically, negative values indicate concave (and potentially stabilizing) selection, and positive values indicate convex (and potentially disruptive) selection. This leads to the second trend in selection data noted by Kingsolver, concerning the widespread belief that stabilizing selection is far more common than disruptive selection (Chapter 28). Rather than seeing this pattern (a skew toward negative γ_{ii} values), Kingsolver observed an essentially symmetric distribution of γ_{sd} values with a mean of zero (Figure 30.5), which implied that positively and negatively curved fitness surfaces are equally common. Further, the average strength of quadratic selection was weak, with an (again overestimated) median value of 0.10 for $|\gamma_{sd}|$. A more recent analysis of larger datasets reaffirmed this trend (Kingsolver and Diamond 2011; Kingsolver et al. 2012).

Kingsolver's third trend was that variance-standardized gradients, β_{sd} , for mating success and fecundity were larger than those for viability selection (Figure 30.6). This pattern of the weakest gradients often being associated with episodes of viability selection is seen in later (and larger) studies (Siepielski et al. 2011; Kingsolver and Diamond 2011). All of these authors noted that there is likely to be an intrinsic basis for mating traits in that most studies focused on measuring gradients for highly ornamental traits that were likely to be under strong sexual selection. However, no such apparent bias occurs in the choice of fecundity versus viability traits. This apparent pattern of higher variance-standardized gradients on fecundity than on viability provides some justification for the common tendency of studies of long-lived organisms to use annual fecundity (as opposed to annual survival) as a surrogate for total fitness.

However, this conclusion that fecundity is under stronger selection than viability is based on variance-standardized gradients. Recall our discussion from Chapter 29 on mean-standardized gradients, which measure fitness elasticity, and hence are a more natural metric for fitness effects. Crone (2001) found that most long-lived species had higher mean-standardized gradients for annual survival (viability) than for annual fecundity. Based on this result, Crone suggested that, contrary to the standard practice, annual viability may be a better surrogate for total fitness than annual fecundity. One notable exception to this pattern was in perennial semelparous plants (those with a single episode of reproduction), where the elasticity of growth rate was the largest, followed by fecundity, and then survival. For short-lived species, fecundity tends to have a higher elasticity than in longer-lived species. The most accurate approach for assessing the impact of these fitness components on total fitness is to weight the survival and fecundity gradients by the elasticity of each component on the population growth rate, λ ; see Equation 29.33f.

Directional Selection: Strong or Weak?

Has the case for “weak” selection been made? As pointed out by Conner (2001), even so-called weak selection can be very effective at changing trait means. Consider Kingsolver’s median value of $\beta_{sd} = 0.16$ ($\beta = 0.16 \cdot \sigma_z$). From Equation 13.22a, the single-generation expected change in the mean (in phenotypic standard deviations) is $h^2 \cdot 0.16$. With a typical heritability of 0.4, only 16 generations of selection are required to shift the population mean by one standard deviation, and only 80 generations are required to shift it by five standard deviations. Another way to think about the impact of a “weak” selection gradient of $\beta_{sd} = 0.16$ was mentioned by Hereford et al. (2004). They noted that even a population of modest size spans over four standard deviations of variation, implying a fitness range of $4 \cdot 0.16 = 0.64$, or a 64% variation in relative fitness among individuals within the population (assuming that the fitness-surface approximation holds over this span of phenotypic values).

Conversely, if concerns about publication bias and low power are correct, the true median value of $|\beta_{sd}|$ may be substantially less than the “weak” median value of 0.16 found by Kingsolver. Hersch and Phillips (2004) and Knapczyk and Conner (2007) examined the validity of these concerns. Figure 29.9 presented power curves for a univariate analysis (a single-trait fitness regression), which is a function of $\rho = \bar{\tau}/\sqrt{I}$. Hersch and Phillips showed that when multiple (potentially correlated) traits are considered, the adjusted version of the trait-fitness correlation, ρ , used in power calculations becomes

$$\rho^2 = \frac{\beta_{sd}^T \mathbf{s}}{I} \quad (30.31)$$

Hence, $\bar{\tau}^2$ is replaced by $\beta_{sd}^T \mathbf{s}$ (where \mathbf{s} is the vector of variance-standardized selection differentials, i.e., a vector of selection intensities), which accounts for the correlations among the (measured) traits. Using Equation 30.31, Hersch and Phillips found that most of the studies summarized by Kingsolver for which power calculations could be performed (i.e., those that included estimates of I) were very underpowered, supporting Kingsolver’s concern about the underreporting of small values and hence skewing the distribution of estimates of $|\beta_{sd}|$ upwards.

The impact of publication bias, which is also called the “file-drawer effect” (Rosenthal

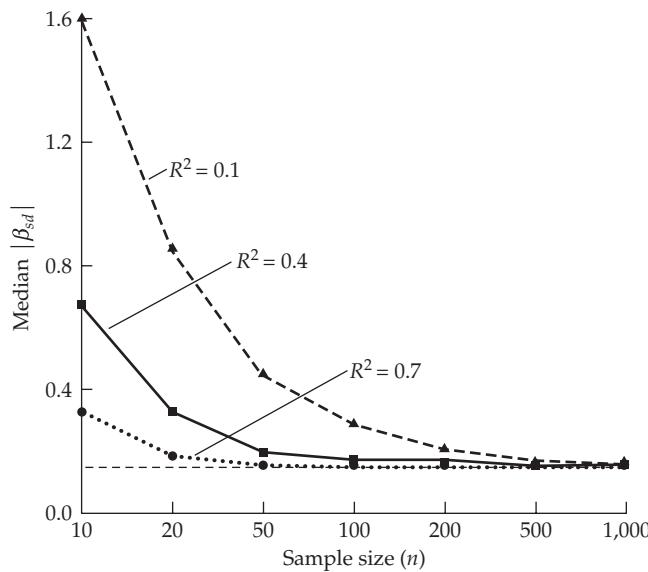

Figure 30.7 Overestimation of selection gradients due to publication bias. Hersch and Phillips (2004) simulated a model in which five values of β_{sd} were drawn from a distribution and only included in the final dataset if at least one of them was significant. The model coefficient of determination (R^2) is the total amount of variation in fitness explained by all of the traits (a small value of R^2 implies low power). The dashed line represents the true median value. Note the overestimation of the median β_{sd} values at small sample sizes and for small R^2 values.

1979; Rosenberg 2005), as nonsignificant results are not published and hence simply “left in a file,” was also examined by Hersch and Phillips (2004). They simulated cases where results were only published when one (or more) of the gradients in a study were found to be significant. Although such a model does indeed allow for many nonsignificant values in the database, these are still biased because they were conditioned on at least one of the results being significant. This ascertainment scheme is certainly one reasonable model for quantifying publication bias. For each “publication,” the simulation chose five “traits” by drawing five β_{sd} values at random. If one (or more) of the five tests was significant, all the values were retained, and if not, they all were discarded. As shown in Figure 30.7, this conditional sampling resulted in the median value of β being substantially overestimated when either the sample size or the amount of variation explained by the effects was small (low R^2 values), both of which are settings that result in low power. This is essentially another manifestation of the Beavis effect, overestimation when using statistics that are conditional on success (significance).

Knapczyk and Conner (2007) also considered sampling error and publication bias, but they arrived at the very different conclusion that “our understanding of selection is not strongly biased by these commonly invoked sources of error.” To examine publication bias, they binned the datasets examined by Kingsolver based on sample size. If there was no publication bias, the distribution of $|\beta_{sd}|$ values should have a similar form over different sample sizes (following the exponential observed for the entire set by Kingsolver). They found departures from this pattern for studies with very small sample sizes (less than 40), but did not find departures for studies with larger sample sizes. Indeed, compared to the exponential distribution, they found an excess of weak selection gradients in the larger studies. Thus, they concluded that publication bias, except in the smallest studies, did not upwardly bias estimates of $|\beta_{sd}|$ in any appreciative way. Appendix 4 presents a number of metrics to assess publication bias.

Further complicating matters is the paper by Hereford et al. (2004), who found that using mean-standardized gradients ($\beta_\mu = \mu\beta$; Equation 29.33a) gave very different results. Recall that the mean-standardized gradient is $\beta_\mu = 1$ when the trait is fitness itself, providing

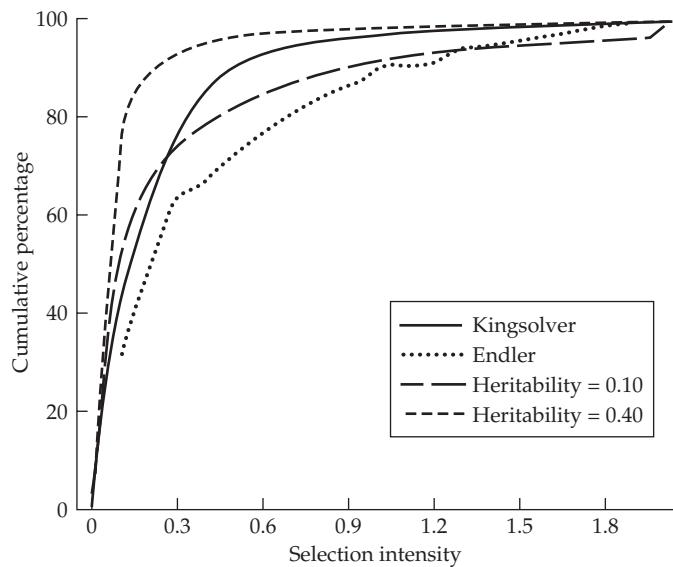

Figure 30.8 Four estimates of the distribution of selection intensities in nature. Two are direct estimates of selection from studies in nature (Endler 1986; Kingsolver et al. 2001), while the other two were estimated using observed rates of microevolution and then estimating \bar{t} using two different assumed heritability values. (After Kinnison and Hendry 2001.)

a benchmark for the strength of selection on a trait (Equation 29.33c). Using a subset of the Kingsolver data (38 studies yielding 580 estimates) that included the required information for this standardization (i.e., those that reported the trait means), they found a median $|\beta_\mu|$ of 0.54, or 54% of the strength of selection on fitness. This is indeed strong selection. Even using a correction for the upward bias generated by sampling error (Equation A4.37a), which reduced the median value to 0.31, still left strong selection. The observed strengths of selection were so large that the authors suggested that the selection gradients were likely inflated by focusing on single episodes of selection rather than lifetime fitness. In essence, they suggested that tradeoffs resulted in the actual gradient of lifetime fitness for a trait being significantly less than the gradients based on single episodes of selection. However, as we discuss shortly, there appears to be little evidence for tradeoffs among the traits in the currently analyzed databases (Figure 30.9).

A final perspective on the strength of directional selection was offered by Hendry and Kinnison (1999) and Kinnison and Hendry (2001), who compiled data on over 2000 estimated rates of microevolution. While rates of divergence in trait means confound the strength of selection with the transmission genetics of the trait, an advantage of this approach is that such estimates focus on an average rate of change over time, thus smoothing out large values caused by brief episodes of strong selection. Such episodes are more likely to catch our attention, and considering only these episodes results in a biased view of the average strength of selection over time. Figure 30.8 plots the cumulative selection intensities obtained by Endler (1986) and Kingsolver et al. (2001) as well as the inferred average selection intensity values given the observed rates of microevolution, assuming heritabilities of 0.1 and 0.4. As can be seen, under either assumed heritability, there is an excess of weak selection (small \bar{t}) values relative to those seen by Kingsolver and Endler. While this suggests that weak selection is the norm, an argument for strong selection can also be made. While strong selection can certainly occur over brief episodes, if it continues over a sufficient amount of time, genetic variation for the selection response will be eroded and further response must wait for new variation (from mutation and immigration). Thus, with strong persistent selection, h^2 will likely become much smaller than 0.1. Conversely, if selection is episodic, selection to reduce h^2 will be smaller and genetic variation will erode less quickly.

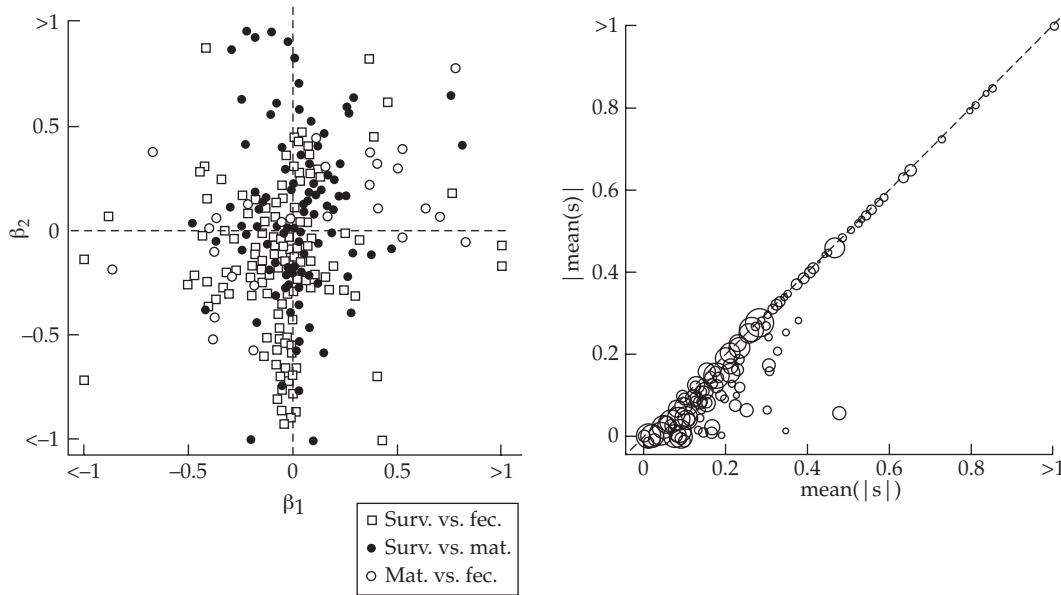

Figure 30.9 Additional results from the meta-analysis of Kingsolver and Diamond (2011). **Left:** Lack of evidence for fitness tradeoffs between survival (Surv.), mating (Mat.), and fecundity (Fec.). The scatterplot displays the variance-standardized linear gradients when a trait was measured for two or three of these components. Evidence of widespread tradeoffs would appear as an excessive number of values in the upper left ($\beta_{sd,1} < 0, \beta_{sd,2} > 0$) and lower right ($\beta_{sd,1} > 0, \beta_{sd,2} < 0$) quadrants. This is not seen. Rather, 57% of the data pairs have the same sign, which magnifies, rather than reduces, the total selective effect. **Right:** Temporal variation in standardized selection differentials ($s = S/\sigma = \bar{s}$) in samples with multiple time points. When sign reversals occur, $|\text{mean}(s)| < \text{mean}(|s|)$. The majority of values fall along the diagonal, indicating that sign reversal is not a common feature in this dataset (although values below the diagonal, and hence reversals, are seen). (After Kingsolver and Diamond 2011.)

An apparent excess of small selection intensities could reflect true low selection intensities when averaged over many generations, thus smoothing out strong episodes. However, it could equally likely reflect strong persistent selection quickly eroding heritability and hence reducing response.

Total Versus Direct Selection, Tradeoffs, and Temporal Variation

Three other evolutionary questions can be partly addressed through a meta-analysis of estimated gradients: the relative importance of correlated traits, the impact of fitness-component tradeoffs, and the magnitude of temporal variation.

The amount of **total selection** on a trait is given by S (and its variance-standardized counterpart, $s = \bar{s}$), which is the sum of the amount of direct (β, β_{sd}) and correlated selection (Equation 30.3). When β_{sd} is estimated from a multiple-trait regression, a plot of s versus β_{sd} can provide insight into the relative importance of direct versus correlated selection. A major caveat concerning this type of analysis is that it is only as good as the characters that are included in the regression. If causally important fitness traits that are correlated with a focal trait are not included, their effect can incorrectly be attributed to direct selection. Using this approach, Kingsolver and Diamond (2011) found that correlated selection had little impact, with s often falling very close to β_{sd} in value. An exception is size, where total selection is generally *less* than direct selection, which suggests negative correlations with other traits under selection. An analysis by Geber and Griffen (2003) of performance traits in plants found a different pattern than was seen by Kingsolver and Diamond. For these traits, they observed that $|\beta_{sd}|$ tended to be smaller than $|s|$, so not only were correlated

effects important, but they also tended to be in the same direction as direct effects. Geber and Griffen estimated that ~40% of the amount of directional selection on a trait was the result of correlated effects. Moreover, they found the same pattern ($|\gamma_{sd}| < |C/\sigma^4|$) for quadratic selection, with correlated effects accounting for an average of ~60% of the total effect.

A second area of interest to evolutionary biologists is the relative importance of trade-offs between different fitness components. For example, a trait that improves variability might do so at the expense of mating success or fecundity, so simply measuring the impact of a trait on one fitness component can give a very misleading view of its evolutionary potential (e.g., Example 29.1). Kingsolver and Diamond (2011) addressed this issue by plotting β_{sd} values for the same trait in those few studies that measured multiple episodes of selection. As shown in Figure 30.9, while examples of tradeoffs exist (the values of β_{sd} have different signs across episodes), there is no evidence that it is widespread. Indeed, in 57% of the comparisons, the two gradients had the *same* sign, thus reinforcing, rather than masking, selective effects.

Another potential tradeoff is, not between different episodes of selection, but rather between the sexes. Males and females may experience different amounts of selection for the same trait, and in the extreme may have opposite signs, or **sexually antagonistic selection (SA)**. In part, the limit that any such SA may place on evolution depends on genetic correlation of a trait between the sexes. If this correlation is less than perfect (i.e., different sets of genes may be involved between the sexes), then we have a two-trait evolution question (Equation 13.26c), and whether the presence of different patterns of selection on the separate traits constrains their joint evolution depends as much on their genetic covariance structure (G) as it does on their strength of selection (β). By ignoring this concern and instead focusing on selection itself, the potential importance of SA was examined in a narrative meta-analysis by Cox and Calsbeek (2009), who compared values of $|\beta_{male} - \beta_{female}|$ over traits, and obtained a median value of 0.13 (for variance-standardized gradients). Note that this is close to the initial Kingsolver value for absolute selection on traits, suggesting that between-sex differences are on par with the level of absolute selection on a trait. When it was broken down by fitness components, Cox and Calsbeek found that the median value of $|\beta_{male} - \beta_{female}|$ was smallest for viability and fecundity selection and largest for both sexual selection and total selection (a median value of around 0.2 to 0.3).

A strong caveat concerning these conclusions was noted by Morrissey (2016). As with $|\beta|$, estimates of an absolute difference, $|\beta_{male} - \beta_{female}|$, are inflated by sampling noise. Indeed, the expected value of $|x_i - x_j|$ for two random draws (x_i, x_j) from the same distribution is $2\sigma_x / \sqrt{\pi}$ (Nair 1936). Morrissey noted that such comparisons are best performed in a bivariate mixed-model framework (similar to the analysis used for Equations 20.26 through 20.29). His reanalysis of the Cox and Calsbeek data found that the correlation between male and female selection gradients was ~0.8, thus showing that selection gradients are highly positively correlated between the sexes and that SA is rare.

The final issue is the impact of temporal variation in selection strength and direction (Siepielski et al. 2009, 2011, 2013; Kingsolver and Diamond 2011). There are numerous ways to quantify temporal variation, such as measuring the standard deviation over a set of estimates (which compounds actual variation with sampling variation) or the fraction of times the sign changes (which can be high for a trait under very weak selection). A simple metric is to plot $|\text{mean}(s)|$ versus $\text{mean}(|s|)$. If sign reversals are common, then $|\text{mean}(s)| < \text{mean}(|s|)$, while if the two are roughly equal, little sign reversal has occurred. While this metric obscures any variation in the strength of selection, it does address the impact of temporal variation in its direction. As shown in Figure 30.9, for the existing data, any directional variation is relatively modest, and it is greatest for traits under weak selection ($\text{mean}(|s|)$ small), which could simply reflect sampling error.

These data were reexamined by Morrissey and Hadfield (2012), who performed a random-effects meta-analysis (Appendix 4) on a subset (consisting of those studies that reported standard errors, and hence allowed for a formal meta-analysis). If we let β_{ij} denote

the j th temporal value from the i th study-trait combination, the model becomes

$$\beta_{ij} = \mu + u_i + t_{ij} + e_{ij}$$

where $\mu + u_i$ is the expected value for the gradient in the i th study-trait combination, t_{ij} is the residual due to temporal variance, and e_{ij} is the sampling error. The last three variables are treated as random effects, and one can estimate their variances in a mixed-model setting. Of interest is the ratio $\sigma_u^2 / (\sigma_u^2 + \sigma_t^2)$, namely, the amount of variance due to among study-trait means relative to the trait plus temporal variance. Morrissey and Hadfield found this ratio was quite high, measuring 0.88 (with a 95% credible interval of 0.82 to 0.91), thus leading to the conclusion that selection over time is remarkably constant.

Siepielski et al. (2011) examined how the temporal strength of selection varied over different fitness components (viability, mating success, and fecundity). The temporal variation among variance-standardized gradients was highest for mating success and roughly equal for survival and fecundity. Given potential differences in sampling error over these different fitness components, this result could simply imply higher sampling variation in mating success over other components. They also found that reversals of signs were highest for survival, followed by mating, and then fecundity. They noted that frequent sign reversals could occur if a trait under viability stabilizing selection has its mean close to the optimum (θ). In such a setting, small fluctuations of the mean around θ result in sign variation in β .

To examine if this is the case, Siepielski et al. applied a result from Estes and Arnold (2007), who used β_{sd} and γ_{sd} to estimate the distance of a population mean from an optimum,

$$\frac{|\bar{z} - \theta|}{\sigma} \approx \left| \frac{\beta_{sd}}{-\gamma_{sd}} \right| \quad (30.32)$$

This follows from Equation 30.21a, and it assumes a normally distributed trait with a fitness function that is well approximated (over the bulk of its phenotypic distribution) by a quadratic. Using Equation 30.32, Siepielski et al. found a value for the standardized difference of the mean from an optimum of 2.28 ± 0.54 for survival traits in their dataset, but values of 14.59 ± 9.14 for mating success and 11.62 ± 5.48 for fecundity. While Equation 30.32 is a crude metric, which is fraught with numerous pitfalls, it does suggest that survival traits might be closer to their optimum (provided it exists).

Directional Selection on Body Size and Cope's Law

Body size has several outlier features relative to other traits. As shown in Figure 30.10, while the distribution of β_{sd} values for morphological traits was symmetric around zero, the distribution for β_{sd} for body size was highly skewed toward positive values (Kingsolver and Pfenning 2004; Kingsolver and Diamond 2011). Kingsolver and Pfenning suggested that individual selection for larger body size underlies **Cope's law** (the tendency for the size of species within a lineage to increase over evolutionary time). This suggestion also presents a paradox: if it is true, why are most of the largest animals not present today? Kingsolver and Pfenning (2004, 2007) suggested that this is a consequence of differential extinction, pointing out that during the last widespread extinction of North American mammals, the largest species were the hardest hit. However, as we noted above, Kingsolver and Diamond (2011) also found that direct selection on size is greater than the total selection ($\beta_{size} > s_{size}$), suggesting the presence of selection against traits that are phenotypically correlated with body size, whose values tend to become more deleterious as body size increases. Further, they found that the distribution of γ , while symmetric for most classes of traits, was significantly negative for body size, suggesting that it is often under stabilizing selection. Figure 30.10 shows that another class of characters, phenological traits (season timing events such as breeding), also shows a skewed distribution, toward negative (i.e., earlier) values.

Quadratic Selection: Strong or Weak?

Discussions of whether the observed amount of quadratic selection is strong or weak are highly problematic. If estimates of β_{sd} are underpowered (and thus significant estimates are likely overvalued; i.e., the Beavis effect), the same is certainly true for quadratic estimates.

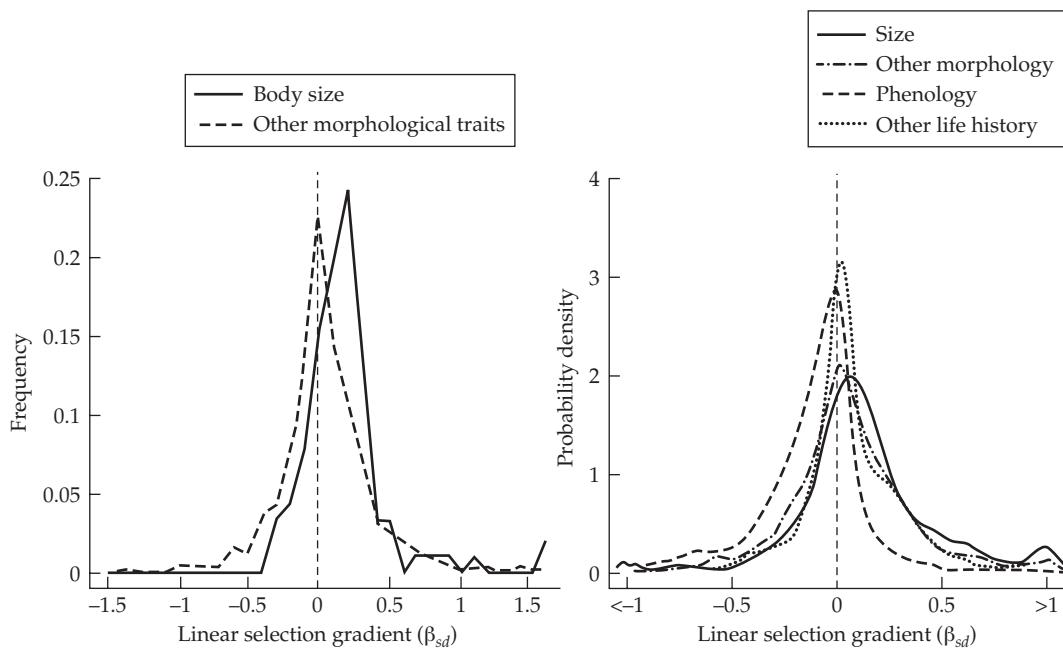

Figure 30.10 **Left:** Distribution of variance-standardized selection gradients, β_{sd} , for morphological traits and for size. While the distribution for morphological traits is largely symmetric around zero, the distribution of β_{sd} for body size is skewed toward positive values. (After Kingsolver and Pfenning 2004.) **Right:** A more recent analysis by Kingsolver and Diamond (2011) showing a positive-skew for size and a negative-skew for phenological traits.

Indeed, simulations by Haller and Hendry (2013) found that there is generally low power for detecting stabilizing selection due to small sample sizes. Simulations for traits under weak stabilizing selection typically resulted in a distribution of γ values similar to that seen in Figure 30.5, namely, largely symmetric about the origin (reflecting low power, and hence a roughly random distribution of estimates around zero). An important feature of the Haller-Hendry simulations was that they used a “**virtual ecologist**” approach, wherein simulated data from the quantitative-genetics model is combined with an **observer model** (i.e., a model for how the data would be ascertained in real-world settings, such as having living individuals that are not recaptured counted as dead). This mimics how real data would be “virtually” observed (Zurell et al. 2009), and hence more correctly reflects the actual power of collected data.

Balancing concerns about inflated estimates due to low power (Beavis effects), there are two reasons why reported estimates of quadratic gradients may be *undervalued*. As mentioned earlier, many published reports have made errors in obtaining γ_{ii} values from the output of standard regression packages, resulting in only half their true value being reported (Stinchcombe et al. 2008). Second, Blows and Brooks (2003) noted that $|\gamma_{ii}|$ likely significantly *underestimates* the strength of quadratic selection when multiple traits are considered (see Example 30.6). An analysis based on the eigenvalues (λ) of the γ matrix is much more informative as to the strength of quadratic selection in nature.

The much more problematic issue is whether γ is even a reasonable measure for non-linear fitness surfaces. As Figure 29.10 illustrated, a value of γ can be entirely misleading when the fitness surface departs from a quadratic. As the above theory on canonical forms illustrates, a quadratic surface in k dimensions (traits) still has (at most) only a single extremum (Equation 30.21a). In this case, fitting a multimodal fitness surface with a quadratic will return a very misleading value of γ . Indeed, even with stabilizing Gaussian selection, if the mean is sufficiently above the optimum, the best quadratic fit will result in $\gamma > 0$, which falsely implies the presence of potentially disruptive selection (Figure 29.10).

Where Is All the Stabilizing Selection?

Perhaps the most striking observation from the meta-analysis of γ values is the lack of a clear trend toward negative values (except for body size), as would be expected if stabilizing selection were widespread. This is highly troubling given the historic view of most ecologists and evolutionary biologists that stabilizing selection is widespread and important over evolutionary time (Charlesworth et al. 1982; Maynard Smith 1983; Estes and Arnold 2007; Hunt et al. 2007a). One explanation is that γ does not capture the correct geometry in multimodal fitness surfaces. The second is the observation from the Haller-Hendry (2013) simulations of low power to detect stabilizing selection.

Haller and Hendry offered several other explanations for this “missing” stabilizing selection. The first is that selection may have already done its job in that the existing phenotypic variation is small relative to the width of the fitness peaks (Chapter 28). In their words, “selection ‘erases its traces’ once populations have adapted to a fitness peak.” The second is the suggestion from Chapter 28 that strong stabilizing selection is likely to be confined to a few dimensions in the multivariate trait space (i.e., a few indices of trait values). This results in only a weak signal in any single component trait and low power of detection. Their final suggestion is that **squashed stabilizing selection** may be common, which again lowers power. Here competition results in disruptive selection among individuals whose trait values are near an adaptive peak, which flattens out (squashes) the fitness surface around the peak, making detection more difficult. An example of this phenomenon is the work of Morno-Rueda (2009) on selection on shell morphology in Spanish land snails (*Iberus gualtieranus*). Predation from black rats (*Rattus rattus*) results in distinctive markings on the shell, and using only such shells showed disruptive selection on shell height. Conversely, when shells lacking these markings were used in the analysis, stabilizing selection was seen. When all shells are considered as a single group, no significant quadratic term is observed.

A Plea to Fully Publish

In 1899, Herman Bumpus published a modest dataset involving 136 domestic sparrows (*Passer domesticus*) immobilized by an ice storm. Of these, 72 (21 females, 51 males) survived, while the remaining 64 (28 females, 36 males) perished. Despite the humble beginning, this has become the most widely analyzed study of selection (Harris 1911; Calhoun 1947; Grant 1972; Johnson et al. 1972; O’Donald 1973; Lande and Arnold 1983; Crespi and Bookstein 1988; Crespi 1990; Pugesek and Tomer 1996). In large part, this is because *Bumpus published all of his data*, allowing investigators to employ their own methods of analysis. In contrast, Kingsolver et al. (2001) lamented that many of the studies included in their meta-analysis did not even report standard errors, much less trait means (which are needed to allow for mean-standardized gradients to be computed), thus limiting their inclusion to only narrative meta-analyses. At a minimum, any published study should report standard errors for all estimates. More generally, studies should make their entire dataset available to the community. Indeed, such fully open access is a requirement for virtually all published molecular studies. As Kingsolver et al. (2012) pleaded “Recycle your hard-won, slightly used, still precious data today!”

UNMEASURED CHARACTERS AND OTHER BIOLOGICAL CAVEATS

Even if we are willing to assume that the best-fitting quadratic regression is a reasonable approximation of the individual fitness surface, there are still a number of important biological caveats to keep in mind (Chapters 20 and 29). For example, the fitness surface can change in both time and space, often over short spatial or temporal scales (e.g., Kalisz 1986; Stewart and Schoen 1987; Scheiner 1989; Jordan 1991; Garant et al. 2007; Siepielski et al. 2009, 2011, 2013; Bell 2010; but see Morrissey and Hadfield 2012), so one estimate of the fitness surface may be quite different from another for a different time or location (Figures 30.11 and 30.12). Hence, considerable care must be taken before pooling data from different times or sites to improve the precision of estimates. Conversely, fitness data are noisy,

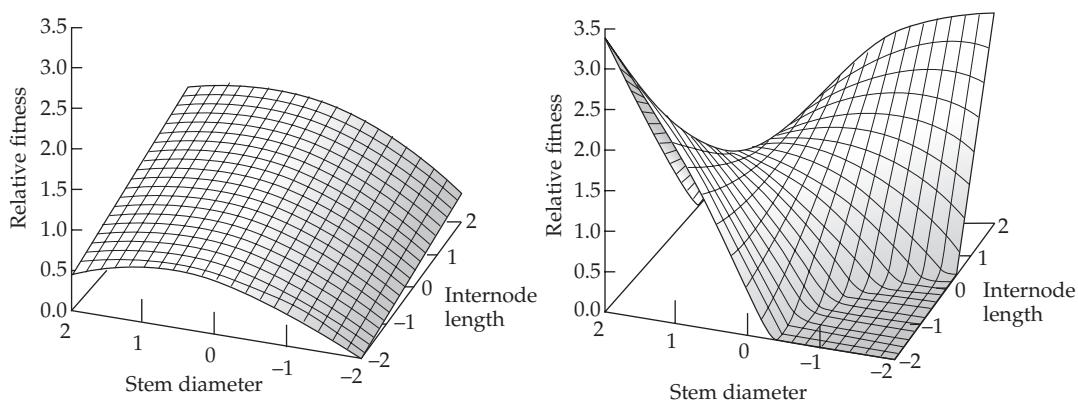

Figure 30.11 The selection surface can change over time. These two surfaces are the best-fitting quadratic surfaces for relative fitness as a function of stem diameter and internode length for a population of the annual plant *Diodia teres* (Rubiaceae) in North Carolina. **Left:** Estimate for June 1985 data. **Right:** Estimate for July 1985 data. (After Jordan 1991.)

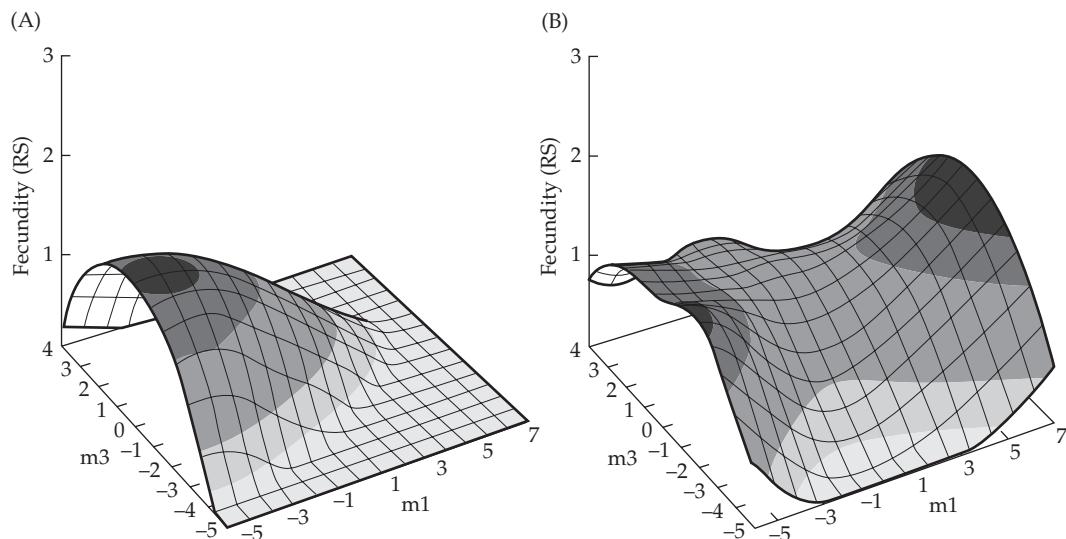

Figure 30.12 The fitness surface can change over space. The fecundity surface for great tits (*Parus major*) in two populations in Oxfordshire (U. K.) separated by less than four kilometers. Here, m_1 and m_3 correspond to the first and third canonical axes (weighted trait combinations) of the fitness surface. (After Garant et al. 2007.)

and the resulting surfaces have considerable uncertainty, so two, visually rather different-looking, surfaces might be not statistically significantly different. When the data are such that selection gradients can be estimated separately for different times or areas, interactions of space/time \times gradient can be tested in a straightforward fashion (e.g., Mitchell-Olds and Bergelson 1990). Further, the evolution of a trait may result in a change in the biotic environment, which in turn may change the nature of selection on that trait (Chapters 20 and 22).

Population structure can also influence fitness surface estimation. If the population being examined has overlapping generations, fitness data must be adjusted to reflect this (Chapter 29). Likewise, if members of the population differ in their amount of inbreeding,

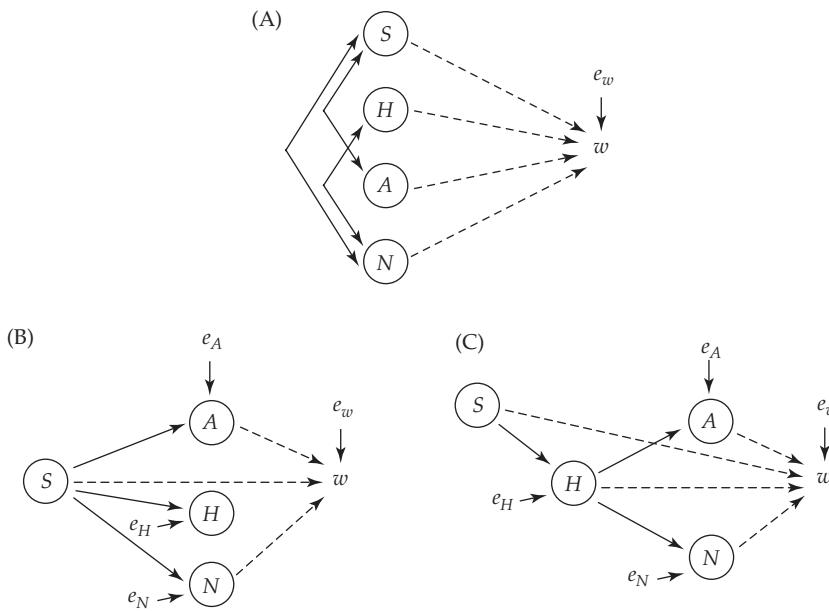

Figure 30.13 Four traits, seed weight (S), plant height (H), leaf area (A), and number of leaves (N), potentially influence fitness, w . Single-headed arrows indicate assumed causality, while double-headed arrows indicate correlations (unspecified causality). Connections between a trait and fitness are shown as dashed arrows for visual clarity. Throughout, e represents a residual input (the variation not accounted for by the causal connections). **A:** The assumptions of a standard fitness regression. All four traits, some of which may be correlated (doubled-headed arrows between trait combinations), potentially impact fitness. **B:** Seed weight impacts the three other traits, giving a direct impact on fitness ($S \rightarrow w$) and indirect effects on fitness through its impact on A , H , N and their subsequent impact on fitness ($S \rightarrow X \rightarrow w$). **C:** Seed weight impacts height directly, but not A or N . Height, in turn, impacts A and N . A key limitation (and also a strength) of a path analysis is that **B** and **C** assume paths (**causality structures**), which can result in rather different interpretations of the patterns of selection, and both (in turn) can depart from the pattern suggested from a standard regression (**A**). For example, when trait A has a large effect on fitness, the path in **B** may find that any correlation between S and w is entirely due to the impact of S on A , while the path in **C** may find that selection is from the impact of H on A .

measured characters and fitness may show a spurious correlation if both are affected by inbreeding depression, which in turn can inflate the apparent strength of directional and concave selection (Willis 1996). Finally, immigration must be accounted for (e.g., Garant et al. 2005), especially if there are different selection regimes within the area that encompasses the study population (e.g., Figure 30.12).

Despite these concerns, the most severe caveat for the regression approach of estimating $w(z)$ is unmeasured characters. Estimates of the amount of direct selection acting on a trait are biased if that trait is phenotypically correlated with unmeasured characters that are also under selection (Lande and Arnold 1983; Mitchell-Olds and Shaw 1987). Adding one or more of these unmeasured characters to the regression can change initial estimates of β and γ . Conversely, selection acting on unmeasured characters that are phenotypically *uncorrelated* with those being measured has no effect on estimates of β and γ .

PATH ANALYSIS AND FITNESS ESTIMATION

As we saw in Figure 29.12, complex life cycles can be represented as graphs, as can a set of cascading developmental traits (Figure 30.13), the elaborate interplay between fitness

components (Figure 30.14), or the connection between traits, fitness components, and population growth rate (Figure 30.16). One way to explore these graphical structures is with **path analysis**, which requires a **path diagram**, which is a *hypothesis* about the structure of causality (LW Appendix 2; Kingsolver and Schemske 1991; Mitchell 1992; Shipley 1997). The strengths of relationships in a path diagram are represented by **path coefficients**, which are correlations among connected items in the path. As a very simple example, consider the impact that seed weight and plant height have on fitness.

One potential path diagram is seed weight → height → fitness, which states that seed weight only impacts fitness through its effect on plant height. A path analysis of this model first variance-standardizes all of the variables and then performs regressions (or partial regressions), generating correlations among the items in the path. Suppose the resulting coefficients are

$$\text{weight} \xrightarrow{0.35} \text{height} \xrightarrow{0.15} w$$

implying a correlation of $\rho = 0.35$ between seed weight and plant height, and a correlation of 0.15 between height and fitness. As drawn, this diagram implies that seed weight does not have a direct effect on fitness, but it does have an indirect effect through height. Because ρ^2 is the fraction of variation accounted for by a factor, we see that seed weight explains 13% ($0.35^2 = 0.13$) of the variance in plant height and that plant height accounts for 2% (0.15^2) of the variance in fitness. Further, the correlation between any two connected items in a path is the product of their path coefficients, giving a correlation between seed weight and fitness of $0.35 \cdot 0.15 = 0.0525$, showing that seed weight accounts for 0.3% (0.0525^2) of the variance in fitness.

Regression and path analysis offer *complementary approaches* for examining relationships between phenotypes and fitness. The purpose of a regression analysis is to predict fitness given character values, while path analysis provides a description of the biological nature of character covariances and how they interact with fitness. While regressions simply rely on the correlations among traits (Figure 30.13A), path analysis examines the *structure* of these correlations (Figures 30.13B and 30.13C), building on the biological intuition of the investigator. A number of authors have applied this approach to the analysis of natural selection (e.g., Arnold 1983b; Maddox and Antonovics 1983; Mitchell-Olds 1987; Crespi and Bookstein 1988; Crespi 1990; Jordan 1991; Weis and Kapelinski 1994; Conner 1996; Pugesek and Tomer 1996; Scheiner et al. 2000; van Tienderen 2000; Coulson et al. 2003; Latta and McCain 2009; Matsumura et al. 2012).

The analysis of selection on graphs falls into four categories. First, we have already seen the use of Aster models on life-history graphs to obtain a statistically rigorous distribution of fitness effects (Chapter 29). Second, path analysis can be used to represent a proposed causal structure among life-history components and traits to provide insights that a standard fitness-trait regression can miss. Third, selection could be on one or more **latent** (unobserved) features that are correlated with observed (and potentially unselected) traits. While the observed traits may show trait-fitness associations, these could all be indirect effects, resulting from the correlation with the latent traits. This setting can also create high collinearity, with many of the measured traits being highly correlated with the latent traits. Path-analysis models can be used in some cases in the analysis of such data. Finally, **elasticity path analysis** connects selection gradients of a trait on fitness components with the elasticity (Chapter 29) of those components on the population growth rate (λ) to provide the elasticity of that trait on λ (van Tienderen 2000). This approach provides a powerful connection between selection and demography. We address these last three topics in order, while Aster model analysis of life-history graphs were introduced in Chapter 29.

While powerful, path-analytic methods are not without significant caveats. First, all of the issues with non-Gaussian fitness residuals that are a concern with regression methods fully apply to path analysis (which, itself, is a modified regression method). Second, path analysis assumes that there are only linear interactions, and hence only model directional selection. Scheiner et al. (2000) described how to include quadratic factors by augmenting

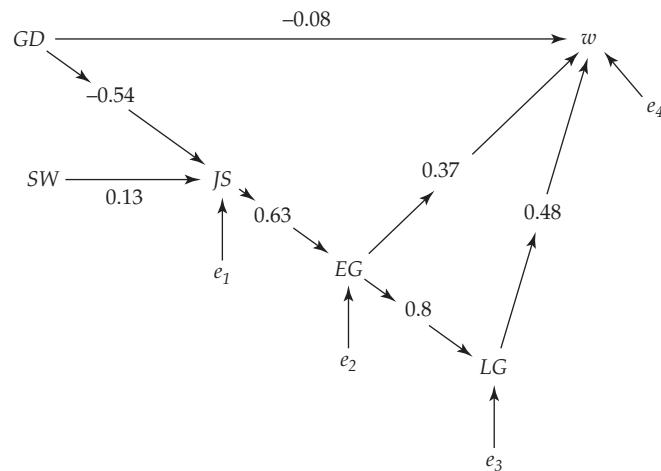

Figure 30.14 An example of the use of path analysis in describing multivariate selection from Mitchell-Olds and Bergelson (1990), who examined fitness (measured by adult size) for the annual plant *Impatiens capensis*. Germination date (GD), seed weight (SW), June size (JS), early growth rate (EG), and late growth rate (LG) were the measured characters, and *e_i* represents residual variance for trait *i*. Only significant paths, with their associated path coefficients (i.e., correlations) are shown. (After Mitchell-Olds and Bergelson 1990.)

each variable with its square and then performing a considerable amount of bookkeeping (see their paper for details). Finally, the results from a path analysis are *extremely* dependent on the assumed causality structure, so the interpretation of the results can be substantially biased if this structure is even slightly incorrect. Echoing the cautionary words of Kingsolver and Schemske (1991), “The uncritical application of path models to the analysis of selection in natural populations is likely to yield misleading and erroneous results.”

Regressions Versus Path Analysis

The key distinction between a regression and a path analysis of selection is that regression attempts to statistically account for the covariance between fitness and the measured traits, while a path analysis further attempts to account for the *processes* generating correlations among the measured traits. Regressions assume that none of the traits are causal to any of the others, while Crespi (1990) noted that “path-analytic reasoning assumes that characters are correlated as a result of biological causes that should be used as information rather than adjusted away.”

As an example, suppose traits are ordered in time, such as

$$\text{germination, } g \rightarrow \text{vegetative growth rate, } r \rightarrow \text{flowering time, } f$$

A regression analysis simply uses each trait’s correlation with fitness without using the ordered structure inherent in the variables, while a path analysis explicitly uses this information. Examples of different causal assumptions for the same set of four traits are given in Figure 30.13. Each diagram displays a different causal structure that was assumed at the start of the analysis. Connections (arrows) that are nonsignificant or have very trivial values are usually left out of the final diagram, with the strength of connections often indicated by the line thickness of the arrows. Double-header arrows indicate correlations, namely, no assumption about the nature of causality between these variables, as would be the case for a standard regression (Figure 30.13A). A key limitation (and also strength) of a path analysis is that these different assumed path diagrams (causality structures) can result in rather different interpretations of the patterns of selection. If it is correct, the path diagram captures unique features missed by a regression (which *assumes* correlations, rather than attempting to *model how they arise*). If it is incorrect, a path analysis can introduce potentially serious biases.

Example 30.8. Mitchell-Olds and Bergelson (1990) measured fitness (using adult size as a proxy) in the annual plant *Impatiens capensis* as a function of five traits: seed weight, germination date, June size, early growth rate, and late growth rate. Figure 30.14 displays the significant paths between these variables and fitness. Note that the path diagram provides a description of the actual nature of the correlations, and in particular, the causal connections assumed between variables. From this diagram, we can examine the contribution to relative fitness from the direct effect of a character and from its indirect effects through its effect on other characters. For example, the direct effect of early growth is 0.37 (the path $EG \rightarrow w$), so this path accounts for 13% of the variation in fitness ($0.37^2 \approx 0.13$). Early growth also influences fitness through an indirect path by influencing late growth rate, which in turn has a direct effect on fitness ($EG \rightarrow LG \rightarrow w$), and their product $0.8 \cdot 0.48 = 0.38$ accounts for an additional 15% (0.38^2) of the total variance in fitness. The total effect of early growth on fitness is the sum of the squared direct and indirect effects; here $0.37^2 + 0.38^2$, or 25%. Proceeding in a similar fashion, the direct and indirect effects for each trait on fitness are

Character	Direct Effect	Indirect Effect
Seed weight	0.04	0.10
Germination date	-0.08	-0.32
June size	-0.02	0.52
Early growth rate	0.37	0.38
Late growth rate	0.48	0.00

Negative coefficients imply that fitness increases with decreasing trait value. Observe that indirect effects are more important than direct effects for most characters.

While we have framed multiple-trait selection in the context of a number of traits in an individual and how these influence fitness, an equally common situation is when the “traits” are not properties of an individual, but rather biotic agents, such as the predators, competitors, or pollinators of the focal species. Path analysis allows one to examine the interactions among these multiple components and how they influence the fitness of the trait in the focal species.

Example 30.9. Weis and Kapelinski (1994) examined the nature of selective forces acting on gall size of a tephritid fly (*Eurosta solidaginis*), whose larvae makes a protective gall on goldrenrods. Larvae residing in small galls are susceptible to a parasitoid wasp (*Eurytoma gigantea*), whose ovipositor can reach the larvae through small, but not large, galls. Countering this, when galls become sufficiently large, they are preyed upon by insectivorous birds (mainly downy woodpeckers, *Picoides pubescens*). The result is selection pressure on both large and small galls, but through different biotic agents. Two other parasitoids, a second wasp and a beetle, also feed on larvae within galls, but here gall size does not appear to be a factor. However, galls attacked by these two insects appear to be distasteful, and the resulting parasitoids are not eaten by birds. Thus, this is a complex system with different agents and the possibility of frequency-dependent search images, all of which are acting to impart selection on the focal trait, which is gall size.

The authors examined two different path diagrams for selection intensity on gall size, one of which represented a conventional model of selection, with gall density and mean gall size included in the model. A second (search image-based) model replaced these two measures with the density of small galls and the density of large galls. Under the conventional model, there was a strong (but not significant) negative association (-0.43) between gall size and attacks by *Eurytoma* and a strong (and significant) association (0.37) between mean gall size and bird attacks. Conversely, under the frequency-dependent model, there was no association between small or large gall density and *Eurytoma* attacks, but a strong (and significant) association between density of small galls (-0.50) and density of large galls (0.46) and bird attacks.

As this example illustrates, a path-analysis model allows an investigator to examine the impact of several possible causality structures by leveraging known biological information (which does not enter into a standard regression analysis).

Morrissey's Extended Selection Gradient Vector, η

Consider the following two path diagrams connecting a focal trait (z), fitness (w), and some unmeasured factor (f):

$$\text{path 1: } z \leftarrow f \rightarrow w \quad \text{path 2: } z \rightarrow f \rightarrow w$$

Both paths generate a correlation between the focal trait and fitness, which results (in a regression analysis) in a nonzero gradient, β , when f is excluded (as z and w are correlated), and a β value of 0 when it is included (as, when it is conditioned on f , z and w are uncorrelated). Path 1 is the “missing trait” concern in a Lande-Arnold regression: if f is not included in the analysis, the regression falsely suggests a direct effect of z on fitness. Conversely, for path 2, z influences the unmeasured factor, f (e.g., some measure of performance; Arnold 1983b, 1988) which in turn influences fitness. While both paths generate a β value of zero when the factor f is included in the analysis, they reflect very different settings. In a regression analysis, we strive to avoid situations like those in path 1, while a nonzero value of β for path 2 when f is not in the analysis typically need not trouble us, as z has a causal influence on fitness (albeit an indirect one). Note that both paths can have identical correlation structures between all pairwise elements (and thus both would yield the exact same Lande-Arnold regression), which shows the importance of a causal diagram in the analysis of selection on correlated traits.

Motivated by situations like path 2, where z has an indirect causal impact on fitness but a β value of 0 if traits in the causal structure between z and w are included in the analysis (e.g., f in path 2), Morrissey (2014a) proposed the concept of an **extended selection gradient** vector, η . This variable measures the total selection caused by a trait and its downstream causative components. Recall (Equation 30.3) that the selection differential is measure of the total selection on a trait from both direct and indirect (correlated) selection, and that

$$S_i = \beta_i P_{ii} + \sum_{j \neq i} \beta_j P_{ij}$$

Morrissey's idea is that the extended selection gradient, η , is the *total selection* on a trait that is directly connected through its *causal* connections (as opposed to correlations) with w . For a given causal structure (path diagram), suppose we let $\beta_{pa,i}$ denote the selection gradient for the direct effect of a trait on fitness (i.e., for the single-arrow path $i \rightarrow w$). Likewise, let Φ_{ij} be the total impact over all connecting paths of the effect of i on trait j (see Example 30.10 for details). Then, by analogy with Equation 30.3,

$$\eta_i = \beta_{pa,i} \cdot 1 + \sum_{j \neq i} \beta_{pa,j} \Phi_{ij} \quad (30.33a)$$

As with S , the extended gradient decomposes into the direct effect from a trait (the path $i \rightarrow w$) plus the indirect effects from direct selection on all other traits that are causally associated with i ($i \rightarrow \dots \rightarrow j \rightarrow w$).

One can compute the value of Φ_{ij} directly by taking the product of path coefficients for a path connecting i and j , and then summing over all such paths. However, Morrissey found a quicker approach for obtaining Φ_{ij} based on the matrix, B , of path coefficients for a given causal structure. The elements of B are constructed as follows (see below for a worked example): if $i \rightarrow j$, then B_{ij} is the path coefficient between them, while $B_{ji} = 0$ because j does not influence i . Likewise, if there is not a *direct* connection between i and

j , then $B_{ij} = 0$, even if they are causally connected though intermediates; and finally, we define $B_{ii} = 0$. With \mathbf{B} defined in this fashion, Morrissey found that the values of Φ_{ij} are calculated by

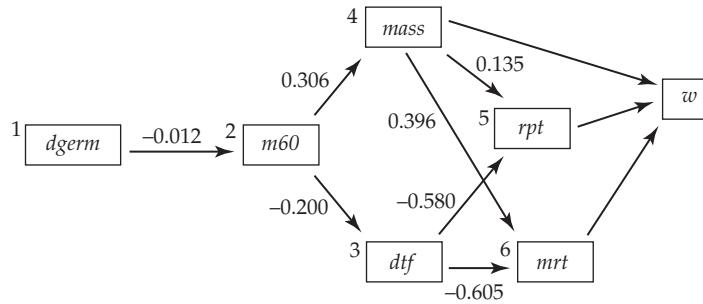

$$\boldsymbol{\Phi} = (\mathbf{I} - \mathbf{B})^{-1} \quad (30.33b)$$

From Equation 30.33a, we have

$$\boldsymbol{\eta} = \boldsymbol{\Phi} \boldsymbol{\beta}_{pa} = (\mathbf{I} - \mathbf{B})^{-1} \boldsymbol{\beta}_{pa} \quad (30.33c)$$

One very desirable feature of η_i is that if trait i has a causal effect (either direct or indirect) on fitness, then η_i is not changed by the addition (or subtraction) of new traits in the causal chain between i and w . In terms of our path 2 above ($z \rightarrow f \rightarrow w$), the value of η_z equals the value of β_z in a model where f is ignored ($z \rightarrow w$).

Example 30.10. Building on the work of Latta and McCain (2009), Morrissey (2014a) examined the relationship between a number of traits in wild oats (*Avena barbata*) and fitness, w (measured by number of reproductive spikes), using the following assumed causality structure. The values above the arrows are correlation coefficients, while the numbers 1 through 6 index the traits in the \mathbf{B} matrix (as detailed below).

The six traits considered were days at germination ($dgerm$), mass at day 60 ($m60$), days to first flower (dtf), final total mass ($mass$), number of reproductive tillers (rpt), and mass of reproductive tillers (mrt). The (variance-standardized) directional selection gradients under Lande-Arnold ($\boldsymbol{\beta}_{LA}$, which is a multiple regression of w using all six traits) and under the path model ($\boldsymbol{\beta}_{pa}$) are quite different, which shows the impact of the assumed causal structure among the traits and with fitness:

$$\boldsymbol{\beta} = \begin{pmatrix} \beta_{dgerm} \\ \beta_{m60} \\ \beta_{dtf} \\ \beta_{mass} \\ \beta_{rpt} \\ \beta_{mrt} \end{pmatrix}, \quad \text{where } \boldsymbol{\beta}_{LA} = \begin{pmatrix} 0.009 \\ 0.004 \\ -0.040 \\ -0.028 \\ 0.142 \\ 0.207 \end{pmatrix}, \quad \boldsymbol{\beta}_{pa} = \begin{pmatrix} 0 \\ 0 \\ 0 \\ -0.033 \\ 0.157 \\ 0.207 \end{pmatrix}$$

Note that only $mass$, rpt , and mrt directly impact fitness under the assumed path model.

The resulting matrix, \mathbf{B} , of path coefficients is constructed as follows. The first row corresponds to those traits that are directly influenced by trait 1 ($dgerm$), which is only trait 2 ($m60$), as all the other entries are zero. The second row involves those traits that are directly influenced by trait 2, which are only traits 3 and 4, as all the other entries are zero. Continuing in this fashion, and noting that traits 5 and 6 influence no traits in the diagram (we are not considering w), yields

$$\mathbf{B} = \begin{pmatrix} 0 & -0.012 & 0 & 0 & 0 & 0 \\ 0 & 0 & -0.200 & 0.306 & 0 & 0 \\ 0 & 0 & 0 & 0 & -0.580 & -0.605 \\ 0 & 0 & 0 & 0 & 0.135 & 0.396 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}$$

which in turn yields

$$\Phi = (\mathbf{I} - \mathbf{B})^{-1} = \begin{pmatrix} 1 & -0.012 & 0.0240 & -0.0037 & -0.0018 & -0.0029 \\ 0 & 1 & -0.2000 & 0.3060 & 0.1573 & 0.2422 \\ 0 & 0 & 1 & 0 & -0.5800 & -0.6050 \\ 0 & 0 & 0 & 1 & 0.1350 & 0.3960 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix}$$

To see that \mathbf{B} recovers the correct values of the Φ_{ij} , we compute a few of these elements by hand. The elements in the first row of Φ correspond to the total causal effects from trait 1 (*dgerm*), which is -0.12 on trait 2 (*m60*), and $-0.012 \cdot 0.306 = -0.0037$ for trait 4 ($1 \rightarrow 2 \rightarrow 4$). A more complicated case is the causal connection of trait 1 on trait 5, as there are two paths, $1 \rightarrow 2 \rightarrow 4 \rightarrow 5$ and $1 \rightarrow 2 \rightarrow 3 \rightarrow 5$, for a total of $[-0.012 \cdot 0.306 \cdot 0.135] + [-0.012 \cdot (-0.200) \cdot (-0.580)] = -0.0018$.

Using Φ , the resulting vector of extended gradients becomes

$$\boldsymbol{\eta} = \begin{pmatrix} \eta_{dgerm} \\ \eta_{m60} \\ \eta_{dtf} \\ \eta_{mass} \\ \eta_{rpt} \\ \eta_{mrt} \end{pmatrix} = \Phi \boldsymbol{\beta}_{path} = \Phi \begin{pmatrix} 0 \\ 0 \\ 0 \\ -0.033 \\ 0.157 \\ 0.207 \end{pmatrix} = \begin{pmatrix} -0.001 \\ 0.065 \\ -0.216 \\ 0.070 \\ 0.157 \\ 0.207 \end{pmatrix}$$

The extended gradient ($\boldsymbol{\eta}$) gives the total amount of selection on each trait caused by all the paths that are causally connected to that trait. The values for *mrt* and *rpt* are the same as their β_{pa} values, as both of these traits have only a direct effect on fitness. Now consider the difference between β_{pa} for *mass* in the path diagram (-0.033) and its η value (0.070). While the direct effect, *mass* \rightarrow *w*, is negative, the total of the causal effects from *mass*, $(\text{mass} \rightarrow w) + (\text{mass} \rightarrow rpt \rightarrow w) + (\text{mass} \rightarrow mrt \rightarrow w)$, is

$$-0.033 + (0.135 \cdot 0.157) + (0.396 \cdot 0.207) = 0.070$$

which is positive and larger in magnitude than the direct negative effect.

Selection on Latent Variables

Another application of path analysis arises when unmeasured traits that are under selection influence measured traits (Maddox and Antonovics 1983; Crespi and Bookstein 1988; Crespi 1990; Pugesek and Tomer 1996). This bane of a regression analysis can, *potentially*, be partly addressed with path analysis. Further, many of the measured traits may be highly correlated, raising issues of high collinearity (and instability in regression estimates). If this correlation structure is in large part due to one, or a few, underlying latent variables, then by focusing on these underlying variables, this problem may largely disappear.

For example, one common concern is that apparent selection on morphological traits may simply be a reflection of general selection on size (Figure 30.15). To this end, Crespi and Bookstein (1989) and Crespi (1990) suggested first extracting the leading principal component (PC 1) associated with the covariance matrix of the measured traits, which typically returns a generalized measure of size. Crespi and Bookstein then considered the univariate correlation of fitness of each size-adjusted trait, ignoring any further details about their correlation structure once size is removed.

Care must be taken, however, when the traits show any allometry (growth pattern) other than **isometric growth** (shape is independent of size; see LW Chapter 11). In such cases, PC 1 can contain both size *and* shape information. Jolicoeur (1963) and Somers (1986) suggested extracting PC 1 from the *correlation* matrix (as opposed to the covariance matrix)

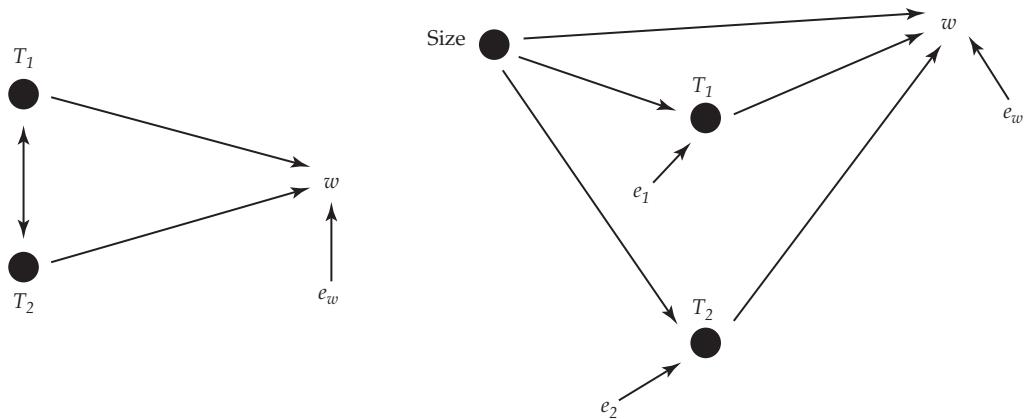

Figure 30.15 Morphological traits T_1 and T_2 being examined for their effects on fitness, w . **Left:** Under a standard Lande-Arnold regression, we allow for direct effects of both traits on fitness (w) as well as for indirect effects from correlations between these two traits (double-headed arrow). Here, e_w represents the additional variance in fitness that is not accounted for by the paths through T_1 and T_2 . **Right:** Suppose size influences both traits as well as fitness. When we ignore size, it is possible that the correlation between trait value and fitness arises because the trait is serving as a surrogate for size. Because this is a missing trait (size was not included in the analysis), this effect would not be detected by a Lande-Arnold regression. However, by extracting a surrogate measure for size (such as PC 1) from the data, we can include it in the analysis. The path diagram allows for direct paths between size and fitness, and between both traits and fitness, after size effects have been removed ($T_1 \rightarrow w$, $T_2 \rightarrow w$).

for log-transformed traits. When isometric growth is present, the eigenvector corresponding to this first PC should have all traits weighted equally (Jolicoeur 1963), with (for n traits) each element in the vector being $1/\sqrt{n}$. This provides a check of whether the assumption of isometric growth is appropriate. Similarly, the latent trait could be some measure of performance (Arnold 1983b, 1988) that selection acts directly upon and that is influenced by the measured traits (Chapter 29).

Elasticity Path Diagrams

As we have seen, even very complex life histories can be represented as graphs (Figures 29.12 and 30.14). The impact of small demographic changes in the resulting transition matrix (or **projection matrix**) associated with this graph is measured by the elasticities of the elements in this matrix with respect to their impact on the population growth rate, λ (Chapter 29; Caswell 1989, 2001). If an element in the projection matrix has an elasticity of e , then a proportional change of f in that element results in a proportional change of $f \cdot e$ in λ (Equation 29.4b). Changes in elements with larger elasticities have a proportionally greater impact on λ . For example, recall that Sæther and Bakke (2000) found average elasticity values in birds of 0.6 and 0.25 for viability and fecundity, respectively, which showed that changes in viability result in a much greater proportional change in the growth rate.

Conner (1996) suggested that path analysis can be used to connect traits, their impact on fitness components, and the impact of those fitness components on the population growth rate, λ (namely, how changing the mean of a trait alters the mean population growth rate). In a traditional path-analysis setting, such an analysis would return correlations between these various elements (e.g., Example 30.8; Figure 30.14), and while these correlations have a straightforward biological interpretation, they are disconnected from our standard metric of selection gradients and population growth. In a classic (but often underappreciated) paper, van Tienderen (2000) showed that using elasticities in place of path coefficients (an **elasticity path analysis**, or **elastogram**) connects trait selection, fitness components, and the population growth rate. Equation 29.33f describes the elasticity of a trait on λ as the sum over all

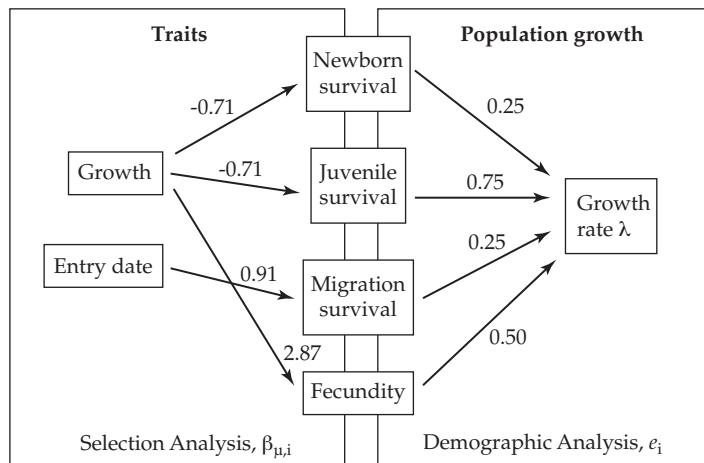

Figure 30.16 An example of the use of elastograms for problems arising in fishery management, showing an elastogram connecting two traits, annual juvenile growth rate and date of entry of a migrating individual into a river, with four fitness components influencing the population growth rate, λ . The impact of traits on the fitness components is assessed through their mean-standardized selection gradients ($\beta_{\mu,i}$) on each fitness component, while a matrix projection model was constructed to obtain the elasticities (e_i) of these fitness components on λ . Details are presented in Example 30.11. (After Matsumura et al. 2012.)

fitness components of the product of its mean-standardized gradient ($\beta_{\mu,i}$) for fitness component, W_i , times the elasticity, $e_i = \partial \ln(\lambda) / \partial \ln(W_i)$, of that component on λ ,

$$\frac{\partial \ln(\lambda)}{\partial \ln(\mu)} = \sum_{i=1} \frac{\partial \ln(\lambda)}{\partial \ln(W_i)} \frac{\partial \ln(W_i)}{\partial \ln(\mu)} = \sum_{i=1} e_i \beta_{\mu,i} \quad (30.34)$$

Example 30.11 and Figure 30.16 show the power of this approach, and a detailed example is given by Coulson et al. (2003).

Example 30.11. Matsumura et al. (2012) simulated a model examining the impact of traits on the success of spawning migrations of salmon. Two traits of interest were the annual juvenile growth rate and the date of river entry for migrating individuals. Three survival measures (newborn, juvenile, and migration) as well as fecundity were taken as the fitness components. The impact of a trait on each of these components was measured by mean-standardized selection gradients, which correspond to elasticities of these components with respect to the trait (Equation 29.33e). Likewise, a demographic analysis using a population projection matrix (Chapter 29) evaluated the elasticities of these fitness components with respect to the population growth rate λ (see their paper for details). Figure 30.16 presents the resulting elastogram. Consider the impact of entry date on λ . This trait impacts a single fitness component (migration survival) with an elasticity (mean-standardized gradient, $\beta_{\mu,i}$) of 0.91, and migration survival has an elasticity (e_i) of 0.25 on λ , yielding (from Equation 30.34) an elasticity on λ as a function of this trait of $0.91 \cdot 0.25 = 0.23$. Hence, a 10% increase in mean entry date yields a 2.3% increase in the population growth rate. The second trait, juvenile growth rate, has significant effects on three fitness components. Its elasticity on λ through newborn survival is $-0.71 \cdot 0.25 = -0.18$; through juvenile survival is $-0.71 \cdot 0.75 = -0.53$, and through fecundity is $2.87 \cdot 0.50 = 1.44$; for a total elasticity (through all fitness components) of $-0.18 - 0.53 + 1.44 = 0.725$. Thus, a 10% increase in mean juvenile growth rate results in a 7.3% increase in λ , mainly through its impact on fecundity (a 14% increase) and despite decreases of 1.8% and 5.3% in newborn and juvenile survival, respectively.

LEVELS OF SELECTION

Finally, while our focus (thus far) has been on predicting fitness given the phenotype of an *individual*, it is also possible that selection acts at levels above the individual, e.g., through **group-level effects** (Chapter 22). For example, Breden and Wade (1989) found that increasing larval group size in the imported willow leaf beetle (*Plagiodera versicolora*) increases individual survivorship, with each additional group member increasing fitness by ~7%. Here, we briefly examine the analysis of selection at multiple levels. While one can use Price's equation to decompose the selection differential of a trait into within-group and among-group components, as we will show, this can be misleading. Akin to the fact that selection differentials are unreliable indicators of the targets of selection when traits are correlated, this is also the case when the traits have selective impacts at both the individual and group levels. As above, the amount of direct selection on a trait at a specific level of selection can be determined by using the appropriate multiple regression.

Contextual Analysis

Heisler and Damuth (1987) proposed that any effects of selection acting at some level above that of the individual can be estimated with the method of **contextual analysis**, which is widely used in the social sciences (e.g., Boyd and Iversen 1979). This regression-based approach amounts to simply adding group-level traits to a Lande-Arnold regression. Traits scored at the level of groups can be **aggregate characters** (simple functions of the individual phenotypes within a group, such as the group mean), or they can be **global** or **emergent characters** that can only be defined at the group level (such as number of group members or group density). As the following example illustrates, incorporating group-level traits into the Lande-Arnold fitness regression is straightforward.

Example 30.12. Aspi et al. (2003) examined the effects of selection on the riparian plant *Silene tatarica*, a threatened species from Finland in the family Caryophyllaceae. Plants tend to grow in patches and the authors envisioned that plant density within a patch might influence both pollinator visits and herbivory. The individual traits measured were plant height (z_1) and number of stems (z_2), while two aggregate traits were measured (the means \bar{z}_1 and \bar{z}_2 of each trait for the patch) along with the group-level trait of plant density, d . The resulting regression model for predicting the relative fitness of individual j in patch i becomes

$$w_{ij} = 1 + \beta_1 z_{1,ij} + \beta_2 z_{2,ij} + \beta_3 \bar{z}_{1,i} + \beta_4 \bar{z}_{2,i} + \beta_5 d_i + e_{ij}$$

The regression coefficients β_1 and β_2 correspond to direct selection on individual trait values, while β_3 and β_4 correspond to direct selection on the patch mean of each trait, and β_5 to direct selection on the density within a patch. Aspi et al. variance-standardized all variables, so a one standard deviation change in the variable of interest results in an expected change of β in fitness. For data collected in 1999, the estimated regression coefficients for a sample of 922 individuals were

	Height	Mean height	Stem No.	Mean stem No.	Density
β	0.589***	0.653***	0.187**	-0.209***	0.631***

All of the β were significant, with ** denoting $p < 0.01$ and *** denoting $p < 0.001$. Note that (on a standardized scale) selection on group density is as strong as individual selection. Selection on height at the individual and group levels was in the same direction, which the authors suggested was due to pollinator attraction. However, selection on stems was in opposite directions, with individual selection increasing the number of stems, but patch-level selection decreasing them. The authors suggested that patch-level selection may be due to herbivory by reindeer.

A contextual analysis need not stop at two levels, as this approach easily extends to additional hierarchical levels of population organization, and hence allows for the potential for selection at these higher levels as well. Indeed, in some settings the individual level is ignored, and only higher levels of organization are contrasted. One example of this involves the work of Banschbach and Herbers (1996), who compared selection on nest- versus colony-level traits in a forest ant (*Myrmica punctiventris*), and found that fertility selection largely operates at the level of the nest, as opposed to the level of multiple-nest colonies.

In many settings, group composition is fairly obvious, due to a patchy distribution of individuals in space. However, in some situations, the appropriate set of individuals to include in a group is unclear. Indeed, for populations where individuals appear to be continuously distributed in space with few obvious breaks, group-level effects may be present when very close individuals are included yet largely disappear as the defined group becomes larger. In theory, one could assign different group sizes and use model-selection approaches to determine the group structure that gives the best fit of the fitness regression. However, care must be taken to distinguish a statistical fit from biological reality. A very reasonable biological definition of a group was offered by Uyenonyama and Feldman (1981), namely, the set of all individuals that influence the fitness of a focal individual.

An alternative to using group means is to model neighbor interactions that influence fitness (e.g., Equation 22.59a). In such cases, the fitness of a focal individual, i , can be written (for a single trait) as

$$w_i = 1 + \beta_1 z_i + \beta_2 \left(\sum_{j \neq i} z_j \right) + e_i \quad (30.35a)$$

Note that under this model, the group mean (which contains the value of the focal individual) is replaced by the interactions caused by the neighbors of the focal individual (the members in the sum). This model is easily connected to the model using the standard selection on group model by noting that

$$\sum_{j \neq i} z_j = n\bar{z} - z_i$$

when i interacts with $n - 1$ neighbors. Hence, we can express Equation 30.35a as

$$\begin{aligned} w_i &= 1 + \beta_1 z_i + \beta_2 \left(n\bar{z} - z_i \right) + e_i \\ &= 1 + (\beta_1 - \beta_2) z_i + \beta_2 n\bar{z} + e_i \end{aligned} \quad (30.35b)$$

The subtle distinction between the group-mean (Equation 30.35b) and neighborhood-fitness (Equation 30.35a) models is apparent in the case where only the neighbors influence the fitness of an individual. In this case, $\beta_1 = 0, \beta_2 \neq 0$, so that in the neighborhood-fitness model there is no weight on individual value. However, if a group-mean fitness model is fitted to these same data, there will be a nonzero regression slope on individual fitness (a value of $-\beta_2$), reflecting the input of an individual's value to its group mean. One could also weight the interactions in Equation 30.30a, for example, by replacing z_j with $f_{ij}z_j$, where f_{ij} is some measure of the amount of interaction between i and j , such as distance between plants or fraction of time observed interacting (Chapter 22).

Selection Can Be Antagonistic Across Levels

When selection is operating at both the individual and group levels, there is no a priori reason why its direction should be the same at the two levels. When the direction is the same and group-level effects are ignored, the effects of individual selection are overestimated. The more interesting case is that in which individual and group-level selection are **antagonistic**, working in opposite directions. Example 30.12 illustrates both cases: for height, selection at both levels was in the same direction, while for stem number, selection was in opposite directions at the individual and group levels. Antagonistic selection is commonly seen in the

limited number of studies that have estimated multilevel selection components, although this might, in part, be due to a bias in initially choosing traits that are expected to be under differential individual, versus group, selection pressure.

One of the first applications of contextual analysis to levels-of-selection was by Stevens et al. (1995), using jewelweed (*Impatiens capensis*). They found that an overall measure of size was selected to decrease at the group level but to increase at the individual level. This pattern was observed when fitness was taken as either survival rate to two years or as seed production in open-pollinated cleistogamous flowers. The individual and group partial regression slopes (variance-standardized over trait values) for survival rate on overall size were $\beta_I = 1.74$ and $\beta_{group} = -3.03$. Hence, group selection was stronger (and of opposite sign) than individual selection. The partial regression slopes for cleistogamus seed production on size were $\beta_I = 0.51$ and $\beta_{group} = -0.52$. Similar observations were made by Weinig et al. (2007), who used a set of recombination inbred lines (RILs) in *Arabidopsis thaliana*, and found that two composite traits (size and elongation) were favored to increase under individual selection but to decrease under group selection. For both traits, individual selection was stronger than group selection (the variance-standardized β values were roughly twice as large). A final example is a study by Tsuji (1995), who worked with the Japanese queenless ant (*Pristomyrmex pungens*), an unusual species with no queens, whose workers are able to reproduce parthenogenetically. Larger size was favored at the individual level ($\beta_I = 0.07$), but selected against at the colony level ($\beta_{group} = -0.11$).

Group Selection Is Likely Density-Dependent

A number of workers (Goodnight et al. 1992; Donohue 2003, 2004) have suggested that at low density, group selection may be weak (or essentially absent), with individual selection dominating. As group density increases, so does competition, which may increase group effects. An empirical observation from plant ecology, the **law of constant final yield** (Harper 1977; Weiner and Freckleton 2010), has been offered as support for this view (Goodnight et al. 1992). Plant ecologists have noted that the total yield of a group initially increases with low density, but after a certain critical density is reached, the total biomass of the group remains roughly constant. Even though more plants are now in the group, their individual contribution has decreased. Goodnight et al. suggested that this law results from a balance between group and individual selection. One consequence of potential *density*-dependence at the group level is that an analysis of individual selection that ignores a group selection component can be mistaken for *frequency*-dependent selection (Uyenonyama and Feldman 1980, 1981; Damuth and Heisler 1988).

Working with the Great Lake sea rocket (*Cakile edentula*), a plant in the family Brassicaceae, Donohue (2004) did indeed observe that plant density influenced the relative strengths of individual and group selection. For plant height and stem mass, she observed antagonistic individual and group selection at varying densities, with individual selection favoring smaller plants with more stem mass, and group selection favoring larger plants with less stem mass. At all densities, individual selection remained significantly stronger than group selection. Surprisingly, group selection was strongest at the intermediate, as opposed to the high, density. Weinig et al. (2007) also found a density-dependent effect in *Arabidopsis thaliana*, where the density must be above some threshold before group selection becomes important.

Selection Differentials Can Be Misleading in Levels of Selection

Price (1972a) and Wade (1985) showed how to decompose the selection differential into individual and group components. They did so by using the Robertson-Price identity (Equation 6.10), which states that the within-generation change in a trait can be written as its covariance with relative fitness, $S = \sigma(w, z)$. This also holds more generally for levels of selection. Suppose we let w_{ij} and z_{ij} denote, respectively, the fitness and phenotype of the j th individual in group i . Using the definition of the covariance, Price showed that the total selection

differential can be decomposed as

$$\sigma(z, w) = E_i[\sigma(w_{ij}, z_{ij})] + \sigma(\bar{z}_i, \bar{w}_i) \quad (30.36)$$

The first term is the covariance between individual phenotype and fitness within a group, and we take its average over all groups to obtain the within-group covariance between individual value and fitness. The second term is the covariance between the mean trait value, \bar{z}_i , and the mean fitness, \bar{w}_i , of the group. Equation 30.36 decomposes the selection differential into components from individual effects within groups and components from group effects.

Motivated by Equation 30.36, Price suggested that group selection implies a nonzero covariance between the mean trait value and mean fitness of groups, namely, $\sigma(\bar{z}_i, \bar{w}_i) \neq 0$. Under this definition, group selection cannot occur if there are no among-group differences in mean fitness. While this sounds reasonable, as we will see shortly, there are indeed situations where each group has the same mean fitness but there is still selection on the group means. Hence, group selection can occur even when the covariance between mean trait value and mean fitness is zero. Likewise, even when there is selection only on individual phenotypes, if group means differ, then (as we will show shortly) one can easily get a nonzero value for $\sigma(\bar{z}_i, \bar{w}_i)$.

Hence, this **covariance definition** (a nonzero group selection differential) for group selection is misleading, as one can have a group selection differential of zero when group selection *is* occurring, and a nonzero group selection differential when it *is not*. The root cause of this is a familiar problem: selection on phenotypically correlated traits can modify the selection differential of a focal trait, in the extreme showing an indirect response (nonzero S) when there is no direct selection on the trait. This also applies when considering selection differentials on group means. Indeed, by analogy to using a multiple regression to control for correlated traits, this was the motivation of Heisler and Damuth (1987; also Goodnight et al. 1992) for using contextual analysis. The partial regression coefficients in a contextual analysis control for any indirect effects of other correlated traits included *within the analysis*.

One consequence of indirect effects generating nonzero covariances (and hence nonzero selection differentials) is that an analysis restricted to one level of selection can be misleading. For example, suppose an investigator assumes that group selection might be important, and therefore only includes group means in the analysis. For a single trait, the investigator might consider the slope of a simple (i.e., univariate) regression of mean fitness on group trait mean,

$$\bar{w}_i = 1 + \beta \bar{z}_i + e_i \quad (30.37a)$$

If we recall (LW Chapter 3) that the slope of a univariate regression is the covariance divided by variance of the predictor variable, the slope becomes

$$\beta = \frac{\sigma(\bar{z}_i, \bar{w}_i)}{\sigma^2(\bar{z}_i)} \quad (30.37b)$$

Hence, a nonzero covariance implies a nonzero slope, and an investigator using this simple univariate regression would conclude that group selection is occurring on this trait. In reality, as we will see shortly, strict individual selection can generate a group-level covariance, and hence (in this case), a spurious assignment of a group-level effect to selection. By using a multiple regression that includes both individual and group mean values, a contextual analysis corrects for this concern (provided selection is limited to only these two levels).

Example 30.13. Recall the previous example, discussing the work of Aspi et al. (2003), who applied contextual analysis to height and stem number in *Silene tatarica*. They reported the within- and among-patch selection differentials as

Trait	Within-patch S	Among-patch S
Height	0.485***	0.025 ns
Stem number	0.855***	-0.006 ns

The use of selection differentials correctly determined the presence of positive directional selection on both individual height and stem number. However, the analysis also suggested that there were no among-patch effects (no selection on patch means), when in fact contextual analysis shows that these effects are highly significant for both traits (Example 30.12).

Hard, Soft, and Group Selection: A Contextual Analysis Viewpoint

Evolutionary biology has had an unfortunate history of, at times, being constrained by thinking about complex evolutionary processes in terms of simple catch phrases. We have seen examples of this with kin versus group selection, showing in Chapter 22 that these are special cases of the more general problem of selection with interacting individuals. Likewise, in this (and the previous) chapter, we have seen that the widely used terms of stabilizing and disruptive selection are special cases of the more general situation of a quadratic term (curvature) in the individual fitness surface. It should therefore not be surprising that there is some confusion with the exact meaning of group selection in the more general context of multilevel selection (reviewed by Okasha 2004, 2006). In the Price covariance framework, group selection is indicated by a nonzero covariance between the mean fitness and the mean trait value of a group, $\sigma(\bar{z}_i, \bar{w}_i) \neq 0$. This line of reasoning implies that across groups there must be variance in mean fitness, $\sigma^2(\bar{w}_i) \neq 0$, for group selection to exist. However, as stressed by Goodnight et al. (1992; Goodnight 2013, 2015), these covariance conditions for defining group selection are misleading. One can have group selection in the absence of variance in mean fitness across groups, and likewise, strict individual selection can still generate a covariance between group mean fitness and group mean trait value.

Just as the more general framework of selection in interacting populations removes much of the historical confusion between group selection and kin selection (Chapter 22), multilevel selection removes much of the confusion over whether group selection is occurring. Under multilevel selection, we simply have the fact that the fitness of a focal individual is influenced by other individuals, and hence selection has both individual and group components. The latter are very clearly defined by nonzero regression coefficients on group traits in a contextual analysis. As succinctly stated by Goodnight et al. (1992), “with contextual analysis, whether selection is acting at a particular level becomes a statistical rather than a philosophical question.”

Wallace’s (1968, 1976) distinction between hard and soft selection serves to highlight the differences between the covariance and multiple-regression definitions of group selection (Goodnight et al. 1992). **Hard selection** occurs when the fitness of a focal individual is solely determined by its phenotype and is unaffected by any group members. This results in the mean fitness of groups differing, with some groups leaving more offspring than others, as by chance, some groups are comprised of more fit individuals than others. Conversely, **soft selection** occurs when each group contributes equally to the next generation, which means that group mean fitness is a constant and there is no variance in mean fitness among groups. The law of constant yield is an example of soft selection, with fitness (number of seeds) being largely independent of patch density. Figure 30.17 shows the different consequences of hard, soft, and (strict) group selection on the within- and among-group regressions of phenotype on fitness.

As summarized in Table 30.2, hard, soft, and strict group selection can all be modeled as special cases of a contextual analysis regression. For simplicity, we focus on a single trait, and the resulting regression has the form

$$w_{ij} = 1 + \beta_1 z_{ij} + \beta_2 \bar{z}_i + e_{ij} \quad (30.38a)$$

We can also rewrite this regression in terms of selection on the within-group deviation plus selection on the group means,

$$w_{ij} = 1 + \beta_1^* (z_{ij} - \bar{z}_i) + \beta_2^* \bar{z}_i + e_{ij} \quad (30.38b)$$

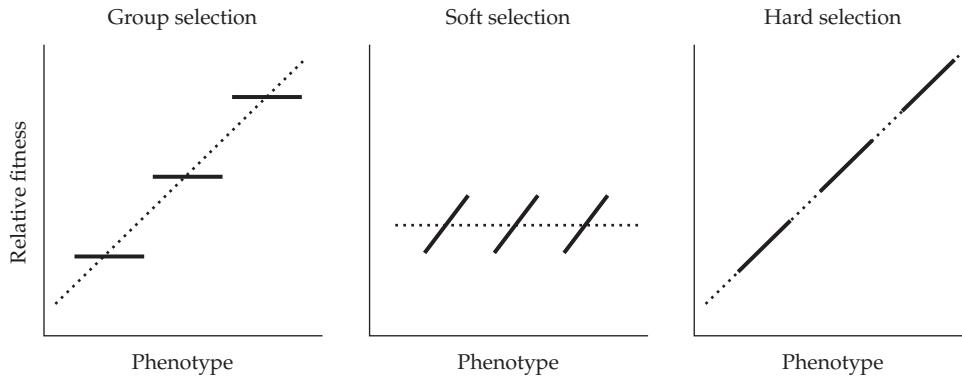

Figure 30.17 The regression of fitness on trait value within each group (solid line) and between the group means (dotted line). Under strict group selection (**left**), an individual's phenotypic value within a group has no predictive value on fitness (a within-group regression slope of zero), while the regression of fitness on group means is positive (a nonzero regression of individual fitness on group mean). Under soft selection (**center**), fitness is entirely determined by the within-group deviation. The result is a significant within-group regression but no among-group regression. Finally, under hard selection (**right**), fitness is entirely a function of phenotype, so that both the within-group and among-group regressions have the same slope (solid lines embedded with the dotted line with the same slope). (After Goodnight et al. 1992.)

Table 30.2 Hard, soft, and strict group selection can all be expressed as special cases of a more general contextual analysis. Model 1 presents the contextual regression coefficients (Equation 30.38a) on individual value (z_{ij}) and group mean (\bar{z}_i). Model 2 presents the regression coefficients when the contextual analysis is framed in terms of within-group deviations and group means (Equation 30.38b). To contrast these results with those from the covariance criteria for group selection, the table also shows whether the type of selection results in a nonzero within-group (S_w) or among-group (S_b) selection differential and whether the among-group variance in mean fitness, $\sigma^2(\bar{w}_i)$, is nonzero.

Selection	Model 1		Model 2		$S_w \neq 0$	$S_b \neq 0$	$\sigma^2(\bar{w}_i) > 0$
	z_{ij}	\bar{z}_i	$(z_{ij} - \bar{z}_i)$	\bar{z}_i			
Hard	β	0	β	β	Yes	Yes	Yes
Soft	β	$-\beta$	β	0	Yes	No	No
Strict group	0	β	0	β	Yes	Yes	Yes

We use β_i^* to stress to the reader that the regression coefficients in Equation 30.38b can differ from those in Equation 30.38a. To see the connection, note that

$$w_{ij} = 1 + \beta_1^* z_{ij} + (\beta_2^* - \beta_1^*) \bar{z}_i + e_{ij} \quad (30.38c)$$

showing that β_1 is the same under both models ($\beta_1 = \beta_1^*$), while $\beta_2 = \beta_2^* - \beta_1^*$.

Hard selection occurs when selection is entirely on individual value, so that $\beta_2 = 0$ and hence there is no group component to multilevel selection. However, by chance, some groups will have more high-fitness individuals than others. This generates variance in group mean fitness and a nonzero covariance between group-mean trait values and mean fitness (Goodnight et al. 1992). Under this covariance criteria, one would infer group selection, even though it is absent. Here, a nonzero among-group selection differential arises as a correlated response to direct selection on individual value. In this simple case, the contextual analysis clearly shows no multilevel selection, but a simple univariate regression might suggest otherwise (e.g., Equation 30.37a).

The opposite conclusion arises with soft selection. Here selection is entirely based on within-group deviations (such as within-family selection; Chapter 21). Hence, $\beta_1 = -\beta_2$ as

the regression of fitness becomes

$$\begin{aligned} w_{ij} &= 1 + \beta(z_{ij} - \bar{z}_i) + e_{ij} \\ &= 1 + \beta z_{ij} - \beta \bar{z}_i + e_{ij} \end{aligned} \quad (30.39a)$$

Under soft selection, there is no variation in mean fitness across groups and $\sigma(\bar{z}_i, \bar{w}_i) = 0$. Hence, under Price's covariance definition, one might infer that there was no group selection. However, there is clearly multilevel selection occurring, as $\beta_2 \neq 0$ (cf. Equation 30.38a and Equation 30.39a). The lack of among-group variance in fitness shows that the effects of individual selection at the group level are exactly countered by selection at the group level.

Finally, consider strict group selection, when an individual's fitness is entirely a function of its group mean,

$$w_{ij} = 1 + \beta \bar{z}_i + e_{ij} \quad (30.39b)$$

while written here as a univariate regression, formally we have $\beta_1 = 0$ if the regression given by Equation 30.38a is fitted. If one simply fits an individual selection model ($w_{ij} = 1 + \beta z_{ij} + e_{ij}$), there is a nonzero regression slope if group effects are ignored, and hence $E_i[\sigma(w_{ij}, z_{ij})] \neq 0$ (Goodnight et al 1992). Again this occurs because individual value and group mean are correlated, as $\sigma(z_{ij}, \bar{z}_i) = \sigma_z^2/n$ (plus addition terms if group members are correlated; see Equation 22.25b). Hence, direct selection on one results in indirect selection (and hence a covariance) in the other. With contextual analysis, we reach the correct conclusion of selection only on group values.

Early Survival: Offspring or Maternal Fitness Component?

As mentioned in Chapters 15 and 22, a classic example of a levels-of-selection problem is maternal care, wherein features of both the mother and offspring may influence offspring survival. An area of some contention, especially among biologists working with species that display extensive maternal care (i.e., ornithologists and mammalogists), is whether the fitness associated with early survival should be assigned to the mother (acknowledging her maternal performance) or to the offspring (acknowledging features of their own that enhance survival). As mentioned in Chapter 29, the fitness of a mother is often scored as the number of her offspring remaining *after* some interval of potential early offspring mortality, rather than simply the total number of offspring that she produced. For birds, the number of hatchlings, fledglings, or recruits (offspring that have mated) are used as the measure of female fitness, rather than the number of eggs. In mammals, the number of weaned offspring or recruits is often used in place of number of births. This notion of fitness crossing generations has proponents (e.g., Clutton-Brock 1988) and opponents (Arnold 1983a; Lande and Arnold 1983; Cheverud 1984b; Thomson and Hadfield 2017), in part because different questions are being asked by the two sides. The implications of assigning fitnesses of offspring to their mothers (i.e., their early survival is part of their mother's fitness), and what potential biases this may induce, were examined by Wolf and Wade (2009; also see Thomson and Hadfield 2017), whose approach we closely follow.

Suppose the true fitness (such as early offspring survival) is a function of the offspring phenotype, $z_{o(t)}$, and the value of some trait in their mother, $z_{m(t-1)}$, where t indexes the current offspring generation and $t - 1$ indexes a phenotype (in this case its mother) in the previous generation. This is an example of what Kirkpatrick and Lande (1989) called maternal selection (Chapter 15). The relative fitness of a male offspring is given by

$$w_{(t)}[\text{male}] = \alpha_{(t)} + b_m z_{m(t-1)} + b_o z_{o(t)} + \epsilon_{(t)} \quad (30.40a)$$

where b_o and b_m measure the strengths of selection on offspring value and maternal care, respectively. In female offspring, there is an additional source of potential selection, as a sex-limited maternal trait can have a cost. For example, a mother with a trait for increased

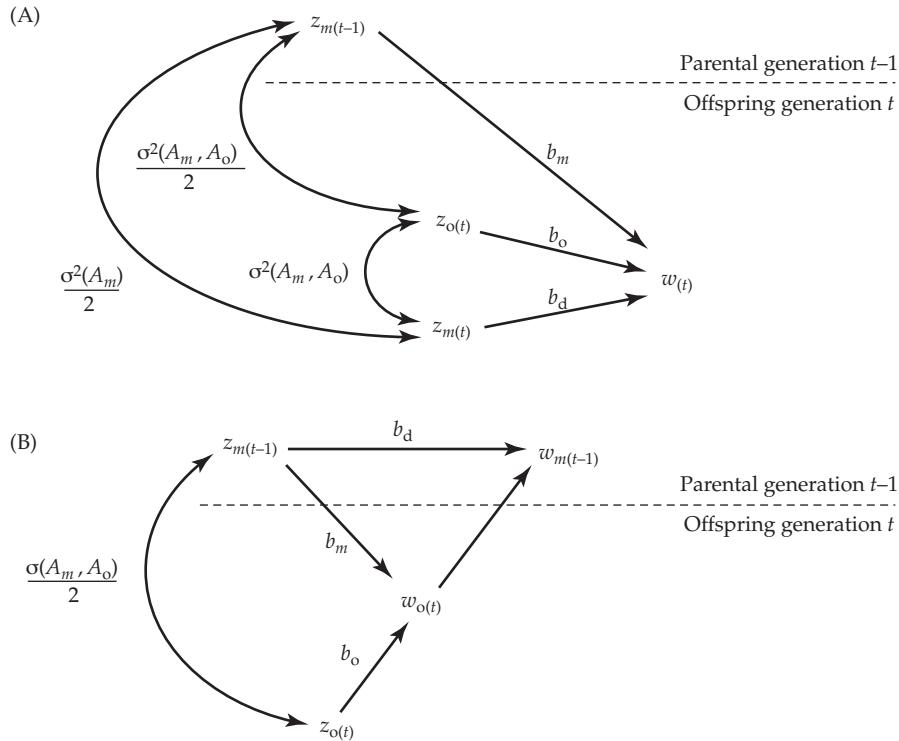

Figure 30.18 Alternate assignment of fitness, w , between an offspring and its mother. **A:** Suppose the true fitness is given by the **offspring-fitness model**. Here, the early survival of an offspring is a function of its phenotype, z_o , and the value of a maternal trait, $z_{m(t-1)}$, in its mother. The displayed path diagram is for female offspring, who have a potential extra component of fitness, as there may be a fitness cost when the offspring express the maternal trait, $z_{m(t)}$. This path through $z_{m(t)}$ is absent in males as they are assumed to not display this trait. **B:** The **mixed-fitness model**. Early offspring survival is now assigned to the mother (scoring maternal fitness as her number of fledglings or recruits). Under this model, we only follow the maternal trait value in the mother, $z_{m(t-1)}$, as opposed to the offspring-fitness model, where we also must follow the trait in the offspring, $z_{m(t)}$. As a result, there is only a single covariance (doubleheaded arrow) in the mixed-fitness model, connecting $z_{m(t-1)}$ and $z_{o(t)}$. In contrast, the offspring-fitness model (A) has two additional covariances: a cross-generational one between $z_{m(t-1)}$ and $z_{m(t)}$, and a within-generational one between $z_{m(t)}$ and $z_{o(t)}$. In (A), $z_{m(t)}$ is sex-limited and only impacts female offspring, while in both (A) and (B), all offspring have a mother and hence are impacted by $z_{m(t-1)}$. (After Wolf and Wade 2009.)

foraging enhances the survival of her offspring, but also increases her own risk of predation. Incorporating the *direct* cost (b_d) of such a trait in females yields

$$w_{(t)}[\text{female}] = \alpha_{(t)} + b_m z_{m(t-1)} + b_d z_{m(t)} + b_o z_{o(t)} + \epsilon_{(t)} \quad (30.40b)$$

Figure 30.18A presents the path diagram for this fitness model. If we assume that Equations 30.40a and 30.40b represents the correct fitness model, the selection differential, S_m , on the maternal trait value, z_m , can be computed from the Robertson-Price identity (Equation 6.10). Because $w(t)$ depends on whether the offspring is male or female, we let δ_f be a zero (for male) or one (for female) indicator variable. Equations 30.40a, 30.40b and 6.10 yield

$$\begin{aligned} S_m(\text{off}) &= \sigma(w_{(t)}, z_{m(t)}) \\ &= \sigma(b_m z_{m(t-1)} + \delta_f b_d z_{m(t)} + b_o z_{o(t)}, z_{m(t)}) \\ &= b_m \sigma(z_{m(t-1)}, z_{m(t)}) + \delta_f b_d \sigma(z_{m(t)}, z_{m(t)}) + b_o \sigma(z_{o(t)}, z_{m(t)}) \end{aligned} \quad (30.40c)$$

Because the total differential is the weighted average over both sexes (Equation 13.5),

$$\begin{aligned} S_m(\text{off}) &= b_m \sigma(z_{m(t-1)}, z_{m(t)}) + \frac{b_d}{2} \sigma(z_{m(t)}, z_{m(t)}) + b_o \sigma(z_{o(t)}, z_{m(t)}) \\ &= \frac{b_m}{2} \sigma^2(A_m) + \frac{b_d}{2} \sigma^2(z_m) + b_o \sigma(A_m, A_o) \end{aligned} \quad (30.40\text{d})$$

This last step assumes that $\sigma(z_{o(t)}, z_{m(t)}) = \sigma(A_{o(t)} + e_{o(t)}, A_{m(t)} + e_{m(t)}) = \sigma(A_m, A_o)$, namely, that the environment effects between the maternal and direct effects are uncorrelated within an individual.

Now suppose that an investigator assumes the offspring fitness is assigned to its mother (Figure 30.18B), which Thomson and Hadfield (2017) call the **mixed-fitness model**. The mother's total fitness can be considered as the sum of two separate episodes: selection on early survival in her offspring, $w_{o(t)}$, and selection on her maternal trait, $w_{m(t-1)}$, where

$$w_{o(t)} = \alpha_{o(t)} + b_m z_{m(t-1)} + b_o z_{o(t)} + \epsilon_{(t)} \quad (30.41\text{a})$$

$$w_{m(t-1)} = \alpha_{m(t-1)} + b_d z_{m(t-1)} + \epsilon_{(t-1)} \quad (30.41\text{b})$$

giving her total fitness as

$$w_{o(t)} + w_{m(t-1)} = (\alpha_{o(t)} + \alpha_{m(t-1)}) + b_m z_{m(t-1)} + b_d z_{m(t-1)} + b_o z_{o(t)} + (\epsilon_{(t)} + \epsilon_{(t-1)}) \quad (30.41\text{c})$$

The difference between this expression (mother-assigned offspring early-viability fitness) and Equation 30.40b (offspring assigned their own fitness) is in the direct fitness of the maternal effect. This component is weighted by $b_m z_{m(t-1)}$ in Equation 30.41c (the value of the mother), and by $b_m z_{m(t)}$ in Equation 30.40b (the cost to the offspring). Following the same logic leading to Equation 30.40d, the selection differential on the maternal trait becomes

$$\begin{aligned} S_m(\text{mother}) &= \sigma(w_{o(t)} + w_{m(t-1)}, z_{m(t-1)}) \\ &= \frac{1}{2} \left[(b_m + b_d) \sigma^2(z_m) + b_o \sigma(z_{o(t)}, z_{m(t-1)}) \right] \\ &= \frac{1}{2} \left[(b_m + b_d) \sigma^2(z_m) + b_o \frac{\sigma^2(A_m, A_o)}{2} \right] \end{aligned} \quad (30.41\text{d})$$

Subtracting Equation 30.41d from Equation 30.40d yields

$$S_m(\text{mother}) - S_m(\text{off}) = \frac{b_m}{2} \left[\sigma^2(z_m) - \sigma^2(A_m) \right] - \frac{3}{4} b_o \sigma(A_m, A_o) \quad (30.42)$$

The first term shows that maternal selection is *overestimated* by assigning fitness to mothers, as only a fraction (the additive variance, $\sigma^2[A_m]$) of the total maternal trait variation, $\sigma^2(z_m)$, is passed to the offspring. The second term either reduces this overestimation or amplifies it, depending on the sign of the genetic covariance between the maternal trait and the offspring trait. Wolf and Wade (2001) stated that there is no reason to expect that these terms will largely cancel, making estimates of maternal selection when offspring fitness is assigned to mothers problematic in many cases.

Conversely, Equation 30.42 shows the conditions under which assigning fitnesses to mothers is unbiased. First, the maternal and offspring traits must be uncorrelated

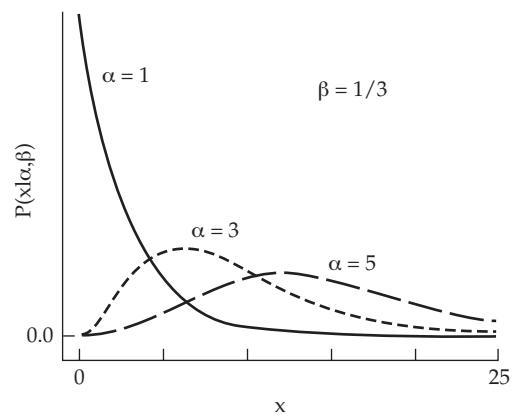

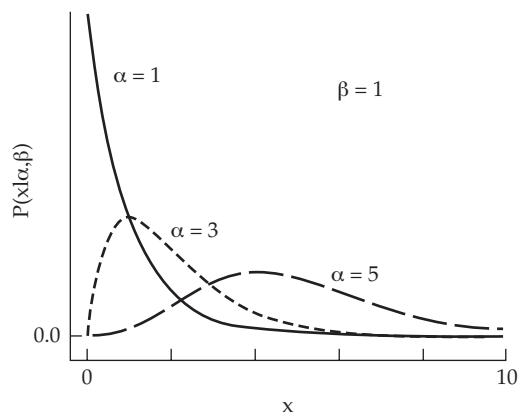

$$\sigma(z_{o(t)}, z_{m(t)}) = 0$$

implying that $\sigma(A_m, A_o) = 0$, provided that $\sigma(e_o, e_m) = 0$. Second, and more problematic, the maternal trait must have a very high heritability, such that $\sigma^2(z_m) \simeq \sigma^2(A_m)$. As a result, as Wolf and Wade (2001) suggested, assigning offspring viability as a component of offspring fitness is less biased. Thomson and Hadfield (2017) echoed this point, noting that the conditions are even more restrictive for the mixed-fitness model to be unbiased if the parental trait influencing offspring fitness (upon which selection against the parent can occur) is not sex-limited. They also note that roughly 40% of fecundity estimates in the literature (mainly from birds and mammals) are based on mixed-fitness estimates (namely, weighted by some concept of offspring survival).

Both sets of authors pointed out that unless a fitness regression of the form given by Equation 30.40b is used, the levels-of-selection impact from a parent can easily be missed. Unfortunately, this requires one to either know, or at least have a good idea of, the potential parental traits that impact offspring survival. By using a list of such candidate traits, one can fit regressions of this form to test which traits (if any) have a significant impact on offspring fitness.

Diffusion Theory

I believe that no one who is familiar, either with mathematical advances in other fields, or with the range of special biological conditions to be considered, would ever conceive that everything could be summed up in a single mathematical formula, however complex. Fisher (1932a)

Exact solutions of the dynamics of many random processes arising in population and quantitative genetics are either unknown or extremely cumbersome. Nevertheless, starting with Fisher (1922), Wright (1945), and Kimura (1955a, 1955b), the use of **diffusion approximations** in place of the exact dynamics of these processes has proven to be extremely powerful. Useful introductions to diffusion theory with special reference to genetics were given by Ewens (1979, 2004) and Karlin and Taylor (1981), with additional applications considered by Crow and Kimura (1970), Maruyama (1977), Kimura (1983), and Gale (1990). The goal of diffusion theory is to obtain expressions for $\varphi(x, t, p)$, the probability distribution for the random variable, x , at time t , given that the process starts at a value of p . It is often the case that for sufficiently large time, the probability distribution approaches a stationary value, $\varphi(x)$, independent of both time (t) and the starting value (p). Diffusion theory also provides approximations for a number of summary statistics of a particular process, such as probabilities and times to fixation for the various boundaries of the process (such as the loss or fixation of an allele). We will consider these issues in turn.

FOUNDATIONS OF DIFFUSION THEORY

Consider a continuous random variable, x_t , indexed by continuous time, t . If $\delta_x = x_{t+\delta_t} - x_t$ (the change in x_t over a very small time interval, δ_t) satisfies

$$E(\delta_x | x_t = x) = m(x)\delta_t + o(\delta_t) \quad (\text{A1.1a})$$

$$\sigma^2(\delta_x | x_t = x) = v(x)\delta_t + o(\delta_t) \quad (\text{A1.1b})$$

$$E(|\delta_x|^k) = o(\delta_t) \quad \text{for } k \geq 3 \quad (\text{A1.1c})$$

then x_t is said to be a **diffusion process**, provided the additional technical restriction that x_t is a **Markov process** (the transition probabilities depend only on the current value of the process and no other aspects of its history) is satisfied. The functions $m(x)$ and $v(x)$ are defined shortly, while the notation $o(\delta_t)$ means that any remaining terms are of order δ_t^2 (or higher), and hence small relative to δ_t . Formally, $\lim_{\delta_t \rightarrow 0} o(\delta_t)/\delta_t = 0$, so we can ignore terms of order δ_t^2 (or higher) when δ_t itself is very small. Likewise, the notation $O(x)$ means terms of order x , and so for example, $O(x^2) = o(x)$.

The Infinitesimal Mean, $m(x)$, and Variance, $v(x)$

The **infinitesimal mean**, $m(x)$, and **infinitesimal variance**, $v(x)$, correspond to the mean and variance of the process (given that it is at x) over a very small time interval. These are formally defined by

$$m(x) = \lim_{\delta_t \rightarrow 0} \frac{E(x_{t+\delta_t} - x_t | x_t = x)}{\delta_t} \quad (\text{A1.2a})$$

$$v(x) = \lim_{\delta_t \rightarrow 0} \frac{E[(x_{t+\delta_t} - x_t)^2 | x_t = x]}{\delta_t} \quad (\text{A1.2b})$$

In words, the diffusion assumption is that, over a very small time interval, the mean, $m(x)$, and variance, $v(x)$, around the current position, x , are sufficient to fully describe the process.

In population genetics, diffusion approximations provide an elegant way to rescale a discrete space, discrete time, random variable (usually an allele frequency) to construct a new, continuously distributed random variable. For example, consider X_t , the number of copies of allele A in a discrete-generation population of \bar{N} diploids at generation t . X_t takes on values of $0, 1, \dots, 2\bar{N}$, and time t is in units of discrete generations. Suppose we construct a new random variable $x_{\tau}^{(\bar{N})} = X_{(\tau)} / (2\bar{N})$, where $\tau = t/\bar{N}$. A unit of time on this transformed scale (τ) corresponds to \bar{N} generations on the original scale. If we take the limit as \bar{N} approaches infinity, the limiting process x_{τ} is a continuous space (in x), continuous time (in τ) process that represents the allele frequency at time τ .

Example A1.1. Diffusion processes for allele frequencies are typically obtained by setting $v(x) = x(1-x)/(2N_e)$ (the per-generation variance in the change of allele frequencies due to drift; see Chapter 2), where x is the frequency of allele A . This is simply binomial sampling (Equation 2.1), and it is a function of the variance effective population size, N_e (Chapter 3). The deterministic (i.e., infinite-population) change in allele frequency is subsumed in $m(x)$. Because there is no deterministic change in allele frequency under pure drift (i.e., no selection or mutation), in this case the diffusion process is simply

$$m(x) = 0 \quad \text{and} \quad v(x) = \frac{x(1-x)}{2N_e} \quad (\text{A1.3})$$

which is defined for $0 < x < 1$.

Now let us consider selection at a diallelic locus (with additive fitnesses of $1 : 1 + s : 1 + 2s$ for the genotypes aa , Aa , and AA , respectively). Recalling Equation 5.2b, in an infinite population,

$$\Delta p = \frac{sp(1-p)}{1+2sp} = sp(1-p)[1+O(s)] = sp(1-p) + o(s)$$

The last step follows because $sO(s) = O(s^2) = o(s)$. Thus, ignoring terms of order $o(s)$ yields a diffusion approximation for the joint effects of drift and selection over $0 < x < 1$ of

$$m(x) = sx(1-x) \quad \text{and} \quad v(x) = \frac{x(1-x)}{2N_e} \quad (\text{A1.4})$$

Finally, consider arbitrary selection with constant fitnesses, again with selection sufficiently weak such that $\bar{W} = 1 + O(s)$, and with forward and back mutation, where ν is the mutation rate from A to a and μ is the mutation rate from a to A . Applying Wright's formula (Equation 5.5b) and including mutation yields

$$m(x) = \frac{x(1-x)}{2} \frac{\partial \ln[\bar{W}(x)]}{\partial x} + (1-x)\mu - x\nu \quad \text{and} \quad v(x) = \frac{x(1-x)}{2N_e} \quad (\text{A1.5})$$

We apply several of these expressions below.

The Kolmogorov Forward Equation

Given $m(x)$, $v(x)$, and an initial frequency of p , the diffusion approximation for the dynamics of the probability density function for the realized value x at time t satisfies the **Kolmogorov forward equation** (or KFE)

$$\frac{\partial \varphi(x, t, p)}{\partial t} = \frac{1}{2} \frac{\partial^2 v(x) \varphi(x, t, p)}{\partial x^2} - \frac{\partial m(x) \varphi(x, t, p)}{\partial x} \quad (\text{A1.6})$$

where $\varphi(x, t, p)$ is the probability density for x at time t , given that the process starts at p , namely,

$$\Pr[c \leq x(t) \leq d | x(0) = p] = \int_c^d \varphi(x, t, p) dx$$

A derivation of the KFE is given below. When they can be found, closed-form solutions of $\varphi(x, t, p)$ are usually complicated (e.g., Example A1.2). The standard approach is to express the solution as a power series:

$$\varphi(x, t, p) = \sum_{i=1}^{\infty} f_i(x, p) e^{-\lambda_i t} \quad (\text{A1.7})$$

Here, the values of λ_i are the **eigenvalues** associated with the partial differential equation given by Equation A1.6, and the functions, f_i , are the associated **eigenfunctions**. Notice that time, t , only appears as a multiplier of the eigenvalues, while the starting position, p , appears only in the eigenfunctions. Crow and Kimura (1970) presented exact solutions of $\varphi(x, t, p)$ for a number of population-genetic problems. As the next example shows, even in the simplest case (pure drift), the result are rather complex.

Example A1.2. From Equation A1.6, the KFE for the diffusion for pure drift, $m(x) = 0$, is

$$\frac{\partial \varphi(x, t, p)}{\partial t} = \frac{1}{2} \frac{\partial^2 v(x)}{\partial x^2} \varphi(x, t, p)$$

Figure 2.4 plots solutions of this partial differential equation for several time points. As mentioned in Chapter 2, Kimura (1955b) obtained the solution for this particular KFE as

$$\varphi(x, t, p) = \sum_{i=1}^{\infty} p(1-p)i(i+1)(2i+1)g_i(p)g_i(x)e^{-\lambda_i t}$$

where

$$\lambda_i = \frac{i(i+1)}{4N_e} \quad \text{and} \quad g_i(x) = F(1-i, i+2, 2, x)$$

and where F is the hypergeometric function (Equation 15.1.1 in Abramowitz and Stegun 1972). In the notation of Equation A1.7, the eigenfunction associated with the i eigenvalue is

$$f_i(x, p) = p(1-p)i(i+1)(2i+1)F(1-i, i+2, 2, p)F(1-i, i+2, 2, x)$$

Although this solution is obtained using standard tools for the solution of partial differential equations (e.g., Farlow 1982), as one might expect given the form of the solution, this is not a trivial procedure.

While simple inspection of the above closed form solution provides only a small amount of insight into the process, it is clear that $\varphi(x, t, p) \rightarrow 0$ as $t \rightarrow \infty$ (because all $e^{-\lambda_i t} \rightarrow 0$ as $t \rightarrow \infty$). Thus, for large values of time, there is a vanishingly small probability mass in the open interval $0 < x < 1$. This occurs because drift results in an allele eventually either being fixed ($x = 1$) or being lost ($x = 0$). Other forces, such as mutation, are required for nonzero probability mass to remain in the interior space ($0 < x < 1$). For large spans of time, the solution is dominated by the first few eigenvalues. If we focus on just the eigenfunctions associated with the two leading eigenvalues, λ_1 and λ_2 , the result is

$$\varphi(x, t, p) \simeq 6p(1-p)e^{-t/(2N_e)} + 30p(1-2p)(1-2x)e^{-3t/(2N_e)}$$

Notice that the eigenfunction for the dominant eigenvalue ($1/2N_e$) is independent of x , so for large values of t , the probability density is a constant independent of x (i.e., a uniform over $0 < x < 1$), which decays to zero at a rate of $e^{-t/(2N_e)}$ (see Figure 2.4).

Boundary Behavior of a Diffusion

A critical feature of the density $\varphi(x, t, p)$ is its range of validity. Formally speaking, the diffusion approximation only applies within some *open* interval between two **boundary values**, a and b . The behavior *exactly* at the boundaries ($x = a$ and $x = b$) is beyond the realm of the approximation. In many cases, x_t does not change value once it reaches a boundary, in which case it is called **absorbing**. For example, in the absence of mutation and migration, once an allele frequency reaches either 0 or 1, it remains there, which means that both of these extreme states are absorbing boundaries. Further, a boundary is said to be **accessible** if it can be reached in finite time. When considering fixation probabilities, we are examining absorbing, accessible boundaries. Note that a finite boundary point may not be accessible. Suppose we consider a simple mutation-drift equilibrium. If the mutational pressure is sufficiently strong near a boundary (say for the loss of an allele), the resulting boundary may be **inaccessible**, with the population never being in a state where all copies of an allele are lost.

Derivation of the Kolmogorov Forward Equation

For completeness, we present a derivation of Equation A1.6, using the diffusion-approximation assumptions (Equations A1.1a–A1.1c). This section is a bit technical and can be skipped if readers desire. Consider the change from the probability distribution, $\varphi(x, t, p)$, at time t to a new distribution, $\varphi(x, t + \delta_t, p)$, after some very small time interval, δ_t . To arrive at x at time $t + \delta_t$, the frequency must have previously been at some value, $x - \delta_x$, and then moved by an amount, δ_x , over the interval δ_t . Let $\phi(\delta_x, x, \delta_t)$ be the probability of jumping by an amount, δ_x , over the time δ_t given the starting point, x . In our case, because we are assuming that there is a move from $x - \delta_x$ to x , we consider $\phi(\delta_x, x - \delta_x, \delta_t)$. Integrating over all possible jump values yields the **Chapman-Kolmogorov equation**

$$\varphi(x, t + \delta_t, p) = \int \varphi(x - \delta_x, t, p) \phi(\delta_x, x - \delta_x, \delta_t) d\delta_x \quad (\text{A1.8a})$$

To simplify notation in the following derivation, we write $\varphi(x, t, p)$ as $\varphi(x, t)$, although the dependence on the initial value p should be kept in mind.

To solve the Chapman-Kolmogorov equation, we start by using the Taylor series approximation

$$f(x - a) = f(x) - a \frac{\partial f(x)}{\partial x} + \frac{a^2}{2} \frac{\partial^2 f(x)}{\partial x^2} - \frac{a^3}{6} \frac{\partial^3 f(x)}{\partial x^3} + o(a^3)$$

Expanding the function in the integral about $a = \delta_x$ yields

$$\begin{aligned} \varphi(x - \delta_x, t) \phi(\delta_x, x - \delta_x, \delta_t) &= \varphi(x, t) \phi(\delta_x, x, \delta_t) - \delta_x \frac{\partial [\varphi(x, t) \phi(\delta_x, x, \delta_t)]}{\partial x} \\ &\quad + \frac{\delta_x^2}{2} \frac{\partial^2 [\varphi(x, t) \phi(\delta_x, x, \delta_t)]}{\partial x^2} - \frac{\delta_x^3}{6} \frac{\partial^3 [\varphi(x, t) \phi(\delta_x, x, \delta_t)]}{\partial x^3} + o(\delta_x^3) \end{aligned}$$

If we ignore terms of $o(\delta_x^3)$, i.e., of order δ_x^4 and higher, and integrate, the result is

$$\begin{aligned} \int \varphi(x - \delta_x, t) \phi(\delta_x, x - \delta_x, \delta_t) d\delta_x &\simeq \int \varphi(x, t) \phi(\delta_x, x, \delta_t) d\delta_x - \int \delta_x \frac{\partial [\varphi(x, t) \phi(\delta_x, x, \delta_t)]}{\partial x} d\delta_x \\ &\quad + \int \frac{\delta_x^2}{2} \frac{\partial^2 [\varphi(x, t) \phi(\delta_x, x, \delta_t)]}{\partial x^2} d\delta_x - \int \frac{\delta_x^3}{6} \frac{\partial^3 [\varphi(x, t) \phi(\delta_x, x, \delta_t)]}{\partial x^3} d\delta_x \end{aligned}$$

Because integration is done with respect to δ_x , partials with respect to x can be moved outside of the integrals, as can functions not involving δ_x , yielding

$$\int \varphi(x - \delta_x, t) \phi(\delta_x, x - \delta_x, \delta_t) d\delta_x = \varphi(x, t) \int \phi(\delta_x, x, \delta_t) d\delta_x - \frac{\partial}{\partial x} \left(\varphi(x, t) \int \delta_x \phi(\delta_x, x, \delta_t) d\delta_x \right)$$

$$+ \frac{1}{2} \frac{\partial^2}{\partial x^2} \left(\varphi(x, t) \int \delta_x^2 \phi(\delta_x, x, \delta_t) d\delta_x \right) - \frac{1}{6} \frac{\partial^3}{\partial x^3} \left(\varphi(x, t) \int \delta_x^3 \phi(\delta_x, x, \delta_t) d\delta_x \right) \quad (\text{A1.8b})$$

Because $\phi(\delta_x, x, \delta_t)$ is the probability distribution of moves of size δ_x over the time interval δ_t given we start at position x , we have

$$\int \phi(\delta_x, x, \delta_t) d\delta_x = 1 \quad (\text{A1.8c})$$

$$\int \delta_x \phi(\delta_x, x, \delta_t) d\delta_x = E(\delta_x | x_t = x) = m(x)\delta_t + o(\delta_t) \quad (\text{A1.8d})$$

The first identity follows from the fact that the integral over a probability distribution is equal to one, and the second is simply our first diffusion assumption (Equation A1.1a). Next, if we recall that $E(x^2) = \sigma_x^2 + [E(x)]^2$, we have

$$\int \delta_x^2 \phi(\delta_x, x, \delta_t) d\delta_x = \sigma_x^2 + [E(\delta_x)]^2$$

which, using the diffusion approximation (Equations A1.1a and A1.1b), reduces to

$$\begin{aligned} \int \delta_x^2 \phi(\delta_x, x, \delta_t) d\delta_x &= [v(x)\delta_t + o(\delta_t)] + [m(x)\delta_t + o(\delta_t)]^2 \\ &= v(x)\delta_t + o(\delta_t) \end{aligned} \quad (\text{A1.8e})$$

The last step follows because the contribution from the squared change in the mean is $o(\delta_t)$, and we sweep all such terms into a single expression. Finally, under the diffusion assumption given by Equation A1.1c, moments of δ_x^3 and higher are negligible. Substituting the approximations given by Equations A1.8d and A1.8e into Equation A1.8b yields

$$\varphi(x, t + \delta_t) = \varphi(x, t) - \frac{\partial \{ [m(x)\delta_t + o(\delta_t)] \varphi(x, t) \}}{\partial x} + \frac{1}{2} \frac{\partial^2 \{ [v(x)\delta_t + o(\delta_t)] \varphi(x, t) \}}{\partial x^2} \quad (\text{A1.9})$$

Subtracting $\varphi(x, t)$ from both sides, dividing both by δ_t , and taking the limit at $\delta_t \rightarrow 0$ gives the left-hand side as

$$\lim_{\delta_t \rightarrow 0} \frac{\varphi(x, t + \delta_t) - \varphi(x, t)}{\delta_t} = \frac{\partial \varphi(x, t)}{\partial t}$$

Likewise, recalling that $\lim_{\delta_t \rightarrow 0} o(\delta_t)/\delta_t = 0$, the last two right-hand-side terms of Equation A1.9 simplify to

$$\begin{aligned} \lim_{\delta_t \rightarrow 0} \frac{1}{\delta_t} \left(\frac{\partial \{ [m(x)\delta_t + o(\delta_t)] \varphi(x, t) \}}{\partial x} \right) &= \frac{\partial [m(x)\varphi(x, t)]}{\partial x} \\ \lim_{\delta_t \rightarrow 0} \frac{1}{\delta_t} \left(\frac{\partial^2 \{ [v(x)\delta_t + o(\delta_t)] \varphi(x, t) \}}{\partial x^2} \right) &= \frac{\partial^2 [v(x)\varphi(x, t)]}{\partial x^2} \end{aligned}$$

Together, these simplifications imply

$$\frac{\partial \varphi(x, t)}{\partial t} = - \frac{\partial [m(x)\varphi(x, t)]}{\partial x} + \frac{\partial^2 [v(x)\varphi(x, t)]}{2 \partial x^2}$$

which recovers the Kolmogorov forward equation (Equation A1.6), provided we again recall that $\varphi(x, t)$ is really $\varphi(x, t, p)$.

Stationary Distributions

At equilibrium, a probability density function does not change over time, namely,

$$\frac{\partial \varphi(x, t, p)}{\partial t} = 0 \quad (\text{A1.10a})$$

When such a function exists, it is called the **stationary distribution** and is denoted by $\varphi(x)$. Stationary distributions are independent of the starting conditions: regardless of where the process starts in the interior of the diffusion, it converges to the same distribution. Hence, $\varphi(x, t, p)$ can be decomposed into a transient deviation (dependent on t and p) and a stationary expectation (independent of both t and p), $\varphi(x, t, p) = \varphi^*(x, t, p) + \varphi(x)$. The transient deviation satisfies $\lim_{t \rightarrow \infty} \varphi^*(x, t, p) = 0$, and the deviation from the equilibrium distribution decays to zero over time.

When Equation A1.10a is satisfied, Equation A1.6 becomes

$$\frac{\partial^2 [v(x) \varphi(x)]}{2 \partial x^2} = \frac{\partial [m(x) \varphi(x)]}{\partial x} \quad (\text{A1.10b})$$

and integration of both sides reduces this to the simple differential equation,

$$\frac{\partial [v(x) \varphi(x)]}{\partial x} = 2m(x) \varphi(x) \quad (\text{A1.10c})$$

Using standard methods for differential equations (e.g., Tenenbaum and Pollard 1963) yields the solution as

$$\varphi(x) = \frac{C}{v(x) G(x)} \quad (\text{A1.11})$$

where G (which is called the **scale function** in the diffusion literature) is defined by the indefinite integral

$$G(x) = \exp \left[-2 \int^x \frac{m(y)}{v(y)} dy \right] \quad (\text{A1.12})$$

and C is a constant such that $\varphi(x)$ integrates to one, ensuring that Equation A1.11 is a proper probability density function. Stationary distributions for population-genetic processes were first obtained by Wright (1931, 1938b), who used a somewhat different approach. Note that $\int [v(x) G(x)]^{-1} dx$ may be infinite, in which case no stationary distribution exists. This happens, for example, in the absence of mutation and migration, where both boundaries (allele frequencies of 0 or 1) are absorbing.

Example A1.3. Consider the case in which random genetic drift is the only force influencing allele-frequency change. From Equation A1.3, $m(x) = 0$ and $v(x) = x(1-x)/(2N_e)$, which yields

$$G(x) = \exp \left[-4N_e \int^x \frac{0}{y(1-y)} dy \right] = e^{-4N_e 0} = 1 \quad (\text{A1.13})$$

and from Equation A1.11,

$$\varphi(x) = \frac{2N_e C}{x(1-x)} \quad (\text{A1.14})$$

The only valid equilibrium distribution is $\varphi(x) = 0$ (e.g., $C = 0$), as

$$\int_0^1 x^{-1}(1-x)^{-1} dx = \infty$$

As shown in Example A1.2, after sufficient time, and in the absence of any force to keep allele frequencies in the interior ($0 < x < 1$), all alleles eventually reach a frequency of zero or one. As a result, the equilibrium distribution on the open interval of $0 < x < 1$ is zero.

Example A1.4. Compute the stationary distribution for the frequency of an allele at a diallelic locus experiencing selection, mutation, and drift, where $\bar{W}(x)$ denotes the mean fitness as

a function of the allele frequency, x . Using the definitions of $m(x)$ and $v(x)$ from Equation A1.5,

$$\begin{aligned} \int^x \frac{m(y)}{v(y)} dy &= 2N_e \int^x \frac{y(1-y)d\ln[\overline{W}(y)]/(2dy) + (1-y)\mu - y\nu}{y(1-y)} dy \\ &= N_e \int^x \frac{d\ln[\overline{W}(y)]}{dy} dy + 2N_e\mu \int^x \frac{1}{y} dy - 2N_e\nu \int^x \frac{1}{1-y} dy \\ &= N_e \ln[\overline{W}(x)] + 2N_e\mu \ln(x) + 2N_e\nu \ln(1-x) \end{aligned}$$

Hence

$$G(x) = \exp \left[-2 \int^x \frac{m(y)}{v(y)} dy \right] = \overline{W}(x)^{-2N_e} x^{-4N_e\mu} (1-x)^{-4N_e\nu}$$

If we substitute this expression for $G(x)$ into Equation A1.11, it returns the stationary distribution as

$$\varphi(x) = C\overline{W}(x)^{2N_e} x^{4N_e\mu-1} (1-x)^{4N_e\nu-1} \quad \text{for } 0 < x < 1 \quad (\text{A1.15})$$

a result first due to Wright (1931), obtained using a different approach.

Example A1.5. A particular application of Equation A1.15 is the case of a deleterious recessive allele maintained by mutation. In an infinite population (Chapter 7), the equilibrium frequency of this allele is approximately $\sqrt{\mu/s}$ (for $s \gg \mu$), where the fitness of the recessive homozygote is $1-s$ and the mutation rate from normal to recessive allele is μ . Here, $\overline{W}(x) = 1-sx^2$, and because $(1-x)^{N_e} \simeq e^{-xN_e}$, we have

$$[\overline{W}(x)]^{2N_e} = (1-sx^2)^{2N_e} \simeq \exp(-2N_e sx^2)$$

resulting in an equilibrium distribution of

$$\varphi(x) = Ce^{-2N_e sx^2} x^{4N_e\mu-1} (1-x)^{4N_e\nu-1} \quad \text{for } 0 < x < 1$$

The Kolmogorov Backward Equation

While the KFE provides both the full solution of $\varphi(x, t, p)$ and, where appropriate, the equilibrium solution, we can obtain much simpler expressions for many quantities of interest when an equilibrium solution does not exist. For example, if one or both of the boundaries are accessible and absorbing, we can compute the fixation probabilities (the probability that the process eventually will reach a specified boundary), the time to reach that boundary (the time to loss or fixation), and the expected value of many other functions of interest. The key to all of these operations is the **Kolmogorov backward equation (KBE)**, which is given by

$$\frac{\partial \varphi(x, t, p)}{\partial t} = \frac{1}{2} v(p) \frac{\partial^2 \varphi(x, t, p)}{\partial p^2} + m(p) \frac{\partial \varphi(x, t, p)}{\partial p} \quad (\text{A1.16})$$

The KBE is derived in a manner similar to the KFE. The KBE starts at the current time, t , and looks *backwards* in terms of how changes ($\partial/\partial p$) in the initial starting value, p , are influenced by the current position, x , hence the name. Conversely, the forward equation (Equation A1.6) examines how changes ($\partial/\partial x$) in the current position, x , are influenced by the starting value, p .

DIFFUSION APPLICATIONS IN POPULATION GENETICS

When no stationary distribution exists, useful summary statistics to describe the diffusion

process are the probabilities of fixation of the various boundaries and the expected time to reach a specified boundary. We consider each in turn.

Probability of Fixation

When at least one boundary is absorbing (and accessible), no stationary distribution exists. In such cases, one important descriptor of the process is the probability of reaching one boundary before the other. One can show that the function $u(p, t)$, the probability of fixation by time t , given that we start at allele frequency p , satisfies the KBE. We are typically interested in the ultimate probability of fixation, $u(p) = \lim_{t \rightarrow \infty} u(p, t)$, in which case the partial derivative of $u(p)$ with respect to time is zero and, from Equation A1.16, $u(p)$ satisfies

$$0 = m(p) \frac{\partial u(p)}{\partial p} + \frac{1}{2} v(p) \frac{\partial^2 u(p)}{\partial p^2}$$

This has a solution of

$$u(p) = \frac{\int_0^p G(x) dx}{\int_0^1 G(x) dx} \quad (\text{A1.17a})$$

where $G(x)$ is defined by Equation A1.12 (Kimura 1962). More generally, for any diffusion (regardless of the nature of the boundaries), the probability that the process reaches a value of b before a value of a , given it starts at p (where $A < a < p < b < B$, with the diffusion defined over $A < x < B$), is

$$u_{b,a}(p) = \frac{\int_a^p G(x) dx}{\int_a^b G(x) dx} \quad (\text{A1.17b})$$

Example A1.6. Here we compute the probability of fixation of an allele under drift alone ($m(x) = 0$). In this setting $G(x) = 1$ (Equation A1.13), so Equation A1.17a reduces to

$$u(p) = \frac{\int_0^p 1 dx}{\int_0^1 1 dx} = \frac{p - 0}{1 - 0} = p$$

In other words, the fixation probability of a neutral allele is simply its starting allele frequency (Chapter 2). This result makes intuitive sense, as there is no expected net change via drift alone, and hence the expected value of the allele frequency over a large number of replicates that have gone to fixation should be p . Likewise, Equation A1.17b shows the probability of reaching frequency b before frequency a (starting at a frequency p that satisfies $0 < a < p < b < 1$) as

$$u_{b,a}(p) = \frac{p - a}{b - a}$$

Now consider a diallelic locus experiencing additive selection and drift in a diploid population. From Equation A1.4,

$$m(x) = sx(1 - x) \quad \text{and} \quad v(x) = \frac{x(1 - x)}{2N_e}$$

which implies

$$G(x) = \exp \left[-4N_e s \int_0^x \frac{y(1 - y)}{y(1 - y)} dy \right] = e^{-4N_e sx}$$

Thus, the probability of fixation of an allele with initial frequency p is

$$u(p) = \frac{\int_0^p e^{-4N_e sx} dx}{\int_0^1 e^{-4N_e sx} dx} = \frac{1 - e^{-4N_e sp}}{1 - e^{-4N_e s}} \quad (\text{A1.18a})$$

as obtained by Kimura (1957, 1962). A case of special interest is an initially rare allele ($p \ll 1$) that is under strong selection ($4N_e s \gg 1$). Here, the term in the denominator is essentially one, and because $1 - e^{-ax} = ax + o(x)$, we have

$$u(p) \simeq 4N_e s p \quad \text{for } 4N_e s \gg 1 \quad \text{and } p \ll 1$$

In particular, for a new mutation, $p = 1/(2N)$ and the fixation probability becomes

$$u\left(\frac{1}{2N}\right) = 4N_e s \frac{1}{2N} = 2s \frac{N_e}{N} \quad (\text{A1.18b})$$

More generally, starting at p , the probability that we will reach b before reaching a is

$$u_{a,b}(p) = \frac{\int_a^p e^{-4N_e sx} dx}{\int_a^b e^{-4N_e sx} dx} = \frac{e^{-4N_e sa} - e^{-4N_e sp}}{e^{-4N_e sa} - e^{-4N_e sb}} \quad (\text{A1.18c})$$

Finally, in allowing for dominance, we assign fitnesses as $1 : 1 + s(1 + h) : 1 + 2s$. Under weak selection (ignoring terms of s^2 and higher),

$$m(x) = sx(1 - x)[1 + h(1 - 2x)] \quad (\text{A1.19a})$$

which yields

$$\begin{aligned} G(x) &= \exp\left[-4N_e s \int^x y(1-y)[1+h(1-2y)] dy\right] \\ &= \exp\{-4N_e sx[1+h(1-x)]\} \end{aligned} \quad (\text{A1.19b})$$

and hence the fixation probability of the beneficial allele is

$$u(p) = \frac{\int_0^p \exp\{-4N_e sx[1+h(1-x)]\} dx}{\int_0^1 \exp\{-4N_e sx[1+h(1-x)]\} dx} \quad (\text{A1.19c})$$

Example A1.7. An important special case of Equation A1.19c is a favored, but completely recessive, allele. In this case $h = -1$, and Equations A1.19a and A1.19b, respectively, become

$$m(x) = 2sx^2(1 - x) \quad \text{and} \quad G(x) = \exp(-4N_e sx^2)$$

giving Equation A1.19c as

$$u(p) = \frac{\int_0^p e^{-4N_e sx^2} dx}{\int_0^1 e^{-4N_e sx^2} dx} \quad (\text{A1.20a})$$

This integral can be expressed in terms of $\text{erf}(x)$, the **error function** (Abramowitz and Stegun 1972), which is very closely related to the cumulative distribution of a unit normal, and is defined as

$$\text{erf}(x) = \frac{2}{\sqrt{\pi}} \int_0^x e^{-t^2} dt \quad (\text{A1.20b})$$

With the change of variables, $t = x\sqrt{4N_e s}$, the numerator of Equation A1.20a becomes

$$\int_0^p e^{-4N_e sx^2} dx = \frac{1}{\sqrt{4N_e s}} \int_0^{p\sqrt{4N_e s}} e^{-t^2} dt = \frac{1}{4} \sqrt{\frac{\pi}{N_e s}} \text{erf}\left(p\sqrt{4N_e s}\right)$$

Hence

$$u(p) = \frac{\operatorname{erf}(p\sqrt{4N_e s})}{\operatorname{erf}(\sqrt{4N_e s})} \quad (\text{A1.20c})$$

Now consider strong selection ($4N_e s \gg 1$), with the result that $\operatorname{erf}(\sqrt{4N_e s}) \simeq 1$ (because $\operatorname{erf}(x) \rightarrow 1$ for $x \gg 1$), and hence $u(p) \simeq \operatorname{erf}(p\sqrt{4N_e s})$. This expression can be further simplified by using the approximation that, for small values of x ,

$$\operatorname{erf}(x) \simeq \frac{2x}{\sqrt{\pi}}$$

(Abramowitz and Stegun 1972). Thus, when the recessive beneficial allele is initially rare ($x = p\sqrt{4N_e s} \ll 1$), its fixation probability is

$$u(p) \simeq \frac{2}{\sqrt{\pi}} p \sqrt{4N_e s} \quad (\text{A1.20d})$$

which, for a newly arisen mutation, $p = 1/(2N)$, becomes

$$u\left(\frac{1}{2N}\right) \simeq \frac{1}{N} \sqrt{\frac{4N_e s}{\pi}} \quad (\text{A1.20e})$$

This result was obtained by Kimura (1957), and for $N = N_e$ it reduces to $\sqrt{4s/N\pi} \simeq 1.13\sqrt{s/N}$. Previously, Haldane (1927) used the theory of branching processes to obtain an approximation of $\sqrt{2s/N} \simeq 1.41\sqrt{s/N}$, while Wright (1942) obtained an approximation of $\sqrt{s/N}$. Note that our expression is slightly different from the common form seen in the literature, as we used the general fitness model presented in Example A1.6 (the homozygote fitness is $1 + 2s$), while in models dealing with recessives, only the fitness is typically assigned as $1 + s$ (e.g., Example A1.5).

Time to Fixation

The time for a process to reach a specified value (or values) is called the **sojourn time**. While we are often interested in the sojourn time to an absorbing boundary (the fixation time), the more general problem of the time to first reach a specific value within the interval over which the diffusion is defined is also tractable. Letting $\bar{t}_{a,b}$ denote the expected time that a diffusion spends in the interval (a, b) given it starts at frequency p , then

$$\bar{t}_{a,b} = \int_0^\infty \Pr(a \leq x_t \leq b) dt = \int_0^\infty \int_a^b \varphi(x, t, p) dx dt \quad (\text{A1.21})$$

If a stationary distribution exists, this time is infinite and hence not really of much biological interest. However, if one or both boundaries are absorbing (and accessible), then $\bar{t}(p)$, the total time the diffusion spends in the interior, is obtained from Equation A1.21 by letting a and b be the lower and upper limits, respectively, of the diffusion (typically, $a = 0, b = 1$).

A very useful approach for solving Equation A1.21, and more general problems, is to consider $h(x, p)$, the expected amount of time that the process (starting at p) spends in the neighborhood of x before it is eventually absorbed. Formally, this is given by

$$h(x, p) = \int_0^\infty \varphi(x, t, p) dt \quad (\text{A1.22a})$$

Thus, Equation A1.21 can be expressed as

$$\bar{t}_{a,b} = \int_a^b h(x, p) dx \quad (\text{A1.22b})$$

$h(x, p)$ is called a **Green's function**, and it will prove very useful in solving a variety of problems. The general solution for $h(x, p)$, obtained by Maruyama (1977), is

$$h(x, p) = \begin{cases} \frac{2[1 - u(p)]}{v(x)G(x)} \int_a^x G(y) dy & \text{for } a < x < p \\ \frac{2u(p)}{v(x)G(x)} \int_x^b G(y) dy & \text{for } p < x < b \end{cases} \quad (\text{A1.22c})$$

where the fixation probability, $u(p)$, is provided by Equation A1.17a.

One can also obtain modified Green's functions for conditional processes, such as processes leading only to loss or processes leading only to fixation. For example, \bar{t}_F , the expected time to fix allele A (in those populations where it is fixed) is given by replacing $h(x, p)$ in Equation A1.22b by

$$h_1(x, p) = h(x, p) \frac{u(x)}{u(p)} \quad (\text{A1.23a})$$

This follows from standard conditional probability arguments (see Ewens 1979, 2004), with $u(x)/u(p)$ correcting for the fact that we are only considering those sample paths over which the allele of interest (A) is fixed. This occurs with probability $u(p)$, and hence $u(x)/u(p)$ is the conditional density. Similarly, \bar{t}_L , the expected time to lose allele A , is obtained by replacing $h(x, p)$ in Equation A1.22b by

$$h_0(x, p) = h(x, p) \frac{1 - u(x)}{1 - u(p)} \quad (\text{A1.23b})$$

Finally, we note that \bar{t} , \bar{t}_F , and \bar{t}_L are related by

$$\bar{t}(p) = u(p)\bar{t}_F(p) + [1 - u(p)]\bar{t}_L(p) \quad (\text{A1.24})$$

That is, the expected time to loss or fixation is equal to the expected time to fixation multiplied by the probability of fixation plus the expected time to loss multiplied by the probability of loss.

Example A1.8. Compute the conditional and unconditional expected time to loss or fixation for a neutral allele. Under neutrality, $u(x) = x$, $v(x) = x(1 - x)/(2N_e)$, and $G(x) = 1$. Hence, $\int_0^x G(y) dy = x$, $\int_x^1 G(y) dy = 1 - x$, and Equation A1.22c simplifies considerably to

$$h(x, p) = \begin{cases} 4N_e(1 - p)/(1 - x) & \text{for } 0 < x < p \\ 4N_e p/x & \text{for } p < x < 1 \end{cases}$$

Thus, the expected amount of time that a neutral allele (with an initial frequency of p) remains polymorphic is

$$\begin{aligned} \bar{t}(p) &= \int_0^1 h(x, p) dx \\ &= 4N_e(1 - p) \int_0^p \frac{dx}{1 - x} + 4N_e p \int_p^1 \frac{dx}{x} \\ &= -4N_e[(1 - p) \ln(1 - p) + p \ln(p)] \end{aligned} \quad (\text{A1.25})$$

Similarly, the conditional fixation times are obtained using Equations A1.23a and A1.23b, with

$$h_0(x, p) = \frac{1-x}{1-p} h(x, p) = \begin{cases} 4N_e & \text{for } 0 < x < p \\ 4N_e \frac{p(1-x)}{x(1-p)} & \text{for } p < x < 1 \end{cases} \quad (\text{A1.26a})$$

for those paths leading to loss, and

$$h_1(x, p) = \frac{x}{p} h(x, p) = \begin{cases} 4N_e \frac{x(1-p)}{p(1-x)} & \text{for } 0 < x < p \\ 4N_e & \text{for } p < x < 1 \end{cases} \quad (\text{A1.26b})$$

for those paths leading to fixation. The integration of Equation A1.22b then yields an expected conditional time to loss of

$$\begin{aligned} \bar{t}_L(p) &= \int_0^1 h_0(x, p) dx = 4N_e \int_0^p dx + 4N_e \frac{p}{1-p} \int_p^1 \frac{1-x}{x} dx \\ &= -4N_e \left(\frac{p}{1-p} \right) \ln(p) \end{aligned} \quad (\text{A1.27})$$

and an expected conditional time to fixation of

$$\begin{aligned} \bar{t}_F(p) &= \int_0^1 h_1(x, p) dx = 4N_e \frac{1-p}{p} \int_0^p \frac{x}{1-x} dx + 4N_e \int_p^1 dx \\ &= -4N_e \left(\frac{1-p}{p} \right) \ln(1-p) \end{aligned} \quad (\text{A1.28})$$

These results were first obtained by Kimura and Ohta (1969a, 1969b). As a check of consistency, we can apply Equation A1.24,

$$\begin{aligned} \bar{t} &= u(p) \bar{t}_F(p) + [1 - u(p)] \bar{t}_L(p) \\ &= -4N_e \left[p \left(\frac{1-p}{p} \ln(1-p) \right) + (1-p) \left(\frac{p}{1-p} \ln(p) \right) \right] \\ &= -4N_e [(1-p) \ln(1-p) + p \ln(p)] \end{aligned}$$

which (as expected) recovers our expression (Equation A1.25) for the unconditional time \bar{t} .

For the special case of a neutral allele introduced as a single copy, $p = 1/(2N)$, which results in the approximations

$$(1-p)/p \simeq 1/p = 2N, \quad p/(1-p) \simeq p = 1/(2N)$$

and

$$\ln(1-p) \simeq -p = -1/(2N), \quad \ln(p) = -\ln(1/p) = -\ln(2N)$$

If we use these approximations, Equation A1.25 reduces to

$$\begin{aligned} \bar{t} &= -4N_e [(1-p) \ln(1-p) + p \ln(p)] \\ &\simeq -4N_e \left[-1/(2N) - \ln(2N)/(2N) \right] \simeq \frac{2N_e}{N} \ln(2N) \end{aligned}$$

Similarly, Equations A1.27 and A1.28 become

$$\bar{t}_L = -4N_e \left(\frac{p}{1-p} \right) \ln(p) \simeq \frac{2N_e}{N} \ln(2N)$$

and

$$\bar{t}_F = -4N_e \left(\frac{1-p}{p} \right) \ln(1-p) \simeq -4N_e (2N) \left(-\frac{1}{2N} \right) = 4N_e$$

Expectations of More General Functions

The expressions for sojourn times are relatively simple examples of computing expected values along a sample path of the diffusion process, and more complex functions can be evaluated in a similar manner. Let x_t , which resides in the open interval $(0, 1)$, denote the values of our random variable along a particular sample path, and suppose that we wish to compute the integral (over all time) of some function f of x_t

$$I_f(p) = \int_0^\infty f(x_t) dt$$

Note that x_t is the realization at a particular time point, and hence the distribution of x_t (and thus ultimately I_f) is a function of p , the starting value of our process. Because x_t is a random variable, the integral $I_f(p)$ is also a random variable. Its expected value is given by

$$E[I_f(p)] = \int_0^\infty \int_0^1 f(x) \varphi(x, t, p) dt dx \quad (\text{A1.29a})$$

Fortunately, we do not have to solve for $\varphi(x, t, p)$, as (recalling Equation A1.22a) the general solution is obtained by using the Green's function, as described by Equation A1.22c, with

$$E[I_f(p)] = \int_0^1 f(x) h(x, p) dx \quad (\text{A1.29b})$$

This makes sense, as $h(x, p)dx$ is the expected amount of time that the process (starting at p) spends in the neighborhood of x before it is eventually lost or fixed. Thus, integration over all possible neighborhoods gives the expected value of the function over all sample paths.

Example A1.9. If we again assume an allele under drift only, consider two different functions, the total number of copies of the allele and total number of homozygotes involving this allele, with both expectations computed along only those paths that lose the allele. The relevant functions are, respectively, $f(x) = 2Nx$ for the total number of copies of the allele and $f(x) = Nx^2$ for the total number of homozygotes (assuming Hardy-Weinberg holds). To obtain the expected cumulative values of each function, we first apply Equation A1.26a, which gives the Green's function for pure drift on paths that are ultimately lost. This gives the general expression for any function, $f(x)$, as

$$\begin{aligned} E(f, p) &= \int_0^1 f(x) h_0(x, p) dx = 4N_e \int_0^p f(x) dx + 4N_e \frac{p}{1-p} \int_p^1 \frac{1-x}{x} f(x) dx \\ &= 4N_e \int_0^p f(x) dx + 4N_e \frac{p}{1-p} \left(\int_p^1 \frac{f(x)}{x} dx - \int_p^1 f(x) dx \right) \end{aligned} \quad (\text{A1.30})$$

Considering the total number of alleles, $f(x) = 2Nx$, the above expression becomes

$$E(2Nx) = 8N_e N \left[\int_0^p x dx + \frac{p}{1-p} \left(\int_p^1 dx - \int_p^1 x dx \right) \right]$$

The solution of the integrals in the square brackets reduces to

$$\frac{p^2}{2} + \frac{p}{1-p} \left((1-p) - \frac{1-p^2}{2} \right) = \frac{p}{2}$$

Hence, the expected total number of copies of the allele, starting at a frequency of p , during its entire sojourn to eventual loss is

$$8N_e N p / 2 = 4N_e N p$$

Note that there are initially $2Np$ copies of the allele at the start of the process, so the total number of copies over the entire life of the conditional process leading to loss is simply $2N_e$ times the initial number. Hence, a single new mutation that is destined to be lost leaves an average of $2N_e$ copies over its lifetime. Of course, the distribution of the actual number of copies is heavily skewed, with a long right tail. Most mutations are quickly lost, but a few become very successful (and hence leave many copies) before eventually dying out.

If we turn to the expected total number of homozygotes, $f(x) = Nx^2$, which yields

$$\begin{aligned} E(Nx^2) &= 4N_e N \left[\int_0^p x^2 dx + \frac{p}{1-p} \left(\int_p^1 x dx - \int_p^1 x^2 dx \right) \right] \\ &= 4N_e N \left[\frac{p^3}{3} + \frac{p}{1-p} \left(\frac{1-p^2}{2} - \frac{1-p^3}{3} \right) \right] \\ &\simeq 4N_e N (p/6) = (2/3)N_e N p \quad (\text{for } p \ll 1) \end{aligned}$$

Again, if we start with a single copy, $E(Nx^2) \simeq N_e/3$.

APPLICATIONS IN QUANTITATIVE GENETICS

While we have focused on population-genetic applications of diffusion processes, this approach is also very useful for solving a number of problems in quantitative genetics. When attention shifts from individual alleles to a quantitative character, diffusions typically follow mean phenotypes instead of allele frequencies. Two well-studied diffusions, **Brownian motion** and the **Ornstein-Uhlenbeck process**, are especially useful (Chapter 12).

Brownian-motion Models

For Brownian motion (also called the **Wiener process**), the diffusion over the interval $-\infty < x < \infty$ is defined as

$$m(x) = a \quad \text{and} \quad v(x) = b \tag{A1.31a}$$

where $b > 0$. The general solution under Brownian motion starting at x_0 is that

$$x_t \sim N(x_0 + at, bt) \tag{A1.31b}$$

namely, the distribution of x_t is normal, with a mean of $x_0 + at$ and a variance of $\sigma_t^2 = bt$. There is no equilibrium solution, as the process converges to a normal distribution with infinite variance (and, if $a \neq 0$, an infinite mean).

Example A1.10. Lande (1976) used the Brownian-motion model to approximate the change in the phenotypic mean of a neutral character with constant additive-genetic variance. In this case there is no directional force to change the mean, so $a = 0$. If we assume that the character has a strictly additive-genetic basis, the per-generation sampling variance in the mean is σ_A^2/N_e (Chapter 12), which is used for b in Equation A1.31a. Hence, at generation t , the distribution of phenotypic means is approximately normal, with expected mean of μ_0 (the initial mean) and a variance of $\sigma_t^2 = t\sigma_A^2/N_e$.

One measure of how quickly phenotypic means drift is the minimum number of generations required for the mean of a random population to have at least a 50% probability of being more than K standard deviations from its initial mean. This is expressed as $\Pr(|x_t - \mu_0| \geq K\sigma_z) = 0.5$, where x_t is the mean of a randomly drawn replicate population and σ_z^2 is the phenotypic variance. Assuming Brownian motion, $(x_t - \mu_0)/\sigma_t$ is a unit normal random variable, and hence

$$\Pr(|x_t - \mu_0| \geq K\sigma_z) = \Pr\left[\frac{|x_t - \mu_0|}{\sigma_t} \geq \frac{K\sigma_z}{\sigma_t}\right] = \Pr\left[|U| \geq \frac{K\sigma_z}{\sigma_t}\right] = 0.5$$

For a unit normal U , $\Pr(|U| \geq 0.675) = 0.5$, which yields $K\sigma_z/\sigma_t = K\sigma_z/(\sigma_A\sqrt{t/N_e}) = 0.675$. Rearranging and substituting $h^2 = \sigma_A^2/\sigma_z^2$ yields

$$t = \frac{K^2 N_e}{h^2 0.675^2} \simeq 2 N_e \frac{K^2}{h^2} \quad (\text{A1.31c})$$

Thus, for $N_e = 10$, a neutral character with a constant heritability of $h^2 = 0.5$ requires $2 \cdot 10 \cdot 9/0.5 = 360$ generations until half the populations have phenotypic means of more than three standard deviations ($K = 3$) from their initial value. For $N_e = 10^5$, this time becomes 3.6 million generations.

The above analysis considers a single population over time (such as in a fossil sequence). Another situation of general interest involves an initial population that splits into two distinct, isolated populations. Here, the divergence between the two means is the sum of the two individual variances, meaning that if the initial difference is 0, then the distribution of the difference in mean after t generations is

$$d_t \sim N\left[0, t \cdot \left(\frac{\sigma_{A_1}^2}{N_{e,1}} + \frac{\sigma_{A_2}^2}{N_{e,2}}\right)\right] \quad (\text{A1.31d})$$

where $\sigma_{A_i}^2$ and $N_{e,i}$ are, respectively, the additive genetic variance and effective population size for population i .

Example A1.11. The careful reader may recall that drift also changes σ_A^2 , with the assumption of a constant σ_A^2 being reasonable only for $t < N_e$ or when the population is at a mutation-drift equilibrium (Chapter 11). In Example A1.10, we fixed the genetic variance but allowed N_e to vary. However, if an ideal population (Chapter 2) has been at its current size for a sufficiently long time, the genetic variance for a neutral trait will be at its mutation-drift equilibrium value of $2N_e\sigma_m^2$, where σ_m^2 is the mutational variance (Equation 11.20c). The distribution of means now has an expected variance of

$$\sigma_t^2 = 2tN_e\sigma_m^2/N_e = 2t\sigma_m^2$$

From our previous example, Equation A1.31c calculates the expected number of generations until 50% of the means exceed K standard deviations as $K\sigma_z/\sigma_t = 0.675$. Using $\sigma_t^2 = 2t\sigma_m^2$ and solving for t yields

$$t = \frac{K^2\sigma_z^2}{2 \cdot 0.675^2 \cdot \sigma_m^2} = 1.1 \frac{K^2\sigma_z^2}{\sigma_m^2} \simeq \frac{K^2\sigma_z^2}{\sigma_m^2} \quad (\text{A1.31e})$$

Because $\sigma_z^2 = \sigma_A^2 + \sigma_E^2 = 2N_e\sigma_m^2 + \sigma_E^2$,

$$t \simeq K^2 \frac{\sigma_z^2}{\sigma_m^2} = K^2 \left(2N_e + \frac{1}{h_m^2} \right)$$

where $h_m^2 = \sigma_m^2 / \sigma_E^2$ is the mutational heritability.

According to LW Table 9.1, h_m^2 has an approximate average value of 0.006. Taking this value, and repeating the calculations from Example A1.10 (e.g., $N_e = 10$ and $K = 3$) yields $t = 9 \cdot (20 + 1/0.006) = 1680$ generations. The reason for the huge increase in time (1680 vs. 360) relative to the fixed variance example above is because the equilibrium additive variance is much smaller due to the small population size, and thus has an equilibrium heritability of

$$h^2 = \frac{2N_e\sigma_m^2}{2N_e\sigma_m^2 + \sigma_E^2} = \frac{2N_e\sigma_m^2/\sigma_E^2}{2N_e\sigma_m^2/\sigma_E^2 + 1} = \frac{2N_e h_m^2}{2N_e h_m^2 + 1} = \frac{0.12}{0.12 + 1} = 0.11$$

or roughly 1/5 of the value used in Example A1.10. When $N_e = 10^5$, the time is 1.8 million generations, half the value obtained in Example A1.10, as now the equilibrium heritability is essentially one (1200/1201), which is twice the value that was assumed in Example A1.10.

Example A1.12. The Brownian motion model easily extends to multiple traits. Suppose we let \mathbf{x} denote a vector of traits, assume an infinitesimal mean change vector of zero, and denote the infinitesimal covariance matrix by \mathbf{V} (the multivariate versions of $m(x)$ and $v(x)$, respectively). If the process starts at value \mathbf{x}_0 , then

$$\mathbf{x}_t \sim \text{MVN}(\mathbf{x}_0, t\mathbf{V}) \quad (\text{A1.32a})$$

where MVN denotes the multivariate normal. Lande (1979a) examined the change in a vector of trait means under drift and mutation. The per-generation sampling variance in the multivariate mean vector is $\mathbf{V} = \mathbf{G}/N_e$, the additive-genetic covariance matrix, \mathbf{G} (Chapter 13), divided by the effective population size. If \mathbf{u}_0 is the starting vector of means, then

$$\mathbf{u}_t \sim \text{MVN}[\mathbf{u}_0, (t/N_e)\mathbf{G}] \quad (\text{A1.32b})$$

A key feature of Equation A1.32b is that we expect the most divergence in population means to occur along the principal components of \mathbf{G} (the eigenvectors corresponding to the leading eigenvalues; Appendix 5), as these are the axes with the most variance, and hence the most spread in the realizations of \mathbf{u}_t . Thus, if drift dominates, the divergence between two populations is largely in the direction of the first few principal components of \mathbf{G} (a topic we return to in Volume 3).

Lande (1979a) assumed that over long periods of time, the genetic covariance matrix would approach its mutation-drift equilibrium value. Suppose we let \mathbf{U} denote the matrix of mutational variances and covariances, which means that U_{ii} corresponds to the mutational (additive-genetic) variation in trait i generated in each generation (σ_m^2 in the univariate case), and U_{ij} is the mutational additive-genetic covariance between traits i and j (i.e., pleiotropy). For an effective population size of N_e , drift decays the current additive-genetic variance by an amount of $1/(2N_e)$ in each generation, but this is countered by new mutation, yielding an expected change in the average covariance matrix of

$$\Delta\mathbf{G} = \mathbf{G}/(2N_e) + \mathbf{U}$$

At equilibrium, $\Delta\hat{\mathbf{G}} = \mathbf{0}$, or

$$\hat{\mathbf{G}} = 2N_e \mathbf{U}$$

As expected, this reduces to the single-trait result of $2N_e\sigma_m^2$ (Equation 11.20c) when $\mathbf{U} = (\sigma_m^2)$. Hence, the sampling variance of the mean becomes $\hat{\mathbf{G}}/N_e = 2\mathbf{U}$, which reduces Equation A1.32b to

$$\mathbf{u}_t \sim \text{MVN}(\mathbf{u}_0, 2t\mathbf{U}) \quad (\text{A1.32c})$$

The neutral divergence between two populations now follows the leading eigenvectors of \mathbf{U} , rather than those of the initial \mathbf{G} matrix. This interesting finding requires the strong assumption that the population has been in mutation-drift equilibrium during the bulk of the divergence.

Ornstein-Uhlenbeck Models

The Ornstein-Uhlenbeck process is an extension of the Brownian-motion model to include a linear restoring force back to the origin. The one-dimensional version of this diffusion process for $-\infty < x < \infty$ is given by

$$m(x) = -ax \quad \text{and} \quad v(x) = b \quad (\text{A1.33a})$$

with $a, b > 0$. As with Brownian motion, the distribution of x_t (given the starting condition x_0) is also normal, but now with a mean and a variance of

$$\mu_t = x_0 e^{-at} \quad \text{and} \quad \sigma_t^2 = \frac{b}{2a} (1 - e^{-2at}) \quad (\text{A1.33b})$$

See Karlin and Taylor (1981) for a derivation. The resulting stationary distribution is normal with a mean of zero (on the assumed scale) and a variance of $b/(2a)$. More generally, if $m(x) = -a(x - \theta)$, so that the resorting force is toward the value $x = \theta$, then the variance will be unchanged, while

$$\mu_t = \theta + (x_0 - \theta)e^{-at} \quad (\text{A1.33c})$$

Example A1.13. Lande (1976) examined the distribution of phenotypic means under drift and stabilizing selection, using the Gaussian fitness function (Equation 16.17) as a model of stabilizing selection. Here, the expected fitness of an individual with phenotypic value z is given by

$$W(z) = \exp\left(-\frac{z^2}{2\omega^2}\right)$$

The optimal phenotype is $z = 0$, and the strength of selection is given by the width, ω^2 , with smaller values of ω^2 corresponding to stronger selection (fitness declining faster as one moves away from zero). Under nor-optimal selection, if phenotypes are normally distributed before selection with a mean of μ_t and a phenotypic variance of σ_z^2 , they remain normal after selection, with a new mean of $\mu_t + S$, where

$$S = -\mu_t \frac{\sigma_z^2}{\sigma_z^2 + \omega^2}$$

and a new variance of

$$\sigma_z^2 - \frac{\sigma_z^4}{\sigma_z^2 + \omega^2}$$

We assume that selection is sufficiently weak ($\omega^2 \gg \sigma_z^4$) so that the variance remains effectively unchanged after selection. As expected, nor-optimal selection moves the mean in the direction of the optimum (decreasing the current mean if it is positive, and increasing it if negative). Assuming the breeder's equation ($R = h^2 S$), the change in the mean becomes

$$\Delta\mu = h^2 S = \frac{\sigma_A^2}{\sigma_z^2} \left(-\mu_t \frac{\sigma_z^2}{\sigma_z^2 + \omega^2} \right) = -\mu_t \left(\frac{\sigma_A^2}{\sigma_z^2 + \omega^2} \right)$$

Suppose we let $x_t = \mu_t$ be the mean in generation t of a randomly drawn replicate population. From Equation A1.33a, the resulting distribution of means can then be approximated by an Ornstein-Uhlenbeck process, with

$$a = \frac{\sigma_A^2}{\sigma_z^2 + \omega^2} \quad \text{and} \quad b = \frac{\sigma_A^2}{N_e}$$

where a follows from the change in mean and b is the drift variance under Brownian motion (Example A.10). From Equation A1.33b, the resulting distribution of phenotypic means in generation t is normal, with a mean of

$$\mu_t = \mu_0 \exp\left(-t \frac{\sigma_A^2}{\sigma_z^2 + \omega^2}\right) \quad (\text{A1.34a})$$

and variance of

$$\sigma_t^2 = \frac{\sigma_z^2 + \omega^2}{2N_e} \left[1 - \exp\left(-2t \frac{\sigma_A^2}{\sigma_z^2 + \omega^2}\right) \right] \quad (\text{A1.34b})$$

At equilibrium, the distribution of the means of replicate populations is normal, with mean of zero (i.e., centered at the fitness optimum) and a variance of $(\sigma_z^2 + \omega^2)/(2N_e)$.

Example A1.14. Example A1.13 shows how diffusion approximations yield a stationary distribution for the phenotypic mean under the joint action of drift and stabilizing selection. More general forms of selection can be considered as well. Suppose our concern is simply the change in the mean of a trait that is under arbitrary selection. Provided the phenotypes are normally distributed within a population, then, from Equation 13.27a the change in mean is

$$\Delta\mu = \sigma_A^2 \frac{\partial \ln[\bar{W}(\mu)]}{\partial \mu}$$

where the mean fitness, $\bar{W}(\mu)$, is a function of the population mean, μ . Because no assumptions were made about the nature of selection, any function for mean fitness can be used, *provided* the distribution of offspring phenotypes remains roughly normal. Hence, an approximating diffusion for the behavior of the mean under selection and drift is to let x equal the current mean and set

$$m(x) = \sigma_A^2 \frac{\partial \ln(\bar{W})}{\partial x} \quad \text{and} \quad v(x) = \frac{\sigma_A^2}{N_e} \quad (\text{A1.35})$$

Substituting Equations A1.35 into Equation A1.12 yields

$$G(x) = \exp\left[-2N_e \int^x \frac{\partial \ln(\bar{W})}{\partial y} dy\right] = \exp[-2N_e \ln(\bar{W})] = \bar{W}(x)^{-2N_e}$$

Thus, Equation A1.11 gives the equilibrium distribution of population means as

$$\varphi(x) = \frac{C}{v(x)G(x)} = \frac{CN_e}{\sigma_A^2} \bar{W}(x)^{2N_e} \propto \bar{W}(x)^{2N_e} \quad (\text{A1.36})$$

This result, which is from Lande (1976), shows that as the effective population size increases, the probability that the population mean is near a local maximum in fitness also increases. This follows because $\varphi(x)$ becomes increasingly peaked around local maxima relative to other parts of the fitness surface as we increase N_e . If \bar{W} has multiple peaks, then so does $\varphi(x)$. Equations A1.35 and A1.36 rely on the assumptions that the phenotypic and additive-genetic variances remain constant as the mean changes and (as mentioned above) that the phenotypic distribution remains normal.

Appendix 2

Introduction to Bayesian Analysis

*Now I've heard a Bayesian is half a man
With robustness not on his side,
But as the problems get tougher,
I just watch and wonder
As the frequentists run and hide!*
— Ain't Too Proud to Bayes, B. Carlin (ISBA 2000)

The history of statistical methods in genetics closely parallels advances in computation. Before the widespread use of computers, **method-of-moments** approaches were common as they are relatively easy to obtain. Here, a summary statistic of the data is computed whose expected value is the parameter of interest (e.g., using the sample mean, \bar{x} , as an estimate of the true mean, μ_x , as $E[\bar{x}] = \mu_x$). In the mid-1970s, maximum-likelihood (ML) methods became much more common place, as they offer a very flexible platform for statistical analysis (estimation, determining precision, and hypothesis testing), but at the cost of numerically searching an often highly complex multidimensional likelihood surface (LW Appendix 4). Both these approaches typically return point estimators for the variables of interest, along with some measure of their uncertainty. As opposed to these classical (or **frequentist**) approaches, **Bayesian statistics** (which can be viewed as a natural extension of likelihood methods) is concerned with generating the full *distribution* for the parameters, Θ , given the data, x , namely, obtaining the posterior distribution, $p(\Theta | x)$. As such, Bayesian statistics provides a much more complete picture of the uncertainty in the estimation of the unknown parameters, especially after the confounding effects of nuisance parameters are removed.

Our treatment here is intentionally quite brief. A number of texts have presented excellent treatments of the statistical theory (e.g., Lindley 1965; Berger 1985; Carlin and Louis 2000; Lee 2012; Gelman et al. 2013). Blasco (2017) provided a very lucid introduction to applications in quantitative genetics, while Sorensen and Gianola (2002) offered a more comprehensive treatment. While very deep (and very subtle) differences in philosophy separate hard-core Bayesians from hard-core frequentists (Efron 1986; Glymour 1981), our treatment of Bayesian methods is motivated simply by their use as a powerful statistical tool. This appendix focuses on the basic theory, while the computational approaches that make these methods feasible are examined in Appendix 3.

WHY ARE BAYESIAN METHODS BECOMING MORE POPULAR?

In addition to providing a more formal framework for dealing with parameter uncertainty, two specific features have fueled the rapid growth of Bayesian approaches in genetics and genomics. First, under a Bayesian analysis, all parameters are random effects as opposed to fixed effects (Chapter 19). This has profound implications for degrees of freedom. Consider a gene expression study with 30,000 features (genes of interest), whose mRNA levels are contrasted over a set of 100 normal liver cells versus 100 cancerous ones. If we treat the differential expression level of any particular gene as a fixed effect (an unknown constant to be estimated) we will very quickly use all of the degrees of freedom, given the small sample size. Conversely, if these levels are treated as **random effects**, with the expression difference associated with a particular gene being a random variable drawn from some underlying (and unknown) distribution, then the only degrees of freedom lost will be those used to estimate the associated parameters for this underlying distribution. Further, prediction of the random realization that corresponds to a particular gene borrows information over all

the genes. Thus, a Bayesian analysis can handle high-dimensional experiments in which the number of parameters, p , greatly exceeds the number of observations, n , in a framework that fully manages the uncertainty over all these estimates. Second, Bayesian methods are computationally feasible, as approaches such as MCMC (Appendix 3) allow high-dimensional datasets to be analyzed in a computationally efficient manner. In settings with a large number of nuisance parameters or a high-dimensional dataset, a Bayesian approach not only has considerable appeal, it may be the only approach that is even feasible.

BAYES' THEOREM

The foundation of Bayesian statistics is **Bayes' theorem**. Suppose we observe a random variable, x , and wish to make inferences about another random variable, θ , in the case where θ is drawn from some distribution, $\Pr(\theta)$. From the definition of conditional probability

$$\Pr(\theta | x) = \frac{\Pr(x, \theta)}{\Pr(x)} \quad (\text{A2.1a})$$

where (for now) x and θ are discrete random variables. Again from the definition of conditional probability, we can express the joint probability by conditioning on θ to give

$$\Pr(x, \theta) = \Pr(x | \theta) \Pr(\theta) \quad (\text{A2.1b})$$

Putting these together yields Bayes' theorem

$$\Pr(\theta | x) = \frac{\Pr(x | \theta) \Pr(\theta)}{\Pr(x)} \quad (\text{A2.2a})$$

Bayes' theorem flips the conditioning variable, allowing us to move from $\Pr(x | \theta)$ to $\Pr(\theta | x)$. With k possible values of θ (θ_1 through θ_k), the discrete version of Bayes' theorem becomes

$$\Pr(\theta_j | x) = \frac{\Pr(x | \theta_j) \Pr(\theta_j)}{\Pr(x)} = \frac{\Pr(x | \theta_j) \Pr(\theta_j)}{\sum_{i=1}^k \Pr(\theta_i) \Pr(x | \theta_i)} \quad \text{for } 1 \leq j \leq k \quad (\text{A2.2b})$$

In Bayesian statistics, x represents an observable variable (the data), while θ represents a parameter describing the distribution of x . In this setting, $\Pr(\theta)$ is the **prior distribution** of possible parameter values, while $\Pr(\theta | x)$ is the subsequent **posterior distribution** of θ given the observed data x and the prior. In classical statistics, the unknown parameters are treated as fixed and the data are considered random, whereas under a Bayesian analysis, the data are considered fixed and the unknown parameters that generated the data are considered random.

All of the above statements also hold for continuous random variables, for which the probability density function, p , replaces the discrete probability value, \Pr . In particular, the continuous multivariate version of Bayes' theorem is

$$p(\boldsymbol{\Theta} | \mathbf{x}) = \frac{p(\mathbf{x} | \boldsymbol{\Theta}) p(\boldsymbol{\Theta})}{p(\mathbf{x})} = \frac{p(\mathbf{x} | \boldsymbol{\Theta}) p(\boldsymbol{\Theta})}{\int p(\mathbf{x}, \boldsymbol{\Theta}) d\boldsymbol{\Theta}} \quad (\text{A2.3})$$

where $\boldsymbol{\Theta} = (\theta_1, \theta_2, \dots, \theta_n)$ is a vector of n (potentially) continuous variables. As with the univariate case, $p(\boldsymbol{\Theta})$ is the assumed prior distribution of the unknown parameters, while $p(\boldsymbol{\Theta} | \mathbf{x})$ is the posterior distribution given the prior, $p(\boldsymbol{\Theta})$, and the data, \mathbf{x} .

The origin of Bayes' theorem has a fascinating history (Stigler 1983). It is named after the Rev. Thomas Bayes, a priest who never published a mathematical paper during his lifetime. The paper in which the theorem appears was posthumously read before the Royal Society by his friend Richard Price in 1764. Stigler suggests it was first discovered by Nicholas

Saunderson, a blind mathematician and optician who, at age 29, became Lucasian Professor of Mathematics at Cambridge (the position held earlier by Isaac Newton). This is an example of **Stigler's Law of Eponomy** (Stigler 1980), wherein no discovery or invention is named after its first discoverer (an **eponym**). As is fitting, Stigler's law is self-consistent, as this phenomenon was previously mentioned by Merton (1965).

Example A2.1. Consider a recessive color locus in cattle in which the genotypes BB and Bb are black, while bb is red. Two black-coated parents are crossed, and produce some red offspring, which implies that both parents must be Bb . A black-coated son of theirs is crossed to n red dams (bb), and all of his offspring are black. What is the posterior probability that he is BB ?

To solve this problem using Bayes' theorem, we first define the indicator random variable

$$\theta = \begin{cases} 0 & \text{son is } Bb \\ 1 & \text{son is } BB \end{cases}$$

Given that both parents are Bb , the expected priors for their offspring are $1/4$ for BB and $1/2$ for Bb , resulting in a $3/4$ prior for a black-coated offspring. Further, from conditional probability (Equation A2.1a), the prior that a black offspring is BB is

$$\Pr(BB | \text{Black}) = \frac{\Pr(BB, \text{Black})}{\Pr(\text{Black})} = \frac{\Pr(BB)}{\Pr(\text{Black})} = \frac{1/4}{3/4} = 1/3$$

where we used the fact that all BB are black, so that $\Pr(BB, \text{Black}) = \Pr(BB)$. Hence, the prior becomes

$$\Pr(\theta) = \begin{cases} 0 & \text{is } 2/3 \\ 1 & \text{is } 1/3 \end{cases}$$

Further

$$\Pr(\text{all } n \text{ offspring are black} | \text{sire is } BB) = 1$$

$$\Pr(\text{all } n \text{ offspring are black} | \text{sire is } Bb) = (1/2)^n$$

and

$$\begin{aligned} \Pr(\text{all } n \text{ black}) &= \Pr(\text{all black} | BB) * \Pr(BB) + \Pr(\text{all black} | Bb) * \Pr(Bb) \\ &= 1 \cdot 1/3 + (1/2)^n \cdot (2/3) \end{aligned}$$

If we combine the above values, Bayes' theorem yields

$$\Pr(\theta = 1 | n \text{ black offspring}) = \frac{\Pr(n | \theta = 1) \Pr(\theta = 1)}{\Pr(n)} = \frac{1 \cdot (1/3)}{1 \cdot (1/3) + (1/2)^n \cdot (2/3)}$$

which returns values of $0.5, 0.67, 0.8, 0.89, 0.94$, and 0.998 for $n = 1, 2, 3, 4, 5$, and 10 , respectively.

Example A2.2. Suppose a major gene (with alleles Q and q) underlies a character of interest. The distribution of phenotypic values for each major-locus genotype follows a normal distribution with a variance of 1 and means of 2.1, 3.5, and 1.3 for QQ , Qq , and qq , respectively. Suppose the frequencies of these genotypes for a random individual drawn from the population are 0.3, 0.2, and 0.5 (for QQ , Qq , and qq , respectively). If an individual from this population has a phenotypic value of 3, then what is the probability of it being QQ ? Qq ? qq ? Let $\varphi(x | \mu, 1) = (2\pi)^{-1/2} e^{-(x-\mu)^2/2}$ denote the density function for a normal distribution with a mean of μ and variance of 1. To apply Bayes' theorem, note that the values for the priors and the conditionals are as follows:

Genotype, G	Pr(G)	$p(x G)$	$\Pr(G) \cdot p(x G)$
QQ	0.3	$\varphi(3 2.1, 1) = 0.266$	0.078
Qq	0.2	$\varphi(3 3.5, 1) = 0.350$	0.070
qq	0.5	$\varphi(3 1.3, 1) = 0.094$	0.047

Because $p(3) = \sum_G \Pr(G) \cdot p(3|G) = 0.195$, Bayes' theorem gives the posterior probabilities for the genotypes given the observed value of 3 as:

$$\Pr(QQ | x = 3) = 0.078 / 0.195 = 0.400$$

$$\Pr(Qq | x = 3) = 0.070 / 0.195 = 0.359$$

$$\Pr(qq | x = 3) = 0.047 / 0.195 = 0.241$$

Thus, there is a 40 percent chance that this individual has a genotype of QQ, a 36 percent chance it is Qq, and a 24 percent chance it is qq.

FROM LIKELIHOOD TO BAYESIAN ANALYSIS

The method of maximum likelihood (LW Appendix 4) and Bayesian analysis are closely related. Suppose $\ell(\Theta | \mathbf{x})$ is the assumed likelihood function. Under ML estimation, we would compute the mode of the likelihood function (the maximal value of ℓ , as a function of Θ given the data \mathbf{x}), and use the local curvature around the mode to construct confidence intervals. Hypothesis testing follows using likelihood-ratio (LR) statistics. The strengths of ML estimation rely on its *large-sample* properties, namely, that when the sample size is sufficiently large, we can assume both normality of the estimators and that most LR tests follow χ^2 distributions. These features, nice as they are, may not hold for small samples. Conversely, a Bayesian analysis is *exact* for any sample size, given a specified prior.

To transition from a likelihood to a Bayesian analysis, we start with some prior distribution, $p(\Theta)$, that captures our initial knowledge (or best guess) about the possible values of the unknown parameters. From Bayes' theorem, the data (likelihood) is combined with the prior to produce a posterior distribution,

$$p(\Theta | \mathbf{x}) = \frac{1}{p(\mathbf{x})} \cdot p(\mathbf{x} | \Theta) \cdot p(\Theta) \quad (\text{A2.4a})$$

$$= (\text{normalizing constant}) \cdot p(\mathbf{x} | \Theta) \cdot p(\Theta) \quad (\text{A2.4b})$$

$$= \text{constant} \cdot \text{likelihood} \cdot \text{prior} \quad (\text{A2.4c})$$

as $p(\mathbf{x} | \Theta) = \ell(\Theta | \mathbf{x})$ is simply the likelihood function (LW Appendix 4) and $1/p(\mathbf{x})$ is a constant (with respect to Θ). Consequently, the posterior distribution is often written as

$$p(\Theta | \mathbf{x}) \propto \ell(\Theta | \mathbf{x}) \cdot p(\Theta) \quad (\text{A2.4d})$$

where the symbol \propto means “proportional to” (equal up to a constant). Note that the constant $p(\mathbf{x})$ normalizes $p(\mathbf{x} | \Theta) \cdot p(\Theta)$ to one, and hence can be obtained by integration

$$p(\mathbf{x}) = \int_{\Theta} p(\mathbf{x} | \Theta) \cdot p(\Theta) d\Theta \quad (\text{A2.5})$$

The dependence of the posterior on the prior (which can easily be assessed by trying different priors) provides an indication of how much information on the unknown parameter values is contained in the data (the curvature of the likelihood surface). If the posterior is highly dependent on the prior, then the data likely has little signal (a **flat likelihood surface**),

while if the posterior is largely unaffected by different priors, then the data are likely highly informative (a sharply peaked likelihood surface). To see this, taking logs on Equation A2.4c yields

$$\log(\text{posterior}) = \log(\text{likelihood}) + \log(\text{prior}) + \text{constant} \quad (\text{A2.6})$$

When the likelihood signal is strong, it largely dominates the prior in the resulting posterior, but when a likelihood is weak, the prior can dominate.

Marginal Posterior Distributions

Often only a subset of the unknown parameters is of concern to us, and the rest are **nuisance parameters** that are of no interest, but still must be fitted in the model. A strong feature of Bayesian analysis is that we can account for all the uncertainty introduced into the parameters of interest by any uncertainty in the values of nuisance parameters. This is accomplished by integrating the nuisance parameters out of the posterior distribution to generate a **marginal posterior distribution** for the parameters of interest. For example, suppose the mean and variance of data coming from a normal distribution are unknown, but our real interest is only in the variance. Estimating the mean introduces additional uncertainty into our variance estimate, which is not fully captured by standard classical approaches. Under a Bayesian analysis, the marginal posterior distribution for σ^2 is simply

$$p(\sigma^2 | \mathbf{x}) = \int p(\mu, \sigma^2 | \mathbf{x}) d\mu$$

The resulting marginal posterior for σ^2 captures all of the uncertainty in the estimation of μ that influences the uncertainty in σ^2 . This is an especially nice feature when a large number of nuisance parameters must be estimated.

The marginal posterior may involve several parameters (generating **joint marginal posteriors**). Suppose we write the vector of unknown parameters as $\Theta = (\Theta_1, \Theta_{nu})$, where Θ_{nu} is the vector of nuisance parameters. Integrating over Θ_{nu} yields the desired marginal for the vector Θ_1 of parameters of interest as

$$p(\Theta_1 | \mathbf{y}) = \int_{\Theta_{nu}} p(\Theta_1, \Theta_{nu} | \mathbf{y}) d\Theta_{nu} \quad (\text{A2.7})$$

While these complex integrals appear quite daunting (and indeed almost always are from an analytic standpoint), generating draws from the marginal distribution is usually very straightforward using MCMC methods (which are examined in Appendix 3).

SUMMARIZING THE POSTERIOR DISTRIBUTION

How do we extract a Bayesian estimator for some unknown parameter, θ ? If our mindset is to use some sort of point estimator (as is usually done in classical statistics), then there are a number of candidates. We could follow maximum likelihood and use the **mode of the posterior distribution** (its maximal value)

$$\hat{\theta} = \max_{\theta} [p(\theta | \mathbf{x})] \quad (\text{A2.8a})$$

We could take the **expected value of θ** (its mean) given the posterior

$$\hat{\theta} = E[\theta | \mathbf{x}] = \int \theta p(\theta | \mathbf{x}) d\theta \quad (\text{A2.8b})$$

Another candidate is the **median of the posterior**, which is more robust than the mean to outliers. Here the estimator satisfies $\Pr(\theta > \hat{\theta} | \mathbf{x}) = \Pr(\theta < \hat{\theta} | \mathbf{x}) = 0.5$, hence

$$\int_{\hat{\theta}}^{+\infty} p(\theta | \mathbf{x}) d\theta = \int_{-\infty}^{\hat{\theta}} p(\theta | \mathbf{x}) d\theta = \frac{1}{2} \quad (\text{A2.8c})$$

However, using any of the above estimators, or even all three simultaneously, loses the full power of a Bayesian analysis, as *the full estimator is the entire posterior density itself*. If we cannot obtain the full form of the posterior distribution, then these estimates of general features of the distribution can be presented. However, as we will see in Appendix 3, we can generally obtain the full posterior by simulation using MCMC sampling, and hence the Bayesian estimate of a parameter is often presented as a frequency histogram (potentially smoothed) of the MCMC-generated samples from the posterior distribution (an **empirical posterior**).

Highest Density Regions (HDRs)

Given the posterior distribution, the construction of confidence intervals is straightforward. For example, a $100(1 - \alpha)\%$ confidence interval is given by any $(L_{\alpha/2}, H_{\alpha/2})$ satisfying

$$\int_{L_{\alpha/2}}^{H_{\alpha/2}} p(\theta | \mathbf{x}) d\theta = 1 - \alpha$$

To reduce the set of possible candidate intervals, one typically uses **highest density regions**, or **HDRs**, where, for a single parameter, the HDR $100(1 - \alpha)$ region(s) are the shortest intervals giving an area of $(1 - \alpha)$. More generally, if multiple parameters are being estimated, the HDR region(s) are those with the smallest *volume* in the parameter space. HDRs are also referred to as **Bayesian confidence intervals** or (better yet) **credible intervals**.

It is critical to note that there is a *profound difference* between a confidence interval (CI) from classical (frequentist) statistics and a Bayesian analysis. The interpretation of a classical confidence interval is that if we were to repeat the experiment a large number of times, and construct CIs in the same fashion, the fraction of the resulting collection of CIs that enclose the unknown parameter approaches $(1 - \alpha)$. Thus, the frequentist CI is a measure of the *frequency* of occurrences in independent experiments in which the CI encloses the true value (and hence the term frequentist for this type of statistics). In contrast, with a Bayesian HDR, there is a probability of $(1 - \alpha)$ that the interval contains the true value of the unknown parameter. While at first blush these two intervals appear to be essentially identical, they are not, and indeed they are fundamentally (but subtly) different. Often the CI and Bayesian intervals span essentially the same values, but again the interpretational difference remains. The key point is that the Bayesian prior allows us to make *direct probability statements* about θ , while under classical statistics we can only make statements about the behavior of the statistic if we consider *repeating an experiment a large number of times*. Given the important conceptual difference between classical and Bayesian intervals, Bayesians typically avoid using the term *confidence interval*, using the term *credible interval* instead.

Bayes Factors and Hypothesis Testing

In the classical hypothesis-testing framework, we have two alternatives. The null hypothesis, H_0 , that the unknown parameter, θ , belongs to some set or interval, Θ_0 ($\theta \in \Theta_0$), versus the alternative hypothesis, H_1 , that θ belongs to the alternative set, Θ_1 ($\theta \in \Theta_1$). Θ_0 and Θ_1 contain no common elements ($\Theta_0 \cap \Theta_1 = \emptyset$) and the union of Θ_0 and Θ_1 contains the entire space of values for θ (i.e., $\Theta_0 \cup \Theta_1 = \Theta$).

In the classical statistical framework of the frequentists, one uses the observed data to test the significance of a particular hypothesis, and (if possible) compute a *p* value (the probability, p , of observing a value equal to, or more extreme than, that of the test statistic if the null hypothesis is indeed correct). Initially, one would think that the idea of a hypothesis test is trivial in a Bayesian framework, as using the posterior distribution provides the expected *p* values directly, for example,

$$\Pr(\theta > \theta_0) = \int_{\theta_0}^{\infty} p(\theta | \mathbf{x}) d\theta \quad \text{and} \quad \Pr(\theta_0 < \theta < \theta_1) = \int_{\theta_0}^{\theta_1} p(\theta | \mathbf{x}) d\theta$$

The fault in this logic under a Bayesian framework is that we also have *prior information* and Bayesian hypothesis testing addresses whether, *given the data*, we are more or less inclined

to believe the hypothesis than was suggested from the prior. Hence, the *prior probabilities influence hypothesis testing*. To formalize this idea, let

$$p_0 = \Pr(\theta \in \Theta_0 | \mathbf{x}) \quad \text{and} \quad p_1 = \Pr(\theta \in \Theta_1 | \mathbf{x}) \quad (\text{A2.9a})$$

denote the probabilities, given the observed data, \mathbf{x} , that θ is in the null (p_0) and alternative (p_1) hypothesis sets. Note that these are *posterior* probabilities. Because $\Theta_0 \cap \Theta_1 = \emptyset$ and $\Theta_0 \cup \Theta_1 = \Theta$, it follows that $p_0 + p_1 = 1$. Likewise, for the *prior* probabilities we have

$$\pi_0 = \Pr(\theta \in \Theta_0) \quad \text{and} \quad \pi_1 = \Pr(\theta \in \Theta_1) \quad (\text{A2.9b})$$

Thus the **prior odds** of H_0 versus H_1 are π_0/π_1 , while the **posterior odds** are p_0/p_1 .

The **Bayes factor**, B_0 , in favor of H_0 versus H_1 is calculated by the ratio of the posterior odds divided by the prior odds,

$$B_0 = \frac{p_0/p_1}{\pi_0/\pi_1} = \frac{p_0\pi_1}{p_1\pi_0} \quad (\text{A2.10a})$$

The Bayes factor is loosely interpreted as the odds in favor of H_0 over H_1 as given by the data and our prior opinion. Because $\pi_1 = 1 - \pi_0$ and $p_1 = 1 - p_0$, we can also express this as

$$B_0 = \frac{p_0(1 - \pi_0)}{\pi_0(1 - p_0)} \quad (\text{A2.10b})$$

By symmetry, note that the Bayes factor, B_1 , in favor of H_1 versus H_0 is simply $B_1 = 1/B_0$.

Example A2.3. Suppose that the prior distribution of θ is such that $\Pr(\theta > \theta_0) = 0.10$, while for the posterior distribution $\Pr(\theta > \theta_0 | \mathbf{x}) = 0.05$. The latter is significant at the 5% level in a classical hypothesis-testing framework, but the data only doubles our confidence in the alternative hypothesis relative to our belief based on prior information. If $\Pr(\theta > \theta_0) = 0.50$ for the prior, then a 5% posterior probability would greatly increase our confidence in the alternative hypothesis. Consider the first case in this example, where the prior and posterior probabilities for the null were $\pi_0 = 0.1$ and $p_0 = 0.05$, respectively. The Bayes factor in favor of H_1 versus H_0 is

$$B_1 = \frac{\pi_0(1 - p_0)}{p_0(1 - \pi_0)} = \frac{0.1 \cdot 0.95}{0.05 \cdot 0.9} = 4.22$$

Similarly, for the second example, where the prior for the null was $\pi_0 = 0.5$,

$$B_1 = \frac{0.5 \cdot 0.95}{0.05 \cdot 0.5} = 19$$

Here, the data showed close to a 20-fold improvement (relative to the prior) in support of H_1 . Bayes factors and p values represent fundamentally different approaches to an analysis and are not formally comparable. However, a *loose* interpretation is that a factor of 20 is akin to the level of support of a $p = 0.05$, and a factor of 100 to $p = 0.01$.

When the hypotheses are simple (i.e., single values), say $\Theta_0 = \theta_0$ vs. $\Theta_1 = \theta_1$, then

$$p_i \propto p(\theta_i) p(\mathbf{x} | \theta_i) = \pi_i p(\mathbf{x} | \theta_i) \quad \text{for } i = 0, 1$$

Thus

$$\frac{p_0}{p_1} = \frac{\pi_0 p(\mathbf{x} | \theta_0)}{\pi_1 p(\mathbf{x} | \theta_1)} \quad (\text{A2.11a})$$

and from Equation A2.10a, the Bayes factor (in favor of the null) reduces to

$$B_0 = \frac{p(\mathbf{x} | \theta_0)}{p(\mathbf{x} | \theta_1)} \quad (\text{A2.11b})$$

which is simply a *likelihood ratio* (LW Appendix 4).

When hypotheses are **composite** (containing multiple elements), the situation is slightly more complicated. First, note that the prior distribution of θ conditioned on H_0 or H_1 is

$$p_i(\theta) = p(\theta)/\pi_i \quad \text{for } i = 0, 1 \quad (\text{A2.12})$$

as the total probability $\theta \in \Theta_i = \pi_i$, so dividing by π_i normalizes the distribution to integrate to one. Thus,

$$\begin{aligned} p_i &= \Pr(\theta \in \Theta_i | \mathbf{x}) = \int_{\theta \in \Theta_i} p(\theta | \mathbf{x}) d\theta \\ &= \frac{1}{p(\mathbf{x})} \int_{\theta \in \Theta_i} p(\theta) p(\mathbf{x} | \theta) d\theta \\ &= \pi_i \int_{\theta \in \Theta_i} p(\mathbf{x} | \theta) p_i(\theta) d\theta \end{aligned} \quad (\text{A2.13})$$

where the second step follows from Bayes' theorem, while the final step follows from Equation A2.12. The Bayes factor in favor of the null hypothesis becomes

$$B_0 = \left(\frac{p_0}{\pi_0} \right) \left(\frac{\pi_1}{p_1} \right) = \frac{\int_{\theta \in \Theta_0} p(\mathbf{x} | \theta) p_0(\theta) d\theta}{\int_{\theta \in \Theta_1} p(\mathbf{x} | \theta) p_1(\theta) d\theta} \quad (\text{A2.14})$$

which is a ratio of the weighted likelihoods of Θ_0 and Θ_1 .

THE CHOICE OF A PRIOR

Obviously, a critical feature of any Bayesian analysis is the choice of a prior. The key is that when the data have a sufficiently strong signal, even a poor choice of a prior will still not greatly influence the posterior. In a sense, it is an asymptotic (large-sample) property of Bayesian analysis in that all but pathological priors (those with zero probability where the true value lies) can be overcome by sufficient amounts of data. As mentioned above, one can check the impact of the prior by assessing the stability of posterior over a collection of diverse priors. The **location** of a parameter (mean or mode) and its **precision** (the reciprocal of the variance) of the prior is usually more critical than its actual shape in terms of conveying prior information. The shape (family) of the prior distribution is often chosen to facilitate calculation of the posterior, especially through the use of **conjugate priors** that, for a given likelihood function, return a posterior in the same distribution family as the prior (e.g., a gamma prior returns a gamma posterior when the likelihood is Poisson). We will return to conjugate priors, but first we will discuss other approaches for construction of priors.

Diffuse Priors

One of the most commonly used priors is the **flat** or **diffuse** (also called **uninformative** or **naive**) prior, which is simply a constant

$$p(\theta) = \frac{1}{b - a} \quad \text{for } a \leq \theta \leq b \quad (\text{A2.15a})$$

This conveys that we have no a priori reason to favor any particular parameter value over another. With a flat prior, the posterior is just a constant C times the likelihood

$$p(\theta | \mathbf{x}) = C \ell(\theta | \mathbf{x}) \quad (\text{A2.15b})$$

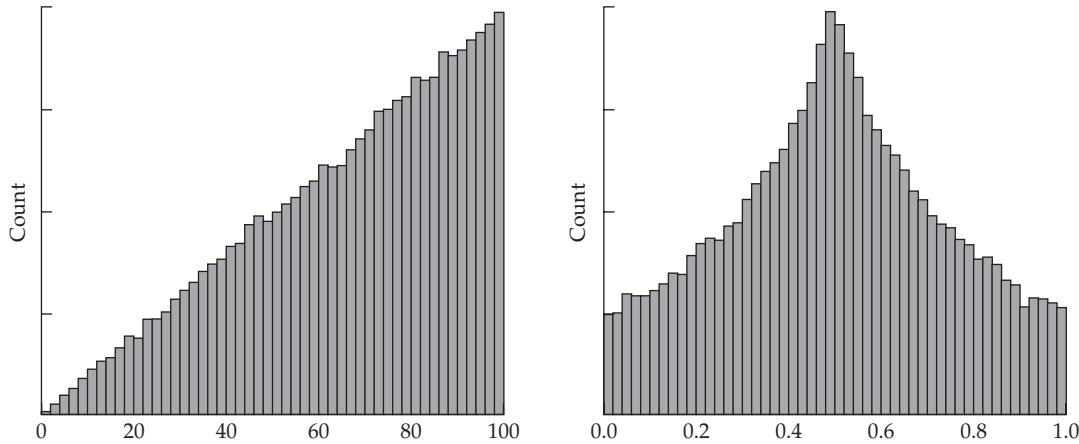

Figure A2.1 A uniform prior on one scale does not result in a flat prior on a transformed scale. Suppose a flat prior on $(0, 10000)$ is assumed for both the additive and residual variances. To mimic what happens under MCMC, we display these priors by using the resulting histograms generated from a large number of random draws, with a uniform expected to return a flat histogram. **Left:** The resulting prior for the standard deviation of either variance (the square root of a random draw). **Right:** The resulting prior for h^2 , the ratio of a random draw for the additive variance divided by this value plus a random draw for the residual variance. Neither of these priors result in a uniform prior (namely, a flat histogram) on the transformed scale.

and we typically write that $p(\theta | \mathbf{x}) \propto \ell(\theta | \mathbf{x})$. In many cases, classical expressions from frequentist statistics are obtained by Bayesian analysis through assuming a flat prior.

If the variable (i.e., parameter) of interest ranges over $(0, \infty)$ or $(-\infty, +\infty)$, then, strictly speaking, a flat prior does not exist as, if the constant takes on any nonzero value, the integral does not exist. In such cases a flat prior (i.e., assuming $p[\theta | \mathbf{x}] \propto \ell[\theta | \mathbf{x}]$) is referred to as an **improper prior**, and care must be taken to ensure that the product of the prior and the likelihood results in a proper posterior (i.e., $\ell[\theta | \mathbf{x}]$ has a finite integral over the parameter range). This is by no means certain.

Another complication involved in using a uniform prior arises when the question of interest resides on a *different scale* than that used for the prior. A variable uniform on one scale may be far from uniform on a transformed scale. Figure A2.1 shows two examples based on the assumption that there was a flat prior on the variance. A uniform prior on the variance does *not* result in a uniform prior on the standard deviation (e.g., Van Dongen 2006). Likewise, if one assumes that the additive and residual variances have flat priors, this does not imply a flat prior for h^2 , but rather a prior that is sharply peaked at 1/2. When assuming a flat prior, care must be taken that it is truly uninformative on the appropriate scale of biological interest. Otherwise, the choice of what superficially appears as an unbiased prior may instead create a bias that the signal in the data must overcome.

The Jeffreys Prior

Jeffreys (1961) proposed a general prior based on the Fisher information information, I , of the likelihood. Recall (LW Appendix 4) that

$$I(\theta | \mathbf{x}) = -E \left[\frac{\partial^2 \ln \ell(\theta | \mathbf{x})}{\partial \theta^2} \right]$$

The **Jeffreys prior** is as follows:

$$p(\theta) \propto \sqrt{I(\theta | \mathbf{x})} \quad (\text{A2.16})$$

A full discussion, with derivation, can be found in Lee (2012).

When there are k parameters, \mathbf{I} is the $k \times k$ Fisher information matrix of the expected second partials, where the elements of \mathbf{I} are calculated by

$$\mathbf{I}(\boldsymbol{\Theta} | \mathbf{x})_{ij} = -E_x \left[\frac{\partial^2 \ln \ell(\boldsymbol{\Theta} | \mathbf{x})}{\partial \theta_i \partial \theta_j} \right]$$

In this case, the Jeffreys prior becomes

$$p(\boldsymbol{\Theta}) \propto \sqrt{\det[\mathbf{I}(\boldsymbol{\Theta} | \mathbf{x})]} \quad (\text{A2.17})$$

Example A2.4. Consider the likelihood of x successes in n independent draws from a binomial with a success parameter of θ ,

$$\ell(\theta | \mathbf{x}) = C\theta^x(1-\theta)^{n-x}$$

where the constant C does not involve θ . Taking logs gives

$$L(\theta | \mathbf{x}) = \ln [\ell(\theta | \mathbf{x})] = \ln C + x \ln \theta + (n-x) \ln(1-\theta)$$

Thus

$$\frac{\partial L(\theta | \mathbf{x})}{\partial \theta} = \frac{x}{\theta} - \frac{n-x}{1-\theta}$$

and likewise

$$\frac{\partial^2 L(\theta | \mathbf{x})}{\partial \theta^2} = -\frac{x}{\theta^2} - (-1) \cdot (-1) \frac{n-x}{(1-\theta)^2} = -\left(\frac{x}{\theta^2} + \frac{n-x}{(1-\theta)^2}\right)$$

Because $E[x] = n\theta$, then

$$-E\left[\frac{\partial^2 \ln \ell(\theta | \mathbf{x})}{\partial \theta^2}\right] = \frac{n\theta}{\theta^2} + \frac{n(1-\theta)}{(1-\theta)^2} = n\theta^{-1}(1-\theta)^{-1}$$

The resulting Jeffreys prior for this likelihood becomes

$$p(\theta) \propto \sqrt{\theta^{-1}(1-\theta)^{-1}} \propto \theta^{-1/2}(1-\theta)^{-1/2}$$

which is a U-shaped beta distribution with parameters $\alpha = \beta = 1/2$ (Equation A2.38a). This prior puts more weight on extreme values relative to assuming a uniform over $(0,1)$, see Figure A2.3.

Example A2.5. Suppose our data consists of n independent draws from a normal distribution with an unknown mean and variance, μ and σ^2 . In LW Appendix 4, we showed that the information matrix in this case is

$$\mathbf{I} = n \begin{pmatrix} \frac{1}{\sigma^2} & 0 \\ 0 & \frac{1}{2\sigma^4} \end{pmatrix}$$

Because the determinant of a diagonal matrix is the product of the diagonal elements, $\det(\mathbf{I}) \propto \sigma^{-6}$, giving the Jeffreys prior for μ and σ^2 as

$$p(\boldsymbol{\Theta}) \propto \sqrt{\sigma^{-6}} = \sigma^{-3}$$

Because the joint prior does not involve μ , this implies a flat prior for μ (i.e., $p[\mu] = c$). Note here that the prior distributions of μ and σ^2 are independent, as

$$p(\mu, \theta) = c \cdot \sigma^{-3} = p(\mu) \cdot p(\sigma^2)$$

POSTERIOR DISTRIBUTIONS UNDER NORMALITY ASSUMPTIONS

To introduce the basic ideas of Bayesian analysis, as well as treating a common assumption in quantitative genetics, consider the case where data are drawn from a normal (Gaussian) distribution, giving the likelihood function for the i th observation, x_i , as

$$\ell(\mu, \sigma^2 | x_i) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left(-\frac{(x_i - \mu)^2}{2\sigma^2}\right) \quad (\text{A2.18a})$$

If we assume independence, the resulting full likelihood for all n data points (with a sample mean of \bar{x}) is

$$\ell(\mu | \mathbf{x}) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left(-\sum_{i=1}^n \frac{(x_i - \mu)^2}{2\sigma^2}\right) \quad (\text{A2.18b})$$

$$= \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left[-\frac{1}{2\sigma^2} \left(\sum_{i=1}^n x_i^2 - 2\mu n \bar{x} + n\mu^2\right)\right] \quad (\text{A2.18c})$$

The form of the posteriors given these normal likelihoods is a function of the assumed priors. By using the appropriate conjugate priors, these posteriors follow fairly standard distributions, and hence are easier to work with, as we now demonstrate.

Gaussian Likelihood With Known Variance and Unknown Mean

As a starting point, assume that the variance, σ^2 , is known, while the mean, μ , is unknown. For a Bayesian analysis, it remains to specify the prior for μ , $p(\mu)$. Suppose we assume a Gaussian prior, $\mu \sim N(\mu_0, \sigma_0^2)$, with

$$p(\mu) = \frac{1}{\sqrt{2\pi\sigma_0^2}} \exp\left(-\frac{(\mu - \mu_0)^2}{2\sigma_0^2}\right) \quad (\text{A2.19})$$

The mean and variance of the prior, μ_0 and σ_0^2 , are referred to as **hyperparameters**. Here, μ_0 specifies a prior location for the parameter (the unknown mean, μ), while σ_0^2 specifies our uncertainty in this prior location—the larger σ_0^2 , the greater is our uncertainty. In the limit as $\sigma_0^2 \rightarrow \infty$, $p(\mu)$ approaches a flat (and in this case, improper) prior.

A useful device when calculating the posterior distribution is to ignore terms that are constants with respect to the unknown parameters. Suppose \mathbf{x} denotes the data and $\boldsymbol{\Theta}_1$ is a vector of *known* model parameters, while $\boldsymbol{\Theta}_2$ is a vector of unknown parameters. If we can write the posterior as

$$p(\boldsymbol{\Theta}_2 | \mathbf{x}, \boldsymbol{\Theta}_1) = f(\mathbf{x}, \boldsymbol{\Theta}_1) \cdot g(\mathbf{x}, \boldsymbol{\Theta}_1, \boldsymbol{\Theta}_2) \quad (\text{A2.20a})$$

then

$$p(\boldsymbol{\Theta}_2 | \mathbf{x}, \boldsymbol{\Theta}_1) \propto g(\mathbf{x}, \boldsymbol{\Theta}_1, \boldsymbol{\Theta}_2) \quad (\text{A2.20b})$$

which follows since $f(\mathbf{x}, \boldsymbol{\Theta}_1)$ is constant with respect to $\boldsymbol{\Theta}_2$.

With the prior given by Equation A2.19, we can express the resulting posterior distribution as

$$\begin{aligned} p(\mu | \mathbf{x}) &\propto \ell(\mu | \mathbf{x}) \cdot p(\mu) \\ &\propto \exp \left[-\frac{(\mu - \mu_0)^2}{2\sigma_0^2} - \frac{1}{2\sigma^2} \left(\sum_{i=1}^n x_i^2 - 2\mu n\bar{x} + n\mu^2 \right) \right] \end{aligned} \quad (\text{A2.21a})$$

We can factor out additional terms not involving μ to obtain

$$p(\mu | \mathbf{x}) \propto \exp \left(-\frac{\mu^2}{2\sigma_0^2} + \frac{\mu \mu_0}{\sigma_0^2} + \frac{\mu n\bar{x}}{\sigma^2} - \frac{n\mu^2}{2\sigma^2} \right) \quad (\text{A2.21b})$$

Factoring in terms of μ , the term in the exponential becomes

$$-\frac{\mu^2}{2} \left(\frac{1}{\sigma_0^2} + \frac{n}{\sigma^2} \right) + \mu \left(\frac{\mu_0}{\sigma_0^2} + \frac{n\bar{x}}{\sigma^2} \right) = -\frac{\mu^2}{\sigma_*^2} + \frac{2\mu\mu_*}{2\sigma_*^2} \quad (\text{A2.22a})$$

where

$$\sigma_*^2 = \left(\frac{1}{\sigma_0^2} + \frac{n}{\sigma^2} \right)^{-1} \quad \text{and} \quad \mu_* = \sigma_*^2 \left(\frac{\mu_0}{\sigma_0^2} + \frac{n\bar{x}}{\sigma^2} \right) \quad (\text{A2.22b})$$

Finally, by completing the square, we have

$$p(\mu | \mathbf{x}) \propto \exp \left[-\frac{(\mu - \mu_*)^2}{2\sigma_*^2} + f(\mathbf{x}, \mu_0, \sigma^2, \sigma_0^2) \right] \quad (\text{A2.22c})$$

Recalling Equation A2.20b, we can ignore the second term in the exponential (as it does not involve μ), and the resulting posterior for μ (given the observed data \mathbf{x}) becomes

$$p(\mu | \mathbf{x}) \propto \exp \left[-\frac{(\mu - \mu_*)^2}{2\sigma_*^2} \right] \quad (\text{A2.23a})$$

demonstrating that the posterior density function for μ is a normal with a mean of μ_* and a variance of σ_*^2 , namely,

$$\mu | (\mathbf{x}, \sigma^2) \sim N(\mu_*, \sigma_*^2) \quad (\text{A2.23b})$$

Notice that the posterior density is in the same form as the prior. This occurred because the prior **conjugated** with the likelihood function—the product of the prior and likelihood returned a distribution in the same family as the prior (but with different distribution parameters). The use of such **conjugate priors** associated with a given family of likelihood functions is a key concept in Bayesian analysis, and we will explore it more fully below.

We are now in a position to inquire about the relative importance of the prior versus the data. Under the assumed prior, the mean (and in this case, the mode as well) of the posterior distribution is

$$\mu_* = \mu_0 \frac{\sigma_*^2}{\sigma_0^2} + \bar{x} \frac{\sigma_*^2}{\sigma^2/n} \quad (\text{A2.24})$$

With a very diffuse prior on μ (i.e., $\sigma_0^2 \gg \sigma^2$), $\sigma_*^2 \rightarrow \sigma^2/n$ and $\mu_* \rightarrow \bar{x}$. Also note from Equation A2.22b that as we collect enough data (i.e., achieve a sufficiently large value of n), $\sigma_*^2 \rightarrow \sigma^2/n$ and again $\mu_* \rightarrow \bar{x}$, implying that primarily the data, rather than the prior, will influence the posterior when the value of n is sufficiently large.

Gamma, χ^2 , Inverse-gamma, and χ^{-2} Distributions

Before examining the Gaussian likelihood with unknown variance, a brief aside is needed to develop the **inverse chi-square distribution**, denoted by χ^{-2} . We do this via the gamma and inverse-gamma distributions, as both χ^2 and χ^{-2} are special cases of these distributions.

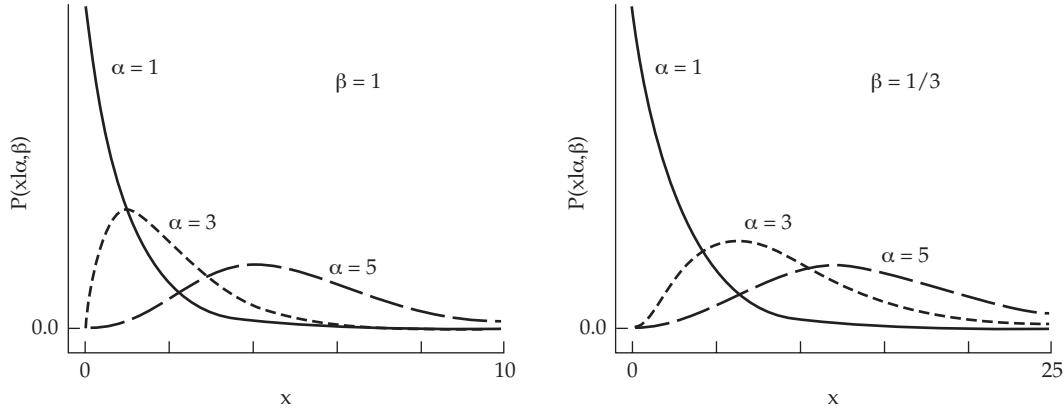

Figure A2.2 The effect of the **shape** (α) and **rate** ($\beta = 1/\lambda$, the inverse of the **scale**) **parameters** on the gamma distribution function. For $\alpha = 1$, the resulting distribution is the simple monotonically decreasing exponential, while for $\alpha > 1$, the distribution is unimodal. The effect of a change in the rate or scale is to keep the general shape but change the scaling with respect to x .

To motivate the **gamma distribution**, first consider the simple exponential waiting-time distribution, where β is the **rate** (the probability of a success in some small time unit, δ_t , is given by $\beta \delta_t$), then the **probability density function (pdf)** for the exponential is

$$p(x | \beta) = \beta e^{-\beta x} \quad \text{for } 0 \leq x < \infty, \quad \beta > 0$$

Because the expected waiting time until a success is $\lambda = 1/\beta$, this can be reparameterized in terms of the **scale** (waiting time) **parameter** as

$$p(x | \beta) = \lambda^{-1} e^{-x/\lambda}$$

The sum of k exponentials with the same rate (or scale) parameter is called an **Erlang distribution**, and it was initially developed for certain problems in telephone queuing theory. Expressed in terms of the rate parameter, the resulting pdf becomes

$$p(x | k, \beta) = \frac{\beta^k}{(k-1)!} x^{k-1} e^{-\beta x} \quad \text{for } 0 \leq x < \infty$$

where the integer k is called the **shape parameter**, with $k = 1$ recovering the exponential.

The gamma distribution follows by allowing the shape parameter to be any positive number, α , with $x \sim \text{Gamma}(\alpha, \beta)$ having its pdf defined by its shape (α) and rate (β) values,

$$p(x | \alpha, \beta) = \frac{\beta^\alpha}{\Gamma(\alpha)} x^{\alpha-1} e^{-\beta x} \quad \text{for } \alpha, \beta, x > 0 \quad (\text{A2.25a})$$

Note that the factorial in the Erlang is replaced by the gamma function, $\Gamma(x)$, which is defined below (Equation A2.26a). Figure A2.2 shows how changes in these two parameters influence the shape of the distribution. Note that, as a function of x ,

$$p(x | \alpha, \beta) \propto x^{\alpha-1} e^{-\beta x} \quad (\text{A2.25b})$$

When expressed in terms of the scale ($\lambda = 1/\beta$) parameter, the pdf becomes

$$p(x | \alpha, \lambda) = \frac{\lambda^{-\alpha}}{\Gamma(\alpha)} x^{\alpha-1} e^{-x/\lambda}$$

Table A2.1 Summary of the functional forms (in terms of x) of various gamma-related distributions. See the text for further details.

Distribution	α	β	$p(x)/\text{constant}$
Gamma (α, β)			$x^{\alpha-1}e^{-\beta x}$
Chi-square, χ_n^2	$n/2$	$1/2$	$x^{n/2-1}e^{-x/2}$
Inverse-gamma (α, β)			$x^{-(\alpha+1)}e^{-\beta/x}$
Inverse chi-square, χ_n^{-2}	$n/2$	$1/2$	$x^{-(n/2+1)}e^{-1/(2x)}$
Scaled inverse chi-square, $\chi_{(n,\sigma_0^2)}^{-2}$	$n/2$	$\sigma_0^2/2$	$x^{-(n/2+1)}e^{-\sigma_0^2/(2x)}$

which yields

$$p(x | \alpha, \lambda) \propto x^{\alpha-1}e^{-x/\lambda} \quad (\text{A2.25c})$$

Because both the rate and scale versions of the gamma distribution are widely used, take care to know which version your software package is using (for example, the default in R uses the scale parameter version). We can parameterize a gamma in terms of its mean and variance by noting that

$$\mu_x = \frac{\alpha}{\beta} = \alpha \lambda \quad \text{and} \quad \sigma_x^2 = \frac{\alpha}{\beta^2} = \alpha \lambda^2 \quad (\text{A2.25d})$$

so that

$$\alpha = \frac{\mu_x^2}{\sigma_x^2} \quad \text{and} \quad \beta = \frac{\mu_x}{\sigma_x^2} \quad (\text{A2.25e})$$

$\Gamma(\alpha)$, the **gamma function** evaluated at α (which normalizes the gamma distribution), is defined by

$$\Gamma(\alpha) = \int_0^\infty y^{\alpha-1}e^{-y}dy \quad \text{for } \alpha > 0 \quad (\text{A2.26a})$$

This is the generalization of the factorial function from the integers to any positive number. If n is an integer, then $\Gamma(n) = (n - 1)!$ Using integration by parts, one can show that Γ satisfies the following identities

$$\Gamma(\alpha + 1) = \alpha\Gamma(\alpha), \quad \Gamma(1) = 1, \quad \text{and} \quad \Gamma(1/2) = \sqrt{\pi} \quad (\text{A2.26b})$$

The chi-square (χ^2) distribution is a special case of the gamma, as a χ^2 random variable with n degrees of freedom follows a gamma distribution with parameters $\alpha = n/2$ and $\beta = 1/2$ ($\lambda = 2$), namely, $\chi_n^2 \sim \text{Gamma}(n/2, 1/2)$, giving the density function as

$$p(x | n) = \frac{2^{-n/2}}{\Gamma(n/2)} x^{n/2-1}e^{-x/2} \quad (\text{A2.27a})$$

Hence for $x \sim \chi_n^2$,

$$p(x) \propto x^{n/2-1}e^{-x/2} \quad (\text{A2.27b})$$

The **inverse-gamma** distribution will prove useful as a conjugate prior for Gaussian likelihoods with unknown variance. It is defined by the distribution of the random variable $y = x^{-1}$, where $x \sim \text{Gamma}(\alpha, \beta)$. The resulting density function is

$$p(x | \alpha, \beta) = \frac{\beta^\alpha}{\Gamma(\alpha)} x^{-(\alpha+1)}e^{-\beta/x} \quad \text{for } \alpha, \beta, x > 0 \quad (\text{A2.28a})$$

The mean and variance for this distribution are only defined (i.e., finite) if α is sufficiently large, with

$$\mu_x = \frac{\beta}{\alpha - 1} \quad \text{for } \alpha > 1 \quad \text{and} \quad \sigma_x^2 = \frac{\beta^2}{(\alpha - 1)^2(\alpha - 2)} \quad \text{for } \alpha > 2 \quad (\text{A2.28b})$$

Note for the inverse gamma that

$$p(x | \alpha, \beta) \propto x^{-(\alpha+1)} e^{-\beta/x} \quad (\text{A2.28c})$$

If $y \sim \chi_n^2$, then $x = 1/y$ follows an **inverse chi-square distribution**, which is denoted by $x \sim \chi_n^{-2}$. This is a special case of the inverse gamma, with (as for a normal χ^2) $\alpha = n/2$, $\beta = 1/2$. For $n > 4$ (i.e., $\alpha > 2$), the resulting density function is

$$p(x | n) = \frac{2^{-n/2}}{\Gamma(n/2)} x^{-(n/2+1)} e^{-1/(2x)} \quad (\text{A2.29a})$$

with a mean and variance of

$$\mu_x = \frac{1}{n-2} \quad \text{and} \quad \sigma_x^2 = \frac{2}{(n-2)^2(n-4)} \quad (\text{A2.29b})$$

The **scaled inverse chi-square distribution** is more typically used in a Bayesian analysis, where the rate parameter, β (which equals 1/2 under a chi-square), is replaced by $\beta = \sigma_0^2/2$, making the resulting pdf

$$p(x | n) \propto x^{-(n/2+1)} e^{-\sigma_0^2/(2x)} \quad (\text{A2.30a})$$

where the $1/(2x)$ term in the exponential is replaced by a $\sigma_0^2/(2x)$ term. The scaled inverse chi-square distribution thus involves two parameters (σ_0^2 and n), and is denoted by $\chi_{(n, \sigma_0^2)}^{-2}$ or $\text{SI}-\chi^2(n, \sigma_0^2)$. Note that if

$$x \sim \chi_{(n, \sigma_0^2)}^{-2}, \quad \text{then} \quad \sigma_0^2 x \sim \chi_n^{-2} \quad (\text{A2.30b})$$

which shows that σ_0^2 is a scaling factor on a standard ($\beta = 1/2$) inverse chi-square.

Gaussian Likelihood With Unknown Variance: Scaled Inverse- χ^2 Priors

Suppose data are drawn from a normal distribution with a known mean, μ , but unknown variance, σ^2 . The resulting likelihood function can be expressed as

$$\ell(\sigma^2 | \mathbf{x}, \mu) \propto (\sigma^2)^{-n/2} \exp\left(-\frac{nS^2}{2\sigma^2}\right) \quad (\text{A2.31a})$$

where

$$S^2 = \frac{1}{n} \sum_{i=1}^n (x_i - \mu)^2 \quad (\text{A2.31b})$$

Notice that since we condition on \mathbf{x} and μ (i.e., their values are known), S^2 is a constant. Further observe that, as a function of the unknown variance, σ^2 , the likelihood is proportional to a scaled inverse χ^2 distribution (Equation A2.30a). If we take the prior for the unknown variance also as a scaled inverse χ^2 with hyperparameters ν_0 and σ_0^2 , the posterior becomes

$$\begin{aligned} p(\sigma^2 | \mathbf{x}, \mu) &\propto (\sigma^2)^{-n/2} \exp\left(-\frac{nS^2}{2\sigma^2}\right) (\sigma^2)^{-\nu_0/2-1} \cdot \exp\left(-\frac{\sigma_0^2}{2\sigma^2}\right) \\ &= (\sigma^2)^{-(n+\nu_0)/2-1} \exp\left(-\frac{nS^2 + \sigma_0^2}{2\sigma^2}\right) \end{aligned} \quad (\text{A2.32a})$$

Equation A2.30a shows the resulting posterior is also a scaled inverse χ^2 distribution with parameters $\nu_n = (n + \nu_0)$ and $\sigma_n^2 = (nS^2 + \sigma_0^2)$. Hence,

$$\text{the prior } \sigma^2 \sim \chi_{\nu_0, \sigma_0^2}^{-2} \text{ yields the posterior } \sigma^2 | (\mathbf{x}, \mu) \sim \chi_{\nu_n, \sigma_n^2}^{-2} \quad (\text{A2.32b})$$

Student's t Distribution

The final distribution needed for a Bayesian analysis of a Gaussian likelihood is the t (or **Student's t**) distribution. Suppose that $x_i \sim N(\mu, \sigma^2)$, so for n independent draws, $\bar{x} \sim N(\mu, \sigma^2/n)$. This implies that $(\bar{x} - \mu)/\sqrt{\sigma^2/n} \sim U$, where $U \sim N(0, 1)$ denotes a unit normal. Likewise, the sample variance, $\text{Var}(x)$, follows a scaled chi-square distribution, with $\text{Var}(x) \sim (n-1)\sigma^2\chi_{n-1}^2$ (LW Equation A5.14c). When the estimated variance, $\text{Var}(x)$, is used in place of the true variance, σ^2 , the quantity $(\bar{x} - \mu)/\sqrt{\text{Var}(x)/n}$ follows a t distribution with $n - 1$ degrees of freedom, giving rise to the very familiar **t -test**. Notice that

$$t_{n-1} = \left(\frac{\bar{x} - \mu}{\sigma/\sqrt{n}} \right) \left(\frac{1}{\sqrt{\text{Var}(x)/\sigma^2}} \right) = \frac{U}{\sqrt{\chi_{n-1}^2/(n-1)}}$$

Thus, a t_ν random variable follows the distribution of a unit normal divided by the square root of a chi-square with ν degrees of freedom,

$$t_\nu = \frac{U}{\sqrt{\chi_\nu^2/\nu}} \quad (\text{A2.33a})$$

Note that $E(\chi_\nu^2) = \nu$, so $E(\chi_\nu^2/\nu) = 1$. Relative to a normal, a t distribution is more peaked and has heavier tails, and this kurtosis becomes more pronounced as ν decreases. Indeed, the tails fall off sufficiently slowly that a t random variable with two degrees of freedom has an infinite variance, while a t with four (or fewer) degrees of freedom has an infinite fourth moment. The coefficient of kurtosis (LW Equation 2.12a) for a t with $\nu > 4$ degrees of freedom is $k_4 = 6/(\nu - 4)$, which approaches the value (zero) for a normal random variable for large values of ν . For $\nu > 30$, the t essentially becomes a unit normal distribution.

As with a unit normal, one can also add scale and location to a standard t_ν -distributed random variable, thus generating a three-parameter family of distributions,

$$t_\nu(\mu, \sigma) = \mu + \sigma \cdot t_\nu \quad (\text{A2.33b})$$

The resulting mean and variance this distribution are

$$E[t_\nu(\mu, \sigma)] = \mu \quad \text{and} \quad \sigma^2[t_\nu(\mu, \sigma)] = \sigma^2 \frac{\nu}{\nu - 2} \quad \text{for } \nu > 2 \quad (\text{A2.33c})$$

Hence, the choice of μ and σ control, respectively, the location and scale (uncertainty about the location), while ν controls the kurtosis, with heavy tails for values of ν that are small and little kurtosis for $\nu > 20$. The resulting probability density function thus becomes

$$p(x | \nu, \mu, \sigma) = \frac{\Gamma([\nu + 1]/2)}{\Gamma(\nu/2)\sigma\sqrt{\pi\nu}} \left[1 + \frac{1}{\nu} \left(\frac{x - \mu}{\sigma} \right)^2 \right]^{-(\nu+1)/2} \quad (\text{A2.33d})$$

The role of the t distribution in Bayesian statistics is twofold. First, it is often used as a *more robust prior*, as its heavier tails may better account for outliers. Using a t distribution with low degrees of freedom (often $\nu = 5$) offers a prior that is similar to a normal but allows for more frequent extreme values. The second scenario is that the marginal posterior for μ of a Gaussian likelihood with a normal prior on the mean and an inverse chi-square prior on the variance is a t distribution. This arises after the joint posterior is integrated over all possible σ^2 values (i.e., over an inverse chi-square).

General Gaussian Likelihood: Unknown Mean and Variance

If we put all these pieces together, the posterior density for draws from a normal with unknown mean and variance is obtained as follows. First, we write the joint prior by conditioning on the variance,

$$p(\mu, \sigma^2) = p(\mu | \sigma^2) \cdot p(\sigma^2) \quad (\text{A2.34a})$$

Table A2.2 Conjugate priors for common likelihood functions. If one uses the distribution family of the conjugate prior with its paired likelihood function, then the resulting posterior is in the same distribution family as the prior (albeit, of course, with different parameters).

Likelihood	Conjugate prior	Equation
Binomial	Beta	A2.38a
Multinomial	Dirichlet	A2.37b
Poisson	Gamma	A2.27a
Normal		
μ unknown, σ^2 known	Normal	A2.18a
μ known, σ^2 unknown	Inverse chi-square	A2.30a
Multivariate normal		
μ unknown, \mathbf{V} known	Multivariate normal	LW 8.24
μ known, \mathbf{V} unknown	Inverse-Wishart	A2.41

As above, we assume a scaled inverse chi-square distribution for the variance and, conditioned on the variance, a Gaussian prior for the mean with hyperparameters of μ_0 and σ^2/κ_0 , namely,

$$\sigma^2 \sim \chi_{\nu_0, \sigma_0^2}^{-2} \quad \text{and} \quad \mu | \sigma^2 \sim N\left(\mu_0, \frac{\sigma^2}{\kappa_0}\right) \quad (\text{A2.34b})$$

We write the variance for the conditional mean prior in this way because σ^2 is known (as we condition on it) and we scale σ^2 by the hyperparameter, κ_0 . The resulting marginal posterior becomes

$$\sigma^2 | \mathbf{x} \sim \chi_{\nu_n, \sigma_n^2}^{-2} \quad \text{and} \quad \mu | \mathbf{x} \sim t_{\nu_n}\left(\mu_n, \frac{\sigma_n^2}{\kappa_n}\right) \quad (\text{A2.35})$$

where $t_n(\mu, \sigma^2)$ denotes a t distribution with n degrees of freedom, mean μ , and scale parameter σ^2 , and where

$$\nu_n = \nu_0 + n, \quad \kappa_n = \kappa_0 + n \quad (\text{A2.36a})$$

$$\mu_n = \mu_0 \frac{\kappa_0}{\kappa_n} + \bar{x} \frac{n}{\kappa_n} = \mu_0 \frac{\kappa_0}{\kappa_0 + n} + \bar{x} \frac{n}{\kappa_0 + n} \quad (\text{A2.36b})$$

$$\sigma_n^2 = \frac{1}{\nu_n} \left(\nu_0 \sigma_0^2 + \sum_{i=1}^n (x_i - \bar{x})^2 + \frac{\kappa_0 n}{\kappa_n} (\bar{x} - \mu_0)^2 \right) \quad (\text{A2.36c})$$

CONJUGATE PRIORS

The use of a prior density that conjugates the likelihood allows us to develop analytic expressions of the posterior density. As we will see in Appendix 3, this is critical in developing Gibbs samplers for problems of interest. Table A2.2 summarizes the conjugate priors for several common likelihood functions, with the various families of distributions discussed below.

The Beta and Dirichlet Distributions

With a binomial, each trial (observation) has two possible outcomes and the likelihood is a function of the sample size (number of trials), n , and a single success probability, p (as the two outcomes on any given trial have probabilities of p and $1 - p$). The generalization of this model is the **multinomial distribution**, where now each trial has k possible outcomes, and which requires $k - 1$ success probabilities to describe the likelihood. In particular, for a total of n observations, the probability that n_1 are in category 1, n_2 in category 2, \dots , and n_k in category k is

$$p(n_1, \dots, n_k) = \frac{n!}{n_1! n_2! \dots n_k!} p_1^{n_1} \dots p_k^{n_k} \quad \text{where} \quad \sum_i n_i = n \quad \text{and} \quad \sum_i p_i = 1 \quad (\text{A2.37a})$$

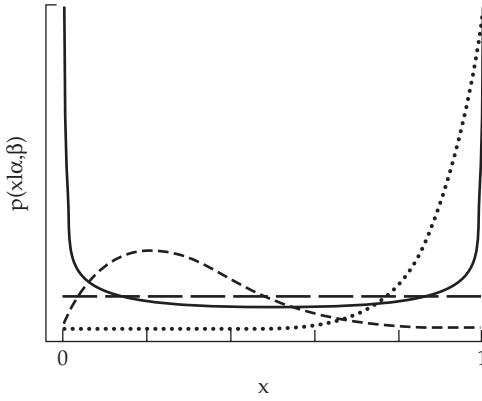

Figure A2.3 For $\alpha = \beta = 1$ (long-dashed curve), the beta distribution is simply the uniform distribution over $(0, 1)$. The pdf for the beta distribution can also be U-shaped ($\alpha = \beta = 0.5$; solid curve), unimodal ($\alpha = 2, \beta = 5$; short-dashed curve), or L-shaped ($\alpha = 10, \beta = 1$; dotted curve). Because the beta distribution is symmetric in α and β , switching their parameter values generates a distribution of the same shape translated about 0.5.

The conjugate prior for the multinomial likelihood is the **Dirichlet distribution**. If we let $\mathbf{x} = (x_1, x_2, \dots, x_k)$ denote the k success probabilities, when pdf for $\mathbf{x} \sim \text{Dirichlet}(\alpha_1, \dots, \alpha_k)$ is

$$p(x_1, \dots, x_k | \alpha_1, \dots, \alpha_k) = \frac{\Gamma(\alpha_0)}{\Gamma(\alpha_1) \dots \Gamma(\alpha_k)} x_1^{\alpha_1-1} \dots x_k^{\alpha_k-1} \quad (\text{A2.37b})$$

where

$$\alpha_0 = \sum_{i=1}^k \alpha_i \quad \text{with} \quad \alpha_i > 0, \quad \text{and} \quad \sum_{i=1}^k x_i = 1 \quad \text{with} \quad 0 \leq x_i \leq 1 \quad (\text{A2.37c})$$

At first glance, this looks like the multinomial density function (with $\alpha_i - 1 = n_i$). The difference is that the multinomial is calculated over a set of discrete random variables (n_i), thus returning the expected probabilities for any vector of discrete numbers of counts (successes) in each category. Conversely, the Dirichlet treats an equivalent of the vector of outcomes (generalized to non-integers) as fixed and returns the continuous distribution for all possible configurations of the success parameters given this data, which means that the data (α_i) is fixed, and the success parameters (x_i) are random. A few key moments of this distribution are

$$\mu_{x_i} = \frac{\alpha_i}{\alpha_0}, \quad \sigma^2(x_i) = \frac{\alpha_i(\alpha_0 - \alpha_i)}{\alpha_0^2(\alpha_0 + 1)}, \quad \text{and} \quad \sigma(x_i, x_j) = -\frac{\alpha_i \alpha_j}{\alpha_0^2(\alpha_0 + 1)} \quad (\text{A2.37d})$$

An important special case of the Dirichlet (for $k = 2$ classes) is the **beta distribution**, whose pdf is given by

$$p(x) = \frac{\Gamma(\alpha + \beta)}{\Gamma(\alpha)\Gamma(\beta)} x^{\alpha-1} (1-x)^{\beta-1} \quad \text{for} \quad 0 \leq x \leq 1, \quad \alpha, \beta > 0 \quad (\text{A2.38a})$$

which has a mean and a variance of

$$\mu = \frac{\alpha}{\alpha + \beta} \quad \text{and} \quad \sigma^2 = \frac{\alpha\beta}{(\alpha + \beta)^2(\alpha + \beta - 1)} \quad (\text{A2.38b})$$

As Figure A2.3 illustrates, the beta distribution is *extremely flexible*, and can be flat, unimodal, U-, or L-shaped, depending on the choice of α and β .

Wishart and Inverse-Wishart Distributions

The **Wishart distribution** can be thought of as the multivariate extension of the χ^2 distribution. Suppose $\mathbf{x}_1, \dots, \mathbf{x}_n$ are independent and identically distributed vectors, with $\mathbf{x}_i \sim \text{MVN}_k(\mathbf{0}, \mathbf{V})$. Using these n draws, and assuming that the mean is known to be zero, the resulting random ($k \times k$ symmetric, positive definite) sample covariance matrix, \mathbf{W} , is given by

$$\mathbf{W} = \sum_{i=1}^n \mathbf{x}_i \mathbf{x}_i^T \sim W_n(\mathbf{V}) \quad (\text{A2.39})$$

This sum is defined as a Wishart distribution with n degrees of freedom and a (matrix) parameter \mathbf{V} . Recalling that the sum of n squared unit normals follows a χ_n^2 distribution, the Wishart is the extension to the multivariate normal. Indeed, for $k = 1$ with $\mathbf{V} = (1)$, the Wishart is simply a χ_n^2 distribution, as $\sum x_i^2 \sim \chi_n^2$, because $x_i \sim N(0, 1)$.

The Wishart is the sampling distribution for covariance matrices (just like the χ^2 is associated with the distribution of a sample variance for data drawn from a normal; Chapter 11). The pdf of the Wishart distribution is

$$p(\mathbf{W} | \mathbf{V}) = 2^{-nk/2} \pi^{-k(k-1)/k} |\mathbf{V}|^{-n/2} |\mathbf{W}|^{(n+k+1)/2} \frac{\exp\left(-\frac{1}{2}\text{tr}[\mathbf{V}^{-1}\mathbf{W}]\right)}{\prod_{i=1}^k \Gamma\left(\frac{n+1-i}{2}\right)} \quad (\text{A2.40})$$

Recall that the trace (tr) of a matrix is just the sum of its diagonal elements, $\text{tr}(\mathbf{A}) = \sum A_{ii}$ (Appendix 5). Odell and Feiveson (1966) presented an algorithm for generating random draws from the Wishart.

If $\mathbf{Z} \sim W_n(\mathbf{V})$, then $\mathbf{Z}^{-1} \sim W_n^{-1}(\mathbf{V}^{-1})$, where \mathbf{W}^{-1} denotes the **inverse-Wishart distribution**. The density function for an inverse-Wishart distributed random matrix, \mathbf{W} , is

$$p(\mathbf{W} | \mathbf{V}) = 2^{-nk/2} \pi^{-k(k-1)/k} |\mathbf{V}|^{n/2} |\mathbf{W}|^{-(n+k+1)/2} \frac{\exp\left(-\frac{1}{2}\text{tr}[\mathbf{V}\mathbf{W}^{-1}]\right)}{\prod_{i=1}^k \Gamma\left(\frac{n+1-i}{2}\right)} \quad (\text{A2.41})$$

which is the distribution of the inverse of the sample covariance matrix.

Appendix 3

Markov Chain Monte Carlo and Gibbs Sampling

Far better an approximate answer to the right question, which is often vague, than an exact answer to the wrong question, which can always be made precise. Tukey (1962)

We are convinced nevertheless that Monte Carlo methods will one day reach an impressive maturity. Hammersley and Handscomb (1964)

The practice of MCMC is simple. Set up a Markov chain having the required invariant distribution, and run it on a computer. The folklore of simulation makes this seem more complicated than it really is. None of this folklore is justified by theory and none of it actually helps users do good simulations. Geyer (2011)

A historical impediment to the more widespread use of Bayesian methods was computational: obtaining the posterior distribution requires the integration of high-dimensional functions. This can be very difficult, but several analytic approximations short of direct integration have been proposed (reviewed by Smith 1991; Evans and Swartz 1995; Tanner 1996). Now, however, the widespread development of **Markov Chain Monte Carlo (MCMC)** methods has made obtaining very complex posteriors relatively easy from a conceptual standpoint (although they may still be rather computationally demanding). Indeed, MCMC allows Bayesian approaches to handle much higher-dimensional problems than other methods. MCMC approaches are so named because one uses the current sample value to randomly generate the next sample value, thus generating a **Markov chain**.

The realization in the early 1990s (Gelfand and Smith 1990) that one particular MCMC method, the **Gibbs sampler**, is widely applicable to a broad class of Bayesian problems sparked much of the current expansion in the use of Bayesian analysis. MCMC methods have their roots in the **Metropolis algorithm** (Metropolis and Ulam 1949; Metropolis et al. 1953), an attempt by physicists to compute complex integrals by expressing them as expectations of a much simpler distribution and then estimating this expectation by drawing samples from that distribution. While the Gibbs sampler had its origins outside of statistics, it is still somewhat surprising that the powerful machinery of MCMC had essentially no impact on the field of statistics until rather recently. MCMC methods were reviewed by Tanner (1996), Gamerman (1997), Chen et al. (2000), Robert and Casella (2004), and Brooks et al. (2011). The types of MCMC machinery used in quantitative genetics (often Gibbs samplers on linear mixed-models, e.g., Chapters 19 and 20) tend to be a bit different from those used in molecular population genetics (ABC methods for treating complex likelihoods, e.g., Chapters 9 and 10). Sorensen and Gianola (2002) extensively reviewed the former, while Marjoram and Tavaré (2006) provided a brief review of the latter. The roundtable discussion on practical issues of MCMC by Kass et al. (1998) is required reading for anyone using MCMC analysis, as is Geyer (2011). Finally, Robert and Casella (2011) presented a nice historical overview of the development of MCMC methods.

MONTE CARLO INTEGRATION

To better understand the historical roots of MCMC, we digress for a moment to discuss the original **Monte Carlo** approach, which used random-number generation to approximate

integrals. Suppose we wish to compute a complex integral,

$$\int_a^b h(x) dx \quad (\text{A3.1a})$$

If we can decompose $h(x)$ into the product of a function, $f(x)$, and a probability density function, $p(x)$, defined over the interval (a, b) , then

$$\int_a^b h(x) dx = \int_a^b f(x) p(x) dx = E_{p(x)}[f(x)] \quad (\text{A3.1b})$$

which means that the integral can be expressed as the expectation of $f(x)$ over the density $p(x)$. After sampling a large number of random variables, (x_1, \dots, x_n) , from the density $p(x)$, we have that

$$\int_a^b h(x) dx = E_{p(x)}[f(x)] \simeq \frac{1}{n} \sum_{i=1}^n f(x_i) \quad (\text{A3.1c})$$

This approach is referred to as **Monte Carlo integration**, and it can be used to approximate posterior (or marginal posterior) distributions required for a Bayesian analysis.

Consider the integral $I(y) = \int f(y | x) p(x) dx$, which we approximate by

$$\hat{I}(y) = \frac{1}{n} \sum_{i=1}^n f(y | x_i) \quad (\text{A3.1d})$$

where again x_i are draws from the density $p(x)$. Since we have framed this integral as an expectation, individual random draws have expected value equal to the integral. The spread of those values around their mean allows us to estimate a **Monte Carlo standard error** for our approximation, with

$$\text{SE}^2[\hat{I}(y)] = \frac{1}{n} \left[\frac{1}{n-1} \sum_{i=1}^n \left(f(y | x_i) - \hat{I}(y) \right)^2 \right] \quad (\text{A3.1e})$$

where the inner term estimates the sampling variance, σ^2 . Notice from Equation A3.1e that the standard error scales as σ/\sqrt{n} , namely, with the square root of the sample size. Thus, a tenfold improvement in precision requires a hundredfold increase in the sample size.

Example A3.1. An interesting quantitative-genetic application of Monte Carlo integration was suggested by Ovaskainen et al. (2008) for comparing whether two **G** matrices are similar. As we detail in Volume 3, there are many proposed methods for comparing matrices, but Ovaskainen et al. suggested a (conceptually) simple approach. The **G** matrix for a given population is really a description of the distribution of breeding values, and, as such we can think of comparing **G** matrices as being akin to comparing two multivariate population distributions, whose densities are denoted by f and g . If \mathbf{x} denotes a draw from one of these distributions, the probability that it originates from distribution g is simply $g(\mathbf{x})/[g(\mathbf{x}) + f(\mathbf{x})]$. Hence, the probability, q , that a random draw from f will be incorrectly assigned to g is calculated as

$$q(f, g) = \int \frac{g(\mathbf{x})}{g(\mathbf{x}) + f(\mathbf{x})} f(\mathbf{x}) d\mathbf{x} \quad (\text{A3.2a})$$

If the two probability distributions are **essentially indistinguishable**, then $q(f, g) = 0.5$, while if they are **completely distinguishable** then $q(f, g) = 0$. Hence, $1 - 2q(f, g)$, which ranges from zero (indistinguishable) to one (fully distinguishable), provides a simple metric of the difference between them, and hence the difference between the two **G** matrices that

comprise the distributions of f versus g . Ovaskainen et al. modified this idea further, suggesting the metric

$$d(f, g) = \sqrt{1 - 2q(f, g)} \quad (\text{A3.2b})$$

While Equation A3.2a involves a complex integral, Equation A3.1d suggests that

$$\hat{q}(f, g) = \frac{1}{n} \sum_{i=1}^n \frac{g(\mathbf{x}_i)}{g(\mathbf{x}_i) + f(\mathbf{x}_i)} \rightarrow q(f, g) \quad (\text{A3.2c})$$

where $\mathbf{x}_1, \dots, \mathbf{x}_n$ are random draws from f . For example, if f is a multivariate normal with a mean vector of $\mathbf{0}$ and a variance-covariance matrix of \mathbf{G}_1 , then

$$f(\mathbf{x}) = (2\pi)^{-n/2} |\mathbf{G}_1| \exp\left(-\frac{\mathbf{x}^T \mathbf{G}_1^{-1} \mathbf{x}}{2}\right)$$

where g is similarly defined, but with \mathbf{G}_2 replacing \mathbf{G}_1 , which yields

$$\hat{q}(f, g) = \frac{1}{n} \sum_{i=1}^n \frac{|\mathbf{G}_2| \exp(-\mathbf{x}_i^T \mathbf{G}_2^{-1} \mathbf{x}_i/2)}{|\mathbf{G}_2| \exp(-\mathbf{x}_i^T \mathbf{G}_2^{-1} \mathbf{x}_i/2) + |\mathbf{G}_1| \exp(-\mathbf{x}_i^T \mathbf{G}_1^{-1} \mathbf{x}_i/2)} \quad (\text{A3.2d})$$

The expression in the sum is not nearly as imposing as it appears. Both of the determinants, $|\mathbf{G}_1|$ and $|\mathbf{G}_2|$, are fixed constants, and they only need to be computed once. Likewise, \mathbf{G}_1^{-1} and \mathbf{G}_2^{-1} need only be inverted once and then can be stored. Monte Carlo integration proceeds by generating a set of random vectors, $(\mathbf{x}_1, \dots, \mathbf{x}_n)$, from a MVN $\sim (\mathbf{0}, \mathbf{G}_1)$.

Importance Sampling

Consider any distribution whose probability density function, $p(x)$, has the same support as some target density, $q(x)$ (i.e., is nonzero over the same range of x values). Then,

$$\int f(x) q(x) dx = \int f(x) \left(\frac{q(x)}{p(x)} \right) p(x) dx = E_{p(x)} \left[f(x) \left(\frac{q(x)}{p(x)} \right) \right] \quad (\text{A3.3a})$$

This forms the basis for the method of **importance sampling**, with

$$\int f(x) q(x) dx \simeq \frac{1}{n} \sum_{i=1}^n f(x_i) \left(\frac{q(x_i)}{p(x_i)} \right) \quad (\text{A3.3b})$$

where again the x_i values are drawn from the distribution given by $p(x)$. For example, if we are interested in a marginal density as a function of y , $J(y) = \int f(y|x) q(x) dx$, we approximate this by

$$J(y) \simeq \frac{1}{n} \sum_{i=1}^n f(y|x_i) \left(\frac{q(x_i)}{p(x_i)} \right) \quad (\text{A3.4})$$

where x_i are drawn from the approximating density p .

This method is so named in that a judicious choice of $p(x)$ ensures that values for which $f(x)$ is large (important) are appropriately sampled, which can result in a smaller Monte Carlo variance, and hence a more accurate estimate of the integral. Further, it can be faster to carry out in cases where p is more straightforward to sample from than q . Ideally, we would like $p(x)$ to be large when $f(x)q(x)$ is large, namely, $p(x) \propto f(x)q(x)$, although assessing when $q(x)$ is large may be problematic.

One issue that can arise is when $q(x)$ denotes a posterior distribution whose integration constant is unknown, and hence $q(x)$, as presented, will not be a formal probability distribution if $\int q(x) \neq 1$. If $C^{-1} = \int q(x)$, then $Cq(x)$ is formally a pdf. Fortunately, a

simple trick allows us to use importance sampling to obtain C . Since $C \int q(x)dx = 1$, then

$$C^{-1} = \int q(x)dx \simeq \frac{1}{n} \sum_{i=1}^n w_i \quad \text{where} \quad w_i = \frac{q(x_i)}{p(x_i)} \quad (\text{A3.5a})$$

with the x_i drawn from $p(x)$. Hence

$$C \cdot \int f(x) q(x)dx \simeq \hat{I} = \sum_{i=1}^n w_i f(x_i) \Bigg/ \sum_{i=1}^n w_i \quad (\text{A3.5b})$$

which has an associated Monte Carlo variance of

$$\text{Var}(\hat{I}) = \sum_{i=1}^n w_i [f(x_i) - \hat{I}]^2 \Bigg/ \sum_{i=1}^n w_i \quad (\text{A3.5c})$$

INTRODUCTION TO MARKOV CHAINS

Before introducing two of the most common MCMC methods, the Metropolis-Hastings algorithm and the Gibbs sampler, a few introductory comments on Markov chains are in order. Let X_t denote the value of a random variable at time t , and let the **state space** refer to the range of possible X values. A random variable is said to follow a **Markov process** if the transition probabilities between different values in the state space depend only on the random variable's current state,

$$\Pr(X_{t+1} = s_j | X_0 = s_k, \dots, X_t = s_i) = \Pr(X_{t+1} = s_j | X_t = s_i) \quad (\text{A3.6})$$

Thus, the only information about the past needed for a Markov random variable to predict the future is the *current state* of the random variable. Knowledge of the values of earlier states does not influence the transition probability. A **Markov chain** refers to a sequence of random variables, (X_0, \dots, X_n) , generated by a Markov process. A particular chain is defined by its **transition probabilities** (or the **transition kernel**), $P(i, j) = P(i \rightarrow j)$, which is the probability that a process at state space s_i moves to state s_j in a single step

$$P(i, j) = P(i \rightarrow j) = \Pr(X_{t+1} = s_j | X_t = s_i) \quad (\text{A3.7a})$$

We use the notation $P(i \rightarrow j)$ to imply a move from i to j , as some texts define $P(i, j) = P(j \rightarrow i)$, so we will use the arrow notation to avoid any potential confusion. Let

$$\pi_j(t) = \Pr(X_t = s_j) \quad (\text{A3.7b})$$

denote the probability that the chain is in state j at time t , and let $\boldsymbol{\pi}(t)$ denote the row vector of the state space probabilities at step (or time) t . We start the chain by specifying a starting row vector, $\boldsymbol{\pi}(0)$. Often all the elements of $\boldsymbol{\pi}(0)$ are zero except for a single element of 1, which corresponds to the process starting in that particular state. As the chain progresses, the probability values become more dispersed over the state space. The probability that the chain has a state value of s_j at time (or step) $t+1$ is obtained from the **Chapman-Kolomogrov (CK) equation**, which sums over the probability of being in a particular state at the current step value, t , and the transition probability from that state into state s_j

$$\begin{aligned} \pi_j(t+1) &= \Pr(X_{t+1} = s_j) \\ &= \sum_i \Pr(X_{t+1} = s_j | X_t = s_i) \cdot \Pr(X_t = s_i) \\ &= \sum_i P(i \rightarrow j) \pi_i(t) = \sum_i P(i, j) \pi_i(t) \end{aligned} \quad (\text{A3.7c})$$

Successive iteration of the CK equations describes the evolution of the chain.

We can more compactly write the CK equations in matrix form, as follows: first we define the **probability transition matrix**, \mathbf{P} , as the matrix whose ij th element is $P(i, j)$, the probability of moving from state i to state j , $P(i \rightarrow j)$. This implies that the rows of \mathbf{P} sum to one, as when considering the i th row, $\sum_j P(i, j) = \sum_j P(i \rightarrow j) = 1$. In matrix form, the Chapman-Kolomogrov equation becomes

$$\boldsymbol{\pi}(t+1) = \boldsymbol{\pi}(t)\mathbf{P} \quad (\text{A3.8a})$$

Hence,

$$\boldsymbol{\pi}(t) = \boldsymbol{\pi}(t-1)\mathbf{P} = [\boldsymbol{\pi}(t-2)\mathbf{P}]\mathbf{P} = \boldsymbol{\pi}(t-2)\mathbf{P}^2 \quad (\text{A3.8b})$$

Continuing in this fashion yields the probability distribution in generation t as

$$\boldsymbol{\pi}(t) = \boldsymbol{\pi}(0)\mathbf{P}^t \quad (\text{A3.8c})$$

Next we define the n -step transition probability, $p_{ij}^{(n)}$, as the probability that the process is in state j , given that it started in state i some n steps ago, namely,

$$p_{ij}^{(n)} = \Pr(X_{t+n} = s_j \mid X_t = s_i) \quad (\text{A3.8d})$$

It immediately follows that $p_{ij}^{(n)}$ is simply the ij th element of \mathbf{P}^n , the n th power of the single-step transition matrix. The classic example of a Markov chain in genetics is the Wright-Fisher model of drift (Equations 2.1 and 2.2; Example 2.1).

Finally, a Markov chain is said to be **irreducible** if there exists a positive integer, n_{ij} , such that $p_{ij}^{(n_{ij})} > 0$ for all ij . That is, all states **communicate** with each other, in that the process can always move from any one state to any other state (although this may require multiple steps). Likewise, a chain is said to be **aperiodic** when the number of steps required to move between two states (say x and y) is not always some multiple of a specific integer. Put another way, the chain is not forced into cycles of fixed length between certain states.

Example A3.2. Suppose the state space consists of three possible weather conditions (Rain, Sunny, Cloudy) and that weather patterns follow a Markov process (of course, they do not!). Under this assumption, the probability of tomorrow's weather simply depends on today's weather, and not on any other previous days. If this is the case, the observation that it has rained for three straight days does not alter the probability of tomorrow's weather compared to the situation where (say) it rained today but was sunny for the last week. Suppose the probability transitions given that today is rainy are

$$\begin{aligned} P(\text{Rain tomorrow} \mid \text{Rain today}) &= 0.5 \\ P(\text{Sunny tomorrow} \mid \text{Rain today}) &= 0.25 \\ P(\text{Cloudy tomorrow} \mid \text{Rain today}) &= 0.25 \end{aligned}$$

This results in the first row of the transition probability matrix being $(0.5, 0.25, 0.25)$. Now suppose that the full transition matrix is

$$\mathbf{P} = \begin{pmatrix} 0.5 & 0.25 & 0.25 \\ 0.5 & 0 & 0.5 \\ 0.25 & 0.25 & 0.5 \end{pmatrix}$$

Note that this Markov chain is irreducible, as all states communicate with each other. Suppose today is sunny. What is the weather expected to be like two days from now? Seven days? Here $\boldsymbol{\pi}(0) = (0 \ 1 \ 0)$, which yeilds

$$\boldsymbol{\pi}(2) = \boldsymbol{\pi}(0)\mathbf{P}^2 = (0.375 \ 0.25 \ 0.375)$$

and

$$\boldsymbol{\pi}(7) = \boldsymbol{\pi}(0)\mathbf{P}^7 = (0.4 \quad 0.2 \quad 0.4)$$

Conversely, suppose today is rainy, so $\boldsymbol{\pi}(0) = (1 \quad 0 \quad 0)$. The expected future weather becomes

$$\boldsymbol{\pi}(2) = (0.4375 \quad 0.1875 \quad 0.375) \quad \text{and} \quad \boldsymbol{\pi}(7) = (0.4 \quad 0.2 \quad 0.4)$$

Note that after a sufficient amount of time, the expected weather is *independent of the starting value*. In other words, the chain has reached a stationary distribution, where the state space probability values are independent of the actual starting value.

As the above example illustrates, a Markov chain may reach a **stationary distribution**, $\boldsymbol{\pi}^*$, where the vector of probabilities of being in a particular state is independent of the initial starting distribution. The stationary distribution satisfies

$$\boldsymbol{\pi}^* = \boldsymbol{\pi}^*\mathbf{P} \tag{A3.9}$$

In other words, $\boldsymbol{\pi}^*$ is the **left eigenvector** associated with the eigenvalue $\lambda = 1$ of \mathbf{P} (Appendix 5). Further, the spectral decomposition of \mathbf{P} (Equation A5.9a) implies that the impact of the initial conditions after t steps decays as λ_2^t , where $\lambda_2 < 1$ is the second largest eigenvalue of \mathbf{P} . If this eigenvalue is very close to one, the impact of the initial conditions can persist for a substantial amount of time. Specifically, if $\lambda_2 = 1 - \delta$, then $\lambda_2^t = (1 - \delta)^t \simeq \exp(-\delta t)$. One condition for the existence of a stationary distribution is that the chain must be irreducible and aperiodic. When a chain is periodic, it can cycle in a deterministic fashion between states and may never settle down to a stationary distribution (in effect, this cycling is the stationary distribution for this chain). Equation A5.11d can be used to show that if \mathbf{P} has no eigenvalues equal to -1 , it is aperiodic.

A sufficient condition for a unique stationary distribution is (for all i and j) that the **detailed balance equation** holds, namely,

$$P(j \rightarrow i) \pi_j^* = P(i \rightarrow j) \pi_i^* \tag{A3.10}$$

That is, at equilibrium, the amount of probability flux from state j to stage i is exactly matched by the probability flux in the opposite direction (for i to j), so a balance is reached, with no *net* flow of probability over the states. If Equation A3.10 holds for all values of i and j , the Markov chain is said to be **reversible**, and hence Equation A3.10 is also called the **reversibility condition**. Note that this condition implies that $\boldsymbol{\pi}^* = \boldsymbol{\pi}^*\mathbf{P}$, as the j th element of the row vector $\boldsymbol{\pi}^*\mathbf{P}$ is

$$(\boldsymbol{\pi}^*\mathbf{P})_j = \sum_i \pi_i^* P(i \rightarrow j) = \sum_i \pi_j^* P(j \rightarrow i) = \pi_j^* \sum_i P(j \rightarrow i) = \pi_j^*$$

where the key middle step follows from Equation A3.10, while the last step follows because rows of \mathbf{P} sum to one.

The basic idea of a discrete-state Markov chain can be generalized to a continuous-state Markov process by replacing \mathbf{P} with a probability kernel, $P(x, y)$, that satisfies

$$\int P(x, y) dy = 1$$

The continuous extension of the Chapman-Kolomogrov equation becomes

$$\pi_t(y) = \int \pi_{t-1}(x) P(x, y) dx \tag{A3.11a}$$

Finally, at equilibrium, the stationary distribution satisfies

$$\pi^*(y) = \int \pi^*(x) P(x, y) dx \quad (\text{A3.11b})$$

THE METROPOLIS-HASTINGS ALGORITHM

The roots of MCMC methods trace back to a problem faced by mathematical physicists in applying Monte Carlo integration, namely, generating random samples from some complex distribution in order to apply Equation A3.1. Their solution was the Metropolis-Hastings algorithm (Metropolis and Ulam 1949; Metropolis et al. 1953; Hastings 1970), which was reviewed by Chib and Greenberg (1995).

Suppose our goal is to draw samples from some distribution, $p(\theta) = f(\theta)/K$, where the normalizing constant, K , may be very difficult to compute. Note that Bayesian posteriors are of this form (Equation A2.4b). The **Metropolis algorithm** (Metropolis and Ulam 1949; Metropolis et al. 1953), which generates a sequence of draws from this distribution, is as follows:

1. Start with any initial value, θ_0 , satisfying $f(\theta_0) > 0$.
2. Using the current value of θ , sample a **candidate point**, θ^* , from some **jumping distribution**, $q(\theta_1, \theta_2) = \Pr(\theta_1 \rightarrow \theta_2)$, which is the probability of returning a value of θ_2 given a previous value of θ_1 . This distribution is also referred to as the **proposal distribution** or **candidate-generating distribution**. The only restriction on the jump density in the Metropolis algorithm is that it is symmetric, with $q(\theta_1, \theta_2) = q(\theta_2, \theta_1)$.
3. Given the candidate point, θ^* , calculate the ratio of the density at the candidate and current, θ_{t-1} , points,

$$\alpha = \frac{p(\theta^*)}{p(\theta_{t-1})} = \frac{f(\theta^*)}{f(\theta_{t-1})}$$

Notice that because we are considering the ratio of $p(x)$ under two different values, the normalizing constant, K , cancels out.

4. If the jump increases the density ($\alpha > 1$), accept the candidate point (set $\theta_t = \theta^*$) and return to step 2. If the jump decreases the density ($\alpha < 1$), then with a probability of α we accept the candidate point, else we reject it and return to step 2. Note that α is a ratio of two likelihoods, so the probability of accepting a move is the ratio of the candidate to current likelihoods.

We can summarize Metropolis sampling as first computing

$$\alpha = \min \left(\frac{f(\theta^*)}{f(\theta_{t-1})}, 1 \right) \quad (\text{A3.12})$$

and then accepting a candidate value, θ^* , with probability α (the **probability of a move**). This generates a Markov chain, $(\theta_0, \theta_1, \dots, \theta_k, \dots)$, as the transition probabilities from θ_t to θ_{t+1} depend only on θ_t and not on $(\theta_0, \dots, \theta_{t-1})$. Following a sufficient **burn-in period** (of, say, k steps), the chain approaches its stationary distribution and (as we will demonstrate shortly) samples from the vector $(\theta_{k+1}, \dots, \theta_{k+n})$ are samples from $p(\theta)$.

Hastings (1970) generalized the Metropolis algorithm by using an arbitrary (as opposed to strictly symmetric) transition probability function, $q(\theta_1, \theta_2) = \Pr(\theta_1 \rightarrow \theta_2)$, and setting the acceptance probability for a candidate point as

$$\alpha = \min \left(\frac{f(\theta^*) q(\theta^*, \theta_{t-1})}{f(\theta_{t-1}) q(\theta_{t-1}, \theta^*)}, 1 \right) \quad (\text{A3.13})$$

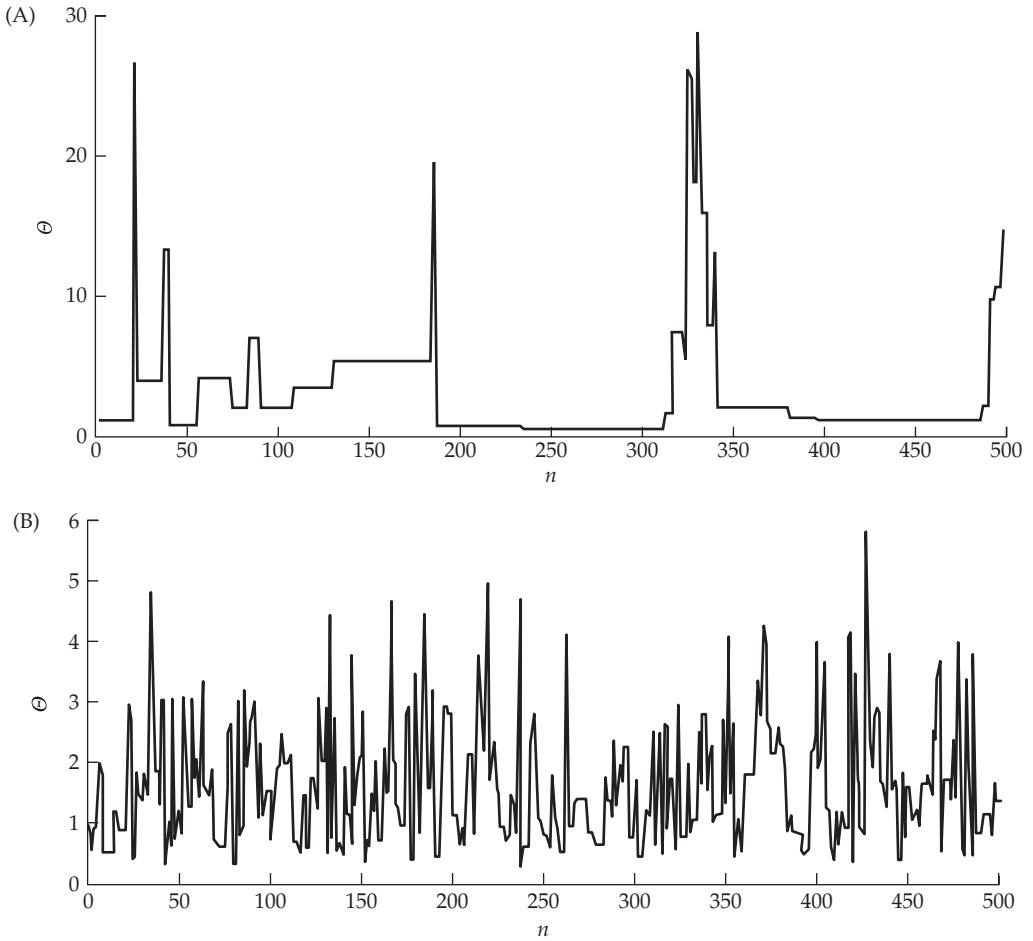

Figure A3.1 Traces for the samplers discussed in Example A3.3. **A:** A sample run when the candidate-generating distribution is a uniform over $(0, 100)$. **B:** A sample run when the candidate-generating distribution is a χ^2_1 .

This is the **Metropolis-Hastings algorithm**, and Equation A3.13 is the **Hastings ratio**. When the proposal distribution is symmetric, $q(x, y) = q(y, x)$, we recover the original Metropolis algorithm.

Example A3.3. As a toy example, consider the scaled inverse- χ^2 distribution (Equation A2.30a),

$$p(x) = C \cdot x^{-(n/2+1)} \cdot \exp\left(\frac{-a}{2x}\right)$$

We wish to use the Metropolis algorithm to simulate draws from this distribution with $n = 3$ degrees of freedom and a scaling factor of $a = 4$. Here

$$f(x) = x^{-5/2} \exp[-4/(2x)] = x^{-2.5} \exp[-2/x]$$

Suppose we take as our candidate-generating distribution a uniform over $(0, 100)$. Clearly, there is probability mass above 100 for the scaled inverse- χ^2 , but we assume this is sufficiently small that we can ignore it. Now let's run the algorithm. Take $\theta_0 = 1$ as our starting value, and suppose the uniform returns a candidate value of $\theta^* = 39.82$. Computing

α ,

$$\alpha = \min \left(\frac{f(\theta^*)}{f(\theta_{t-1})}, 1 \right) = \min \left(\frac{(39.82)^{-2.5} \cdot \exp(-2/39.82)}{(1)^{-2.5} \cdot \exp(-2/2 \cdot 1)}, 1 \right) = 0.0007$$

Since $\alpha < 1$, the candidate value, θ^* , is accepted with a probability of 0.0007: we randomly draw U from a uniform $(0, 1)$ distribution and accept θ^* if $U \leq \alpha = 0.0007$. If $U > \alpha$, the candidate value is rejected, and we draw another candidate value from the proposal distribution and continue as above. A sample run resulting from first 500 values of θ is plotted in Figure A3.1A. Notice that there are long flat periods (corresponding to all candidate values, θ^* , being rejected). Such a chain is said to be **poorly mixing** (showing long periods between jumps) and is numerically inefficient for sampling the entire probability space defined by the target distribution. Conversely, balancing the poor mixing is the fact that when jumps occur, they tend to be large, thus exploring the extreme values of this distribution.

In contrast, suppose our proposal distribution is a χ_1^2 . As this distribution is not symmetric, we must employ Metropolis-Hastings (see Example A3.5 for the details). A resulting Metropolis-Hastings sampling run is shown in Figure A3.1B. Note that the time series looks like **white noise**, and the chain is said to be well mixing. However, note that most jumps are small (< 5), with fewer extreme values sampled than under the uniform proposal distribution.

Example A3.4. This rather technical example shows that the Markov chain generated by the Metropolis-Hastings algorithm has a stationary distribution which corresponds to $p(x)$. Hence, draws from the stationary phase of this chain correspond to random draws from the distribution given by $p(x)$. We do so by showing that, under this chain, $p(x)$ satisfies the detailed balance equation (A3.10), and hence it must be the stationary distribution for the Markov chain.

Under Metropolis-Hastings, we sample from $q(x, y) = \Pr(x \rightarrow y | q)$ and then accept the move with probability $\alpha(x, y)$, so the transition probability kernel is given by

$$\Pr(x \rightarrow y) = q(x, y) \alpha(x, y) = q(x, y) \cdot \min \left[\frac{p(y) q(y, x)}{p(x) q(x, y)}, 1 \right] \quad (\text{A3.14a})$$

If the Metropolis-Hastings kernel satisfies $P(x \rightarrow y) p(x) = P(y \rightarrow x) p(y)$, or

$$q(x, y) \alpha(x, y) p(x) = q(y, x) \alpha(y, x) p(y) \quad \text{for all } x, y \quad (\text{A3.14b})$$

then the stationary distribution from this kernel corresponds to draws from the target distribution, $p(x)$.

We show that the balance equation is indeed satisfied with this kernel by considering the three possible cases for any particular (x, y) pair:

1. $q(x, y) p(x) = q(y, x) p(y)$. Here $\alpha(x, y) = \alpha(y, x) = 1$ implying

$$P(x \rightarrow y) p(x) = q(x, y) p(x) \quad \text{and} \quad P(y \rightarrow x) p(y) = q(y, x) p(y)$$

Under our assumption that $q(x, y) p(x) = q(y, x) p(y)$, this reduces to $P(x \rightarrow y) p(x) = P(y \rightarrow x) p(y)$, showing that (for this case), the detailed balance equation holds.

2. $q(x, y) p(x) > q(y, x) p(y)$, in which case

$$\alpha(x, y) = \frac{p(y) q(y, x)}{p(x) q(x, y)} \quad \text{and} \quad \alpha(y, x) = 1$$

Hence,

$$\begin{aligned} P(x \rightarrow y) p(x) &= q(x, y) \alpha(x, y) p(x) \\ &= q(x, y) \frac{p(y) q(y, x)}{p(x) q(x, y)} p(x) \\ &= q(y, x) p(y) = q(y, x) \alpha(y, x) p(y) \\ &= P(y \rightarrow x) p(y) \end{aligned}$$

3. $q(x, y) p(x) < q(y, x) p(y)$. Here

$$\alpha(x, y) = 1 \quad \text{and} \quad \alpha(y, x) = \frac{q(x, y) p(x)}{q(y, x) p(y)}$$

Following the same logic just used yields

$$\begin{aligned} P(y \rightarrow x) p(y) &= q(y, x) \alpha(y, x) p(y) \\ &= q(y, x) \left(\frac{q(x, y) p(x)}{q(y, x) p(y)} \right) p(y) \\ &= q(x, y) p(x) = q(x, y) \alpha(x, y) p(x) \\ &= P(x \rightarrow y) p(x) \end{aligned}$$

which concludes the proof.

Burning-in the Sampler

A key issue in the successful implementation of Metropolis-Hastings, or any other MCMC sampler, is the number of steps (iterations) until the chain approaches stationarity (the length of the **burn-in period**), as initial values are somewhat dependent upon the starting position. Typically the first 1,000 to 50,000 (or more) values of the chain are discarded, and then various convergence tests (see below) are used to assess whether stationarity has indeed been reached.

A poor choice of either a proposal distribution or a starting value can greatly increase the required burn-in time, and an area of current research is whether an optimal starting point and proposal distribution can be found. One suggestion is to initiate the chain as close to the center of the distribution as possible, for example, taking a value close to the distribution's mode (such as using an approximate MLE as the starting value). Geyer (2011), however, offered the simple advice that "any point you don't mind having in a sample is a good starting point."

A chain is said to be **poorly mixing** if it stays in small regions of the parameter space for long periods of time, as opposed to a **well-mixing** chain, which seems to happily explore the entire space (albeit perhaps by very small steps, requiring very many draws to fully survey the entire space). A poorly mixing chain can arise because the target distribution is multimodal and our choice of starting values (or the chance steps that were initially taken) traps us near one of the modes (such multimodal posteriors can arise if we have a strong prior that is in conflict with the observed data). Two approaches have been suggested for situations where the target distribution may have multiple peaks. The most straightforward is to use widely dispersed initial values to start several different chains (Gelman and Rubin 1992). A less obvious approach, which we will discuss shortly, is to use **simulated annealing** on a single chain.

Even after an apparently successful burn-in, the real fear for the MCMC practitioner is that the chain is simply showing **pseudo-convergence**. It appears to have reached an equilibrium, when in fact it is simply exploring (albeit perhaps rather fully) some subset of the entire distribution. If the transition time between different parts of the full distribution is long relative to the sample size, the MCMC user will happily observe convergence and believe that the simulation is a fair representation of the true posterior. The unfortunate feature is that for *any* MCMC, the skeptic, or a hardened reviewer, can claim (with some justification) that convergence has not been demonstrated. The problem is akin to large-sample results in statistics (such as the large-sample features of ML; LW Appendix 4): the theory says that for a sufficiently large sample, certain desirable properties hold, but usually says rather little about how "large" is large. For a complex posterior, the required chain size might be far, far larger than an investigator envisions. The only real solution is to run the chain for as long as possible. In such a setting, Geyer (2011) argued, a burn-in is not required,

and noted that “Burn-in is mostly harmless, which is perhaps why the practice persists. But everyone should understand that it is unnecessary, and those who do not use it are not thereby making an error.”

Simulated Annealing

Simulated annealing was developed for finding the maximum of complex functions with multiple peaks where standard hill-climbing approaches may trap the algorithm on a less than optimal peak (Kirkpatrick et al. 1983). The idea is that when we initially start sampling the space, we will accept a reasonable probability of a down-hill move in order to explore the entire space. As the process proceeds, we decrease the probability of such down-hill moves. The analogy (and hence the term) is the annealing of a crystal as temperature decreases: initially there is a lot of movement, which gets smaller and smaller as the temperature cools. Simulated annealing is very closely related to Metropolis sampling, differing only in that the probability α of a move is given by

$$\alpha_{SA} = \min \left[1, \left(\frac{f(\theta^*)}{f(\theta_{t-1})} \right)^{1/T(t)} \right] = \alpha^{1/T(t)} \quad (\text{A3.15a})$$

where the function $T(t)$ is called the **cooling schedule** (setting $T = 1$ recovers Metropolis sampling), and the particular value of T at any point in the chain is called the **temperature**. For example, suppose $f(\theta^*)/f(\theta_{t-1}) = 0.5$. If $T = 100$, $\alpha = 0.93$, while for $T = 1$, $\alpha = 0.5$, and for $T = 1/10$, $\alpha = 0.0098$. Hence, we start off with a high probability of a jump and then cool down to a very low jump probability. Replacing α with the Hastings ratio (Equation A3.13) allows us to apply simulated annealing to Metropolis-Hastings.

A function with geometric decline is typically used for $T(t)$. For example, to start at T_0 and cool down to a final temperature of T_f over n steps, we can set

$$T(t) = T_0 \left(\frac{T_f}{T_0} \right)^{t/n} \quad (\text{A3.15b})$$

More generally, if we wish to cool off to T_f by time n and then keep the temperature constant at T_f for the rest of the run, we can take

$$T(t) = \max \left(T_0 \left(\frac{T_f}{T_0} \right)^{t/n}, T_f \right) \quad (\text{A3.15c})$$

In particular, to cool down to Metropolis sampling (by step n), we set $T_f = 1$ and the cooling schedule becomes

$$T(t) = \max \left(T_0^{1-t/n}, 1 \right) \quad (\text{A3.15d})$$

Choosing a Jumping (Proposal) Distribution

The Metropolis sampler works with any symmetric proposal (or jumping) distribution, while Metropolis-Hastings allows for more general distributions. So how do we determine our best option for a proposal distribution? There are two general approaches: random walks and independent chain sampling. Under a sampler using a proposal distribution based on a **random-walk chain**, the new value, y , equals the current value, x , plus a random variable, namely, z ,

$$y = x + z$$

In this case, $q(x, y) = g(y - x) = g(z)$, the density associated with the random variable z . If $g(z) = g(-z)$, i.e., the density for the random variable z is symmetric (as occurs with a

normal or multivariate normal with a mean of zero, or a uniform centered around zero), then we can use Metropolis sampling, as $q(x, y)/q(y, x) = g(z)/g(-z) = 1$. The variance of the proposal distribution can be thought of as a **tuning parameter** that is adjusted to achieve better mixing.

Under a proposal distribution using an **independent chain**, the probability of jumping to point y is *independent* of the current position (x) of the chain, namely, $q(x, y) = g(y)$. The candidate value is simply drawn from a proposal distribution, independent of the current value (see Examples A3.3 and A3.5). Again, any number of standard distributions can be used for $g(y)$. Note that in this case, except for a uniform, the proposal distribution is generally not symmetric, as $g(x)$ is generally not equal to $g(y)$ (for $x \neq y$), and Metropolis-Hastings sampling must be used.

As mentioned, we can tune the proposal distribution to adjust the mixing, and in particular the acceptance probability, of the chain. This is generally accomplished by adjusting the standard deviation (SD) of the proposal distribution. This can be done by adjusting the variance for a normal or adjusting the eigenvalues of the covariance matrix for a multivariate normal. Likewise, one can increase or decrease the range, $(-a, a)$, if a uniform is used, or change the degrees of freedom (df) if a χ^2 is used (variance increases with the df). To increase the acceptance probability, one *decreases* the proposal distribution SD. There is a tradeoff in that if the SD is too large, jumps are potentially large (which is good), but are usually not accepted (which is a problem). This leads to high autocorrelation (see below) and very poor mixing, requiring much longer chains. On the other hand, if the proposal SD is too small, moves will generally be accepted (there is a high acceptance probability), but they will also be small, again generating high autocorrelations and poor mixing.

Example A3.5. Suppose we wish to use a χ^2 as our proposal distribution. Recall from Equation A2.27b, that for $x \sim \chi_n^2$,

$$g(x) \propto x^{n/2-1} e^{-x/2}$$

Thus, $q(x, y) = g(y) = C \cdot y^{n/2-1} e^{-y/2}$. Note that $q(x, y)$ is not symmetric, as $q(y, x) = g(x) \neq g(y) = q(x, y)$. Hence, we must use Metropolis-Hastings sampling, with an acceptance probability of

$$\alpha(x, y) = \min \left[\frac{p(y) q(y, x)}{p(x) q(x, y)}, 1 \right] = \min \left[\frac{p(y) g(x)}{p(x) g(y)}, 1 \right] = \min \left[\frac{p(y) x^{n/2-1} e^{-x/2}}{p(x) y^{n/2-1} e^{-y/2}}, 1 \right]$$

If we use the same target distribution as in Example A3.3 (a scaled inverse- χ^2), $p(x) = C \cdot x^{-2.5} e^{-2/x}$, the rejection probability becomes

$$\alpha(x, y) = \min \left[\frac{(y^{-2.5} e^{-2/y}) (x^{n/2-1} e^{-x/2})}{(x^{-2.5} e^{-2/x}) (y^{n/2-1} e^{-y/2})}, 1 \right]$$

Results for a run of the sampler under two different proposal distributions (a χ_2^2 and a χ_{10}^2) are plotted in Figure A3.2. The χ_2^2 has the smaller variance, and thus a higher acceptance probability. Further, it seems to explore more of the distribution space than a χ_{10}^2 (compare the number of values above 4 in both traces).

Autocorrelation and Sample Size Inflation

We often expect adjacent members from an MCMC sequence to be positively correlated, and we can quantify the nature of this correlation by using an **autocorrelation function**. Consider

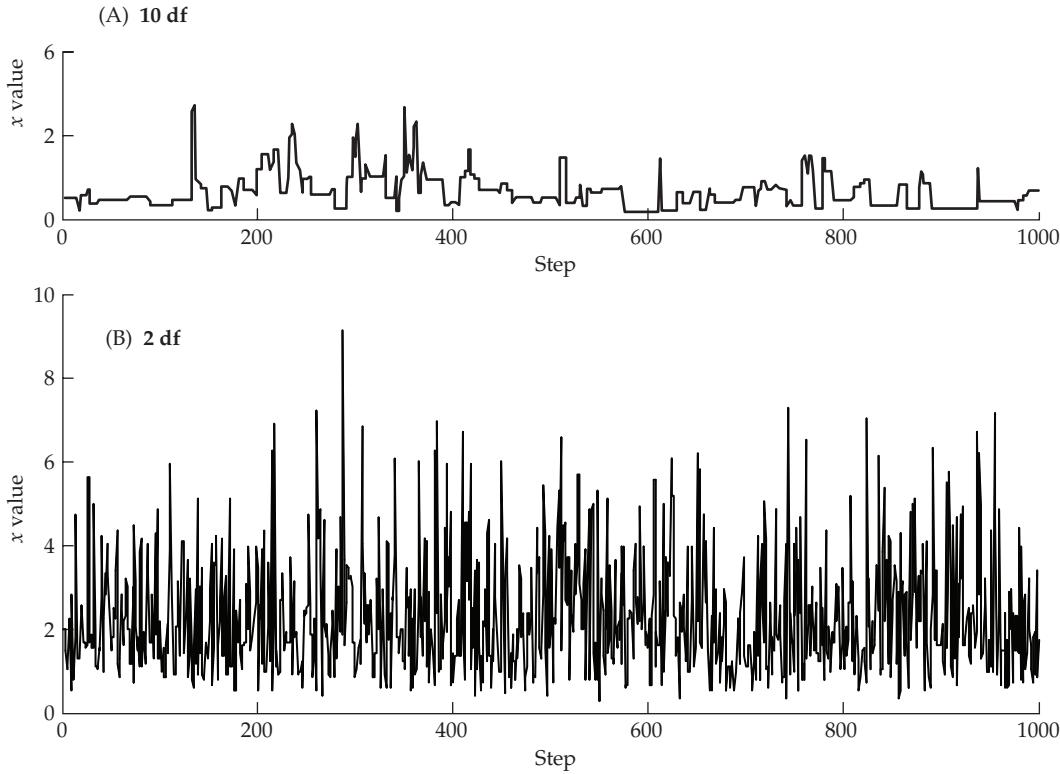

Figure A3.2 Trace plots for the two samplers discussed in Example A3.5. **A:** The proposal distribution is a χ^2_{10} . **B:** The proposal distribution is a χ^2_2 .

a sequence, $(\theta_1, \dots, \theta_n)$, of length n . Correlations can occur between adjacent members, $\rho(\theta_i, \theta_{i+1}) \neq 0$, and, more generally, between more distant members, $\rho(\theta_i, \theta_{i+k}) \neq 0$. The k th order autocorrelation, ρ_k , can be estimated by

$$\hat{\rho}_k = \frac{\text{Cov}(\theta_t, \theta_{t+k})}{\text{Var}(\theta_t)} = \frac{\sum_{t=1}^{n-k} (\theta_t - \bar{\theta})(\theta_{t+k} - \bar{\theta})}{\sum_{t=1}^{n-k} (\theta_t - \bar{\theta})^2}, \quad \text{with } \bar{\theta} = \frac{1}{n} \sum_{t=1}^n \theta_t \quad (\text{A3.16})$$

An important result from the theory of time series analysis is that if the values of θ_t are from a stationary (and correlated) process, correlated draws still provide an unbiased picture of the distribution *provided the sample size is sufficiently large*. The reason for this large-sample stipulation is that, strictly speaking, Equation A3.16 applies only to a stationary process.

Some indication of the required sample size comes from the theory of a **first-order autoregressive process (AR_1)**, where

$$\theta_t = \mu + \alpha(\theta_{t-1} - \mu) + \epsilon \quad (\text{A3.17a})$$

where $|\alpha| < 1$ and ϵ is **white noise**, namely, $\epsilon \sim N(0, \sigma^2)$. Here $\rho_1 = \alpha$ and the k th order autocorrelation is given by $\rho_k = \rho_1^k = \alpha^k$. Under this process, $E(\bar{\theta}) = \mu$ with a standard error of

$$\text{SE}(\bar{\theta}) = \frac{\sigma}{\sqrt{n}} \sqrt{\frac{1+\rho}{1-\rho}} \quad (\text{A3.17b})$$

The first ratio is the standard error for white noise, while the second ratio, $\sqrt{(1+\rho)/(1-\rho)}$, is the **sample size inflation factor (SSIF)**, which shows how the autocorrelation inflates the

sampling variance relative to independent samples. For $\rho = 0.5, 0.75, 0.9, 0.95$, and 0.99 , the associated SSIF values become $3, 7, 19, 39$, and 199 , respectively. With an autocorrelation of 0.95 (which is not uncommon in a Metropolis-Hastings sequence), roughly 40 times as many iterations are required for the same precision as with an uncorrelated sequence.

One historical strategy for reducing autocorrelation is **thinning** (or **subsampling**) the output, which involves storing only every m th point after the burn-in period. Suppose a Metropolis-Hastings sequence follows an AR_1 model, with $\rho_1 = 0.99$. In this case, sampling every 50, 100, and 500 points gives the correlation between the thinned samples as $0.605 (= 0.99^{50})$, 0.366 , and 0.007 , respectively, returning SSIF values of 2, 1.5, and 1.007. In addition to reducing autocorrelation, thinning the sequence also saves computer memory. However, this throws out a huge amount of the data. If computer memory is not an issue, Geyer (1992) and MacEachern and Berliner (1994) found that it is more efficient (yielding smaller Monte Carlo variances) to keep the entire chain than to use thinning.

The Monte Carlo Variance of a MCMC-Based Estimate

Suppose we are interested in using a burned-in MCMC sequence, $(\theta_1, \dots, \theta_n)$, to estimate some function, $h(\theta)$, of the target distribution, such as a mean, variance, or specific quantile (namely, a specific cumulative probability value). Since we are drawing random variables, associated with the Monte Carlo estimate, there is a sampling variance of

$$\hat{h} = \frac{1}{n} \sum_{i=1}^n h(\theta_i) \quad (\text{A3.18})$$

A similar issue arose with the error in Monte Carlo integration, where we used the sample variance around \hat{h} to compute the Monte Carlo variance, dividing this by the number of iterations to yield a standard error (Equations A3.1e and A3.5c). This strategy exploited the fact that draws for Monte Carlo integration are *independent* and therefore uncorrelated. In stark contrast, we expect draws in an MCMC sequence to be highly *dependent*. A standard sample variance estimator ignores these correlations, potentially yielding a highly biased estimate of the Monte Carlo variance (see Equation A3.17b).

One direct approach is to run several chains (or extract subsamples from a very long chain) and use the between-chain variance in \hat{h} as our variance estimate. Specifically, if \hat{h}_j denotes the estimate for chain j ($1 \leq j \leq c$), where each of the c chains has the same length, then the estimated variance of the Monte Carlo estimate is

$$\text{Var}(\hat{h}) = \frac{1}{c-1} \sum_{j=1}^c (\hat{h}_j - \hat{h}^*)^2 \quad \text{where} \quad \hat{h}^* = \frac{1}{c} \sum_{j=1}^c \hat{h}_j \quad (\text{A3.19})$$

Using only a single chain, an alternative approach is to use results from the theory of time series to account for the correlations among members in the chain. To start, we estimate the lag- k autocovariance associated with h by

$$\hat{\gamma}(k) = \frac{1}{n-1} \sum_{i=1}^{n-k} [(h(\theta_i) - \hat{h}) (h(\theta_{i+k}) - \hat{h})] \quad (\text{A3.20})$$

This is natural generalization of the k th order autocorrelation (Equation A3.16) to the random variable generated by $h(\theta_i)$. Geyer (1992, 2011) obtained the resulting estimate of the Monte Carlo variance as

$$\text{Var}(\hat{h}) = \frac{1}{n} \left(\hat{\gamma}(0) + 2 \sum_{i=1}^{2\delta+1} \hat{\gamma}(i) \right) \quad (\text{A3.21})$$

Note that the zero-lag term, $\hat{\gamma}(0)$, is simply the standard variance estimate when observations are uncorrelated, while δ is the largest positive integer satisfying $\hat{\gamma}(2\delta) + \hat{\gamma}(2\delta+1) > 0$, (i.e., the higher order, or lag, autocovariances above δ are zero).

One measure of the effects of autocorrelation between elements in the sampler is the **effective chain size**,

$$\hat{n} = \frac{\hat{\gamma}(0)}{\text{Var}(\hat{h})} \quad (\text{A3.22})$$

where $\hat{\gamma}(0)$ is the standard sample variance for uncorrelated observations. In the absence of autocorrelation between members, $\hat{n} = n$.

CONVERGENCE DIAGNOSTICS

The careful reader will note that we have still not answered the fundamental, and vexing, question of how to determine whether the sampler has reached its stationary distribution. Many tests for stationarity have been proposed, and all can indeed show that stationarity has not yet been reached. However, it is important to stress that *negative results from these tests are not conclusive evidence that the sampler has achieved stationarity*. Comments from various published reviews on the subject stress this point: “all of the methods can fail to detect the sorts of convergence failure that they were designed to identify” (Cowles and Carlin 1996); “It is clear that the usefulness of convergence assessment methods are limited by their potential unreliability” (Brooks and Roberts 1998); “Diagnostics can only reliably be used to determine a lack of convergence and not detect convergence per se” (Brooks et al. 2003); and “no method works in every case” (El Adlouni et al. 2006). Despite this very serious concern, a variety of methods can certainly show a failure of convergence given the burn-in period used for a sampler. The greater question about trust is what we say when convergence diagnostics *do not* indicate a problem. We consider a few basic approaches here, while additional diagnostics were reviewed by Gelman and Rubin (1992), Geyer (1992), Raftery and Lewis (1992b), Cowles and Carlin (1996), Brooks and Roberts (1998), Kass et al. (1998), Mengerson et al. (1999), Robert and Casella (2004), El Adlouni et al. (2006), and Pelttonen et al. (2009).

An extra level of complications occurs in models using **reversible jump MCMC**, wherein the chain actually jumps between difference *classes* of models. For example, suppose the number of QTLs, k , is a random variable. While the chain may come to a nearly equilibrium distribution for the parameters associated with a given value of k fairly quickly, one must also sample a sufficient number of jumps *between models* with different values of k to fully explore the model space. One might incorrectly assume that there appears to be convergence when the model quickly equilibrates for a given value of k , but jumps very slowly between different values of k so that only a small sample of the k space has been explored.

Visual Analysis

As shown in Figures A3.1 and A3.2, one should always examine the **time series trace**, the plot of the random variable being generated versus the number of iterations. In addition to showing evidence for poor mixing, such traces can also suggest a *minimum* burn-in period for some starting value. For example, suppose the trace moves very slowly away from the initial value to a rather different value (say after 5000 iterations), after which it appears to settle down. Clearly, the burn-in period is *at least* 5000 in this case. It must be cautioned that the actual burn-in time *may be far longer* than suggested by the trace. Nevertheless, the trace often indicates that more burn-in time is needed. A second approach is to run either several chains or subsample from a much longer chain, and then compare the traces. The expectation under stationarity is that these samples are drawn from the same distribution. Even if visual analysis suggests that two (or more) chains appear to be very similar and are both well-behaved, the concern is that both might be stuck in the same local maximum region of a complex posterior. In such cases, the impression of stationarity and consistency is presented, but significantly longer runs for each chain would show a different outcome.

Correlograms, which plot serial autocorrelations as a function of the time lag, are also very useful in accessing a run from an MCMC sampler. A plot of ρ_k versus k (the k th order autocorrelation versus the lag) should show geometric decay if the sampler series closely

follows an AR_1 model. A plot of the **partial autocorrelations** as a function of lag is also useful. The k th partial autocorrelation is the excess correlation not accounted for by a $k - 1$ order autoregressive model (AR_{k-1}). Hence, if the first-order model fully fits the data, the second-order partial autocorrelation is zero, as the lagged autocorrelations are accounted for by the AR_1 model (i.e., $\rho_k = \rho_1^k$). Both of these autocorrelation plots can indicate an underlying correlation structure that may not be obvious from the time series trace.

More Formal Approaches

Gelman and Rubin's (1992) proposal was to first generate m separate chains at initial locations that are widely dispersed in the parameter space, with each returning a burned-in and thinned (such that autocorrelations between estimates are near zero) sequence of length n . Their approach is essentially an ANOVA, contrasting the estimated among-chain variance with its within-chain value. For the univariate case, let

$$B = \frac{n}{m-1} \sum_{i=1}^m (\bar{\theta}_{i\cdot} - \bar{\theta}_{..})^2 \quad (\text{A3.23a})$$

be the among-chain variance, where $\bar{\theta}_{i\cdot}$ is the mean parameter value for chain i , and $\bar{\theta}_{..}$ is the grand mean over all chains. Likewise, for the within-chain variance, we define

$$W = \frac{1}{m} \left(\frac{1}{n-1} \sum_{i=1}^m \sum_{j=1}^n (\bar{\theta}_{ij} - \bar{\theta}_{i\cdot})^2 \right) \quad (\text{A3.23b})$$

A combined estimate of the variance is

$$\widehat{\sigma^2} = \frac{n-1}{n} W + \frac{1}{n} B \quad (\text{A3.23c})$$

Gelman and Rubin defined the **potential scale reduction factor (PSRF)** as

$$R = \frac{\widehat{\sigma^2}}{W} = 1 + \frac{1}{n} \left(\frac{B}{W} - 1 \right) \quad (\text{A3.23d})$$

with values of R near one being consistent with convergence. A plot of R over time should converge to a value near one, if the chains are converging.

Because most MCMCs involve many variables, one could either look at the univariate R trace for each or use the multivariate version suggested by Brooks and Gelman (1998),

$$R = \frac{n-1}{n} + \left(1 + \frac{1}{m} \right) \lambda_1 \quad (\text{A3.24})$$

where λ_1 is the leading eigenvalue of the matrix product $\mathbf{W}^{-1}\mathbf{B}/n$, and where \mathbf{W} and \mathbf{B} are the sample within- and among-covariance matrices for the parameters. Again, a value near 1 is consistent with convergence.

The **Geweke test** (Geweke 1992) splits the sample (after removing a burn-in period) into two parts. If the chain is at stationarity, the means of the two samples should be equal. A modified z-test can be used to compare the two subsamples, and the resulting test statistic is often referred to as a **Geweke z-score**. A value larger than 2 indicates that the mean of the series is still drifting and a longer burn-in is required before monitoring the chain (to extract a sampler) can begin.

A more informative approach is the **Raftery-Lewis test** (Raftery and Lewis 1992a). Here, one specifies a particular quantile, q , of the distribution of interest (typically testing both $q = 2.5\%$ and 97.5% , to give a 95% confidence interval), an accuracy, ϵ , of the quantile, and a power, $1 - \beta$, for achieving this accuracy on the specified quantile. With these three

parameter values set, the Raftery-Lewis test breaks the chain into a binary (1, 0) sequence, in which an element in the sequence takes on a value of 1 if $\theta_t \leq q$, otherwise it takes on a value of zero. This generates a two-state Markov chain, and the Raftery-Lewis test uses the sequence to estimate the transition probabilities between states. With these probabilities in hand, one can then estimate the number of additional burn-ins (if any) required to approach stationarity, the thinning ratio (how many points should be discarded for each sampled point), and the total chain length required to achieve the preset level of accuracy.

Practical MCMC: How Many Chains and How Long Should They Run?

One can either use a single long chain (Geyer 1992; Raftery and Lewis 1992b) or multiple chains, with each starting from different initial values (Gelman and Rubin 1992). Note that with parallel processing, using multiple chains may be computationally more efficient (given a fixed amount of analysis time) than a single long chain. One suggested approach (Kass et al. 1998) is to use five parallel chains with widely separated starting values, and to start the j th value for parameter θ_i at $\mu_i + (j - 2)\sigma_i$, where μ_i and σ_i^2 are the prior values for θ_i . Alternatively, one could randomly sample j from $(-2, 1, 0, 1, 2)$ for each parameter to generate the vector of starting values.

Geyer (1992, 2011), however, forcefully argued that using a single long chain is the best approach. If the chain transition times between different parts of a distribution are long, then a series of shorter chains may entirely miss this problem, even if their starting values are widely dispersed. Theory basically tells us that, *provided* we run a chain for a long enough time, the results will be accurate. The best way to do so is to run a single, long chain. Convergent tests (still recognizing their problems mentioned previously) can be applied to subsections of a long chain as efficiently as they can be applied across shorter, parallel-running chains.

Given these concerns, what is the answer to the critical question about how long to run a chain? **Geyer's dictums** (2011) are that (i) “the least one can do is to make an overnight run. What better way for your computer to spend its time?” and (ii) ideally, “one should start a run when the paper is submitted and keep running until the referees' reports arrive.”

THE GIBBS SAMPLER

The **Gibbs sampler** (introduced in the context of image processing by Geman and Geman 1984), is a special case of Metropolis-Hastings sampling wherein the random value is always accepted (i.e., $\alpha = 1$). The key to the Gibbs sampler is that, at any point in the process, one only considers *univariate* conditional distributions—the distribution when all but one of the random variables are assigned fixed values. Such conditional distributions are far easier to simulate than complex joint distributions and usually have simple forms (often they are normals, inverse- χ^2 , or other common prior distributions). An important use of conjugate priors (Table A2.2) is that they often result in relatively simple forms for conditional distributions. Thus, one simulates n random variables sequentially from the n univariate conditionals rather than generating a single n -dimensional vector in a single pass using the full joint distribution. Given their great efficiency (every value is accepted), it is often thought that one should strive to generate a Gibbs sampler whenever possible. However, one should consult Geyer (2011) for a different perspective.

To introduce the Gibbs sampler, consider a bivariate random variable (x, y) , and suppose we wish to compute one or both of the marginals, $p(x)$ and $p(y)$. The idea behind the sampler is that it is far easier to consider a sequence of conditional distributions, $p(x | y)$ and $p(y | x)$, than it is to obtain the marginal by integration of the joint density $p(x, y)$, namely, $p(x) = \int p(x, y) dy$. The sampler starts with some initial value, y_0 , for y and obtains x_0 by generating a random variable from the conditional distribution $p(x | y = y_0)$. The sampler then uses x_0 to generate a new value of y_1 , drawing from the conditional distribution based on the value of x_0 , $p(y | x = x_0)$. The sampler proceeds as follows:

$$x_i \sim p(x | y = y_{i-1}) \quad (\text{A3.25a})$$

$$y_i \sim p(y | x = x_i) \quad (\text{A3.25b})$$

Repeating this process k times generates a **Gibbs sequence** of length k , where a subset of points (x_j, y_j) for $1 \leq j \leq m < k$ are taken as our simulated draws from the full joint distribution. One iteration of all the univariate distributions is often called a **scan** of the sampler. To obtain the desired total of m sample values (here each value in the sampler is a vector of realizations of the two random variables), one samples the chain following a sufficient burn-in to remove the effects of the initial starting values, potentially thinning the sequence as well. The Gibbs sequence converges to a stationary (equilibrium) distribution that is independent of the starting values, and by construction this stationary distribution is the target distribution we are trying to simulate (Tierney 1994). As with any MCMC, a guarantee of convergence at some limit is no guarantee that our sample size is sufficiently large to justify the assumption of stationarity for a burned-in (and potentially thinned) sampler.

Example A3.6. Consider the following distribution from Casella and George (1992). Suppose the joint distribution of $x = 0, 1, \dots, n$ and $0 \leq y \leq 1$ is given by

$$p(x, y) = \frac{n!}{(n-x)!x!} y^{x+\alpha-1} (1-y)^{n-x+\beta-1}$$

Note that x is discrete and y continuous. While the joint density is complex, the conditional densities are simple distributions. To see this, first recall that a discrete binomial random variable z has a density proportional to

$$p(z | q, n) \propto \frac{q^z (1-q)^{n-z}}{z!(n-z)!} \quad \text{for } 0 \leq z \leq n$$

where $0 < q < 1$ is the success parameter and n the number of traits, which we denote by $z \sim \text{B}(n, p)$. Likewise, recall the density for $z \sim \text{Beta}(a, b)$, a beta distribution (Equation A2.38a) with shape parameters a and b is given by

$$p(z | a, b) \propto z^{a-1} (1-z)^{b-1} \quad \text{for } 0 \leq z \leq 1$$

Observe that the conditional distribution of x (treating y as a fixed constant) is $x | y \sim \text{B}(n, y)$, while $y | x \sim \text{Beta}(x + \alpha, n - x + \beta)$.

The power of the Gibbs sampler is that by computing a sequence of these univariate conditional random variables (a binomial and then a beta), we can compute any feature of either marginal distribution. Suppose $n = 10$ and $\alpha = 1, \beta = 2$. We start the sampler with (say) $y_0 = 1/2$ and then take it through three full iterations.

- (i) x_0 is obtained by generating a random $\text{B}(n, y_0) = \text{B}(10, 1/2)$ random variable, returning $x_0 = 5$ in our simulation.
- (ii) y_1 is obtained from a $\text{Beta}(x_0 + \alpha, n - x_0 + \beta) = \text{Beta}(5 + 1, 10 - 5 + 2)$ random variable, returning $y_1 = 0.33$.
- (iii) x_1 is a realization of a $\text{B}(n, y_1) = \text{B}(10, 0.33)$ random variable, returning $x_1 = 3$.
- (iv) y_2 is obtained from a $\text{Beta}(x_1 + \alpha, n - x_1 + \beta) = \text{Beta}(3 + 1, 10 - 3 + 2)$ random variable, returning $y_2 = 0.56$.
- (v) x_2 is obtained from a $\text{B}(n, y_2) = \text{B}(10, 0.56)$ random variable, returning $x_2 = 7$.

Our particular realization of the Gibbs sequence after three iterations is thus $(5, 0.33), (3, 0.56), (7, 0.56)$. We can continue this process to generate a chain of the desired length. Obviously,

the initial values in the chain are dependent upon the value of y_0 chosen to start the chain. This dependence decays as the sequence length increases, so we typically start recording the sequence only after a sufficient number of burn-in iterations have occurred.

When more than two variables are involved, the sampler is extended in the obvious fashion. In particular, the value of the k th variable is drawn from the distribution $p(\theta^{(k)} | \Theta^{(-k)})$, where $\Theta^{(-k)}$ denotes a vector containing all of the variables but k . Thus, during the i th iteration of the sample, to obtain the value of $\theta_i^{(k)}$, we draw from the distribution

$$\theta_i^{(k)} \sim p(\theta^{(k)} | \theta^{(1)} = \theta_i^{(1)}, \dots, \theta^{(k-1)} = \theta_i^{(k-1)}, \theta^{(k+1)} = \theta_{i-1}^{(k+1)}, \dots, \theta^{(n)} = \theta_{i-1}^{(n)})$$

For example, if there are four variables, (w, x, y, z) , the sampler becomes

$$\begin{aligned} w_i &\sim p(w | x = x_{i-1}, y = y_{i-1}, z = z_{i-1}) \\ x_i &\sim p(x | w = w_i, y = y_{i-1}, z = z_{i-1}) \\ y_i &\sim p(y | w = w_i, x = x_i, z = z_{i-1}) \\ z_i &\sim p(z | w = w_i, x = x_i, y = y_i) \end{aligned}$$

Gelfand and Smith (1990) illustrated the power of the Gibbs sampler to address a wide variety of statistical issues, while Smith and Roberts (1993) showed the natural marriage of the Gibbs sampler with Bayesian statistics for obtaining posterior distributions. A nice introduction to the sampler was presented by Casella and George (1992), while further details can be found in Tanner (1996), Besag et al. (1995), Sorensen and Gianola (2002), Robert and Casella (2004), and Lee (2013). Note that the Gibbs sampler can be thought of as a stochastic analog to the Expectation-Maximization (EM) approaches (LW Appendix 4) used to obtain likelihood functions when missing data are present. In the sampler, random sampling replaces the expectation and maximization steps.

Using the Gibbs Sampler to Approximate Marginal Distributions

Any feature of interest for the marginals can be computed from the m realizations of the Gibbs sequence. If $\theta_1, \dots, \theta_m$ is an appropriately burned-in set of realizations from a Gibbs sampler, the expectation of any function, f , of the random variable θ is approximated by

$$E[f(\theta)]_m = \frac{1}{m} \sum_{i=1}^m f(\theta_i) \quad (\text{A3.26a})$$

This is the **Monte-Carlo (MC) estimate** of $f(x)$, as $E[f(\theta)]_m \rightarrow E[f(\theta)]$ as $m \rightarrow \infty$. Likewise, the MC estimate for any function of n variables $(\theta^{(1)}, \dots, \theta^{(n)})$ is calculated by

$$E[f(\theta^{(1)}, \dots, \theta^{(n)})]_m = \frac{1}{m} \sum_{i=1}^m f(\theta_i^{(1)}, \dots, \theta_i^{(n)}) \quad (\text{A3.26b})$$

Example A3.7. Although the sequence of length 3 that was computed in Example A3.6 is too short (and too dependent on the starting value) to be a proper Gibbs sequence, for illustrative purposes we can use it to compute Monte-Carlo estimates. The MC estimates of the means of x and y are

$$\bar{x}_3 = \frac{5 + 3 + 7}{3} = 5, \quad \bar{y}_3 = \frac{0.5 + 0.33 + 0.56}{3} = 0.46$$

We use the subscript 3 throughout to remind the reader of the sample size of this particular Gibbs sampler. Similarly, $(\bar{x}^2)_3 = 27.67$, $(\bar{y}^2)_3 = 0.22$, and $(\bar{xy})_3 = 2.47$, returning the MC estimates of the variances of x and y as

$$\text{Var}(x)_3 = (\bar{x}^2)_3 - (\bar{x}_3)^2 = 2.67, \quad \text{Var}(y)_3 = (\bar{y}^2)_3 - (\bar{y}_3)^2 = 0.25$$

and their covariance as

$$\text{Cov}(x, y)_3 = (\bar{xy})_3 - \bar{x}_3 \cdot \bar{y}_3 = 2.47 - 5 \cdot 0.46 = 0.16$$

While computing the MC estimate for any moment using the sampler is straightforward, computing the actual *shape* of the marginal density is slightly more involved. While one might use the empirical histogram of the Gibbs sequence as a rough approximation of the marginal distribution of x , this turns out to be inefficient, especially for obtaining the tails of the distribution. A better approach is to use the average of the conditional densities $p(x | y = y_i)$, as the function form of the conditional density contains more information about the shape of the entire distribution than the sequence of individual realizations, x_i (Gelfand and Smith 1990; Liu et al. 1991). Because

$$p(x) = \int p(x | y) p(y) dy = E_y [p(x | y)] \quad (\text{A3.27a})$$

one can approximate the marginal density using

$$\hat{p}_m(x) = \frac{1}{m} \sum_{i=1}^m p(x | y = y_i) \quad (\text{A3.27b})$$

Example A3.8. Returning to the Gibbs sequence generated in Example A3.6, recall that the distribution of x given y is binomial, with $x | y \sim B(n, y)$. If we apply Equation A3.27b, the estimate (based on this sequence) of the marginal distribution of x is the weighted sum of three binomials with success parameters of 0.5, 0.33, and 0.56, yielding

$$p_3(x) = \frac{10!}{x!(10-x)!} \left[\frac{0.5^x (1-0.5)^{10-x} + 0.33^x (1-0.33)^{10-x} + 0.56^x (1-0.56)^{10-x}}{3} \right]$$

As Figure A3.3 shows, the resulting distribution (filled bars), although a weighted sum of binomials, departs substantially from the binomial based on the average (here 0.46) of the success parameter (open bars).

REJECTION SAMPLING AND APPROXIMATE BAYESIAN COMPUTATION (ABC)

In the words of Marjoram and Tavaré (2006), for many estimation problems in modern population genetics it is “far easier to simulate than to calculate.” Consider the number of segregating sites in a sample of alleles from a population that went through a bottleneck of undetermined width at some unknown time in the past. A likelihood calculation running over all possible coalescent structures even in this simple case is extremely challenging. Conversely, if we specify the fractional reduction of the bottleneck and the time when this occurred, it is very easy to simulate a coalescent from this population structure and then randomly apply mutations to generate a sample of alleles. This logic forms the basis of an approach that Beaumont et al. (2002) called **approximate Bayesian computation (ABC)**, although its roots trace back to Tavaré et al. (1997), Weiss and von Haeseler (1998), and Pritchard

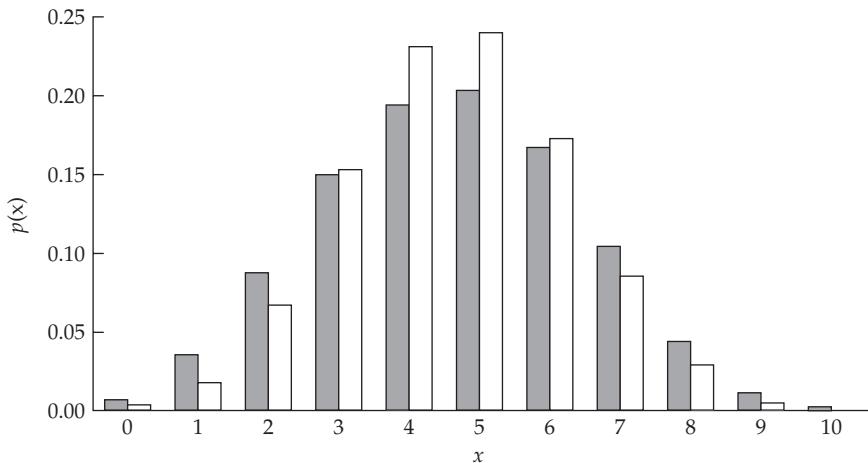

Figure A3.3 The approximation of the marginal posterior distribution for x for the distribution given in Example A3.6 using a Gibbs sequence. The open bars represent the approximation using a binomial with the Gibbs-sequence mean value of y as the success parameter, while the solid bars represent the approximation based on a weighted sum of binomials. See Example A3.8 for details.

et al. (1999). ABC is also referred to as **likelihood-free computation** in the literature (as the likelihood is obtained by simulation, rather than by direct calculation). Reviews of ABC were presented by Marjoram et al. (2003), Beaumont (2010), and Sisson and Fan (2011).

Although much of the early focus of ABC methods was on population-genetic problems, it has broad applicability in quantitative genetics. For example, Technow et al. (2015) used ABC approaches to combine crop growth models and genomic selection, while Csilléry et al. (2010) reviewed a number of applications in evolution and ecology. The use of ABC methods is a rapid growth area and, as such, our treatment is rather basic and likely dated.

A very simple example motivates ABC. Suppose we wish to calculate the posterior distribution for the success probability, p , given that a sample of size 10 has three successes and we assume a prior, $\phi(p)$, for the distribution of possible p values. We can obtain this posterior exactly without ever computing the likelihood as follows: first, we draw a random p value from the prior, $\phi(p)$, and then we generate a random draw from a binomial with $n = 10$ and the sampled value of p . If the binomial random variable generated equals 3, we record the p value (i.e., we accept it into the posterior). If not, we randomly draw a new p from $\phi(p)$ and then simulate using this new value of p , repeating this procedure until we have a sufficiently large number of accepted values to approximate the posterior. This is an example of **rejection sampling**.

More generally, one would draw a candidate vector, Θ , of model parameters from the prior, and then use these in a simulation to generate a dataset, D , which is then compared against the actual dataset, D^* . For our opening example, one would draw values of bottleneck width, time of the bottleneck, and scaled mutation rate from a joint prior. These values are then used to simulate a dataset, D , of polymorphism information for this simulated sample. If $D = D^*$, then we accept this value of Θ into the posterior and draw again. If not, we reject it and draw again. This generates a value in the MCMC sample without ever having to compute a likelihood.

The complication involved in this basic idea obviously arises when datasets become even slightly complex, as the probability that $D = D^*$ becomes vanishingly small and the rejection probability is essentially one. In this case, one instead tries to match *summary statistics* from D and D^* . Ideally, these would be **sufficient statistics** for the parameters of interest. Recall that, conditioned on the value of a sufficient statistic, the distribution of the data does not depend on the parameter of interest—all of the information on that parameter in the data is provided by the sufficient statistic. Suppose S is a vector of sufficient statistics

for the parameters of interest from the *simulated* dataset, D , and \mathbf{S}^* is the analogous vector from D^* (the sufficient statistics based on the *original* data). A strict rejection method would accept the current draw from the prior if \mathbf{S} equals \mathbf{S}^* . Here, again, the rejection probability is likely to be quite high. The approximate aspect of this approach arises when we don't require exact equality, but rather simply require that the two are "close," namely, that $|S - S^*| \leq \epsilon$ for a single sufficient statistic, or $m(\mathbf{S} - \mathbf{S}^*) \leq \epsilon$ for some distance metric, m (often this is Euclidean distance). In this case, the posterior that is generated is only an approximation. Beaumont et al. (2002) suggested regression approaches that attempt to adjust posterior values, given the distance between the simulated and actual data. A far more serious issue is when we do not use sufficient statistics for the parameters of interest (as these are often unknown, and, indeed, may not even exist). This introduces a second source of error that can be rather critical, especially if a significant amount of the information about an unknown parameter (or parameters) is not captured by \mathbf{S} . A number of approaches for dealing with this issue have been suggested (e.g., Joyce and Marjoram 2008; Nunes and Balding 2010; Jung and Marjoram 2011; Aeschbacher et al. 2012), but this is a very active research area with no current clean answer.

Example A3.9. Recall from Chapter 8 that an issue of much evolutionary interest concerns both the rate of selective sweeps and the average strength of selection for the swept allele. We can quantify the rate of sweeps by estimating the per-nucleotide adaptive evolution rate, λ , and quantify their strength by estimating the average selective advantage, s , of a swept allele. As discussed in Chapter 8, most standard estimates based on polymorphism and divergence data usually confound these two parameters. Jensen et al. (2008) developed an ABC approach to obtain separate estimates of λ and s . Their idea was to jointly consider the means and variances of several summary statistics measuring various sweep features from sequence polymorphism data. The features they included were nucleotide diversity, π , and number of segregating sites, S , for polymorphism levels; θ_H for departures in the site-frequency spectrum (Equations 9.27); and Z_{nS} for the local structure of LD (Equation 9.36b).

Their ABC approach proceeds as follows: First, values of λ and s are drawn from some joint prior, and then are used to generate a simulation of the sweep. The summary statistics of interest are then computed on this simulated data, and if they are sufficiently close to their observed values, the joint λ and s values are kept; otherwise, they are rejected and new values are drawn. This procedure is repeated to obtain (at least) several thousand accepted values to generate a joint empirical posterior distribution of λ and s values that is consistent with the observed data.

Appendix 4

Multiple Comparisons: Bonferroni Corrections, False-discovery Rates, and Meta-analysis

If your experiment needs statistics, you ought to have done a better experiment. Ernest Rutherford

Facts are stubborn things, but statistics are pliable. Mark Twain

Often one is faced with interpreting a list of p values (the probabilities of the observed outcomes under their null hypotheses), either from a set of independent experiments all testing the *same* hypothesis, or from a single experiment wherein a large number of *different* hypotheses are tested. Both of these are examples of **multiple comparisons**. In the former setting, the problem is how to best combine information from multiple, often rather disparate, studies to make more global statements. In the latter setting, our concern is controlling error over the entire *collection* of tests from a single experiment.

Issues with combining information across studies can be broken into methods for combining p values and more general methods for combining information on effect size. Given that methods for combining p values and issues related to multiple comparisons within a single experiment share some common features, we examine these first. We then turn to a more detailed look at the field of **meta-analysis (MA)**, namely, how to most efficiently combine information on effect sizes over a series of studies.

The statistical analysis of a large dataset typically involves testing, not just a single hypothesis, but rather many hypothesis (often *very* many). This is especially true in the genomics era, wherein a single **high-dimensional experiment** may test tens of thousands of hypotheses (such as treatment-dependent expression over all of the genes in a genome). For any particular test, we may assign a preset probability, α , of a **Type-I error** (i.e., a **false positive**, declaring a test to be **significant**, namely, $p \leq \alpha$, when in fact the null hypothesis is true). Under this broad setting, there are two different strategies for controlling error. First, if we expect that the vast majority of the hypotheses are truly null, we are interested in controlling the **experiment-wide error rate**, the probability of a false positive over *all* of the tests (as the vast majority will be nulls). The standard approach in this setting is the classic **Bonferroni correction**—obtaining an experiment-wide error rate of π over a set of n comparisons by declaring a test to be significant when $p \leq \alpha = \pi/n$. However, this is usually far too stringent and results in an enormous loss of power.

We review sequential-testing schemes to improve this approach, but often the adjustment for multiple comparisons is best accomplished by a *shift in thinking*. If we expect some reasonable number of the hypotheses to be false, then trying to avoid *any* false positives is not appropriate. Instead, controlling the *fraction* of false positives among the tests that are declared significant (**discoveries**) is a much better aim. This is especially true in large-scale exploratory experiments whose aim is to discover potential candidates for further study. In this setting, we attempt to control the **false-discovery rate (FDR)**, namely, the fraction of all tests *declared to be significant* that are false positives, as opposed to the type I-error (false-positive) rate. The goal is to find a value, τ , such that the set of tests that is declared to be significant using $p \leq \tau$ has the desired false-discovery rate. As we will show below, the distinction between a false positive and a false discovery is very subtle but critically important. The former is simply the probability that a test under a true null will be declared significant, while the latter further depends on whether the null is indeed correct. If the null is wrong, then the probability of a false discovery is zero, while if the null is correct, then the false discovery rate equals the probability of a false positive.

Our treatment of these topics is organized as follows. First, we examine methods for

combining p values over independent tests. We then turn to controlling the overall false-positive rate for a collection of tests from a single experiment through the use of Bonferroni corrections and their extensions. Given that the decision to control false positives versus false discoveries hinges to a large extent on the fraction, π_0 , of the hypotheses that are truly null, we then examine how π_0 can be estimated from the empirical distribution of the p values for a set of tests. Next, we then discuss approaches for controlling the false-discovery rate (settings where we expect some nontrivial fraction of the hypotheses to depart from the null). Finally, we turn to more formal issues in meta-analysis, developing a mixed-model framework for combining estimates across studies. We also examine metrics and graphical tools for assessing possible sources of bias.

COMBINING p VALUES OVER INDEPENDENT TESTS

Hypotheses of interest are often tested in multiple studies, and an important issue (the statistical field of meta-analysis—the analysis of analyses) is how best to combine the results from a set of such studies into a single global statement. The most obvious approach is simply to pool all of the data and perform a single test, but for a variety of reasons this is often not feasible. For example, different tests of the same hypothesis may involve different methodologies or very different settings. Further, published papers may not report the full dataset, but rather may just present a few summary statistics. In such settings, one straightforward approach is to consider the list of p values for the collection of experiments that all purport to test the same hypothesis and try to obtain a single global p value for this entire set. As in normal hypothesis testing, care must be taken in distinguishing between one- and two-tailed hypotheses. For example, we could get a significant p value for a new treatment over a series of tests because it is significantly *worse*, and we would draw an incorrect conclusion if we used combined p values for a two-tailed test when a one-tailed test (the treatment results in an improvement) is more appropriate.

This simple question of how best to combine p values from a set of experiments is potentially fraught with peril for several reasons. First, there is the issue of whether the different tests all really test the same hypothesis. The investigator must take care to assure that this is correct before proceeding. Second, there is concern about the so-called **file-drawer effect**, wherein nonsignificant results remain in the file drawer (i.e., are not published), leading to published results being biased toward smaller p values. One general trend seems to be a publication bias in studies with small sample sizes (where nonsignificant results are often not reported), but a reduction in this bias for larger samples (Easterbrook et al. 1991; Dickersin et al. 1992). The presumptive reason for this sample-size effect in publication bias is that small studies often lack power, so a nonsignificant result does not necessarily provide strong evidence that the null hypothesis is correct. Conversely, due to the higher power of larger studies, authors may feel more comfortable in publishing negative results. We examine several approaches that attempt to quantify the amount of any such **publication bias** in a meta-analysis at the end of this Appendix.

Fisher's χ^2 Method

Fisher (1932b) was among the first to offer a simple approach for combining p values (along with Tippett 1931), based on the important concept that *the distribution of realized p values under the null follows a uniform distribution over (0,1)*. Further, if $p \sim \text{Uniform}(0,1)$, then $-2 \ln(p) \sim \chi^2_2$ (Pearson 1938). Hence, under the null, twice the negative natural log of a p value follows a chi-square distribution with two degrees of freedom. If we have k independent tests, then the sum of their log-transformed p values is the sum of k chi-square variables. Such a sum is itself chi-square, with the degrees of freedom given by the sum of the degrees of freedom for the individual chi-squares (LW Appendix 5). These observations formed the motivation for **Fisher's combined probability test**: for k independent tests,

where p_i denotes the p value for test i , the sum

$$X^2 = -2 \sum_{i=1}^k \ln(p_i) \quad (\text{A4.1a})$$

approximately follows a χ^2_{2k} distribution.

Example A4.1. Suppose five different groups collected data to test the same hypothesis, and these groups (perhaps using different methods of analysis) report p values of 0.10, 0.06, 0.15, 0.08, and 0.07. Notice that while none of these individual tests are significant, the trend is clearly that all are “close” to being significant ($\bar{p} = 0.09$). Fisher’s statistic returns a value of

$$X^2 = -2 \sum_{i=1}^k \ln(p_i) = 24.3921 \quad \text{with} \quad \Pr(\chi^2_{10} \geq 24.39) = 0.0066$$

Hence, when taken together, these five tests show a highly significant p value.

Rice (1990b; also see Whitlock 2005) noted that a problem with Fisher’s method is that smaller p values are differentially weighted compared to complementary larger p values (e.g., p versus $1 - p$). Equation A4.1a can be rearranged to yield

$$X^2 = -2k \ln(\bar{p}_G) \quad (\text{A4.1b})$$

where \bar{p}_G is the geometric mean of the individual p values, which differentially weights smaller values. Under Fisher’s method, an observed p value of (say) 0.001 receives more weight than a complementary value of 0.999, which is as extreme (with $-\ln$ weights of 6.9 vs. 0.001). However, under the Z -score transformation—which is obtained by solving $\Pr(U > Z) = p$, where $U \sim N(0, 1)$ —the two complementary p values are of equal magnitude (Z scores of -3.09 and 3.09). This motivates the Z -score method, which we now consider.

Stouffer’s Z Score

An alternative to Fisher’s approach for combining p values was offered by Stouffer et al. (1949), who transformed the individual p values into Z scores. The sum of k independent unit normals is itself normal, with a mean of zero and a variance of k . These results lead to **Stouffer’s Z score** method: assign a score of Z_i for test i by solving $\Pr(U > Z_i) = p_i$. Let Z_s denote the sum over the transformed p values of k tests, scaled by $k^{-1/2}$ to give it a variance of one, with

$$Z_s = \frac{\sum_{i=1}^k Z_i}{\sqrt{k}} \quad (\text{A4.2a})$$

Because $Z_s \sim N(0, 1)$, the overall p value is obtained as

$$p = \Pr(U > Z_s) \quad (\text{A4.2b})$$

As noted by Whitlock (2005), this test was first proposed in a footnote in Stouffer et al.’s sociological study of army life, making it one of the more obscure origins of a statistical method.

Example A4.2. Reconsider the data from Example A4.1. The Z_i values are easily obtained using R, as the command `qnorm(1-p)` returns Z satisfying $\Pr(U \leq Z) = 1 - p$, or (equivalently) $\Pr(U > Z) = p$. For example, Z_1 is calculated by `qnorm(1-0.1)`, or 1.281. Similarly

computing the other Z_i values yields

$$\sum_{i=1}^5 Z_i = 6.754, \quad \text{hence} \quad Z_s = \frac{6.754}{\sqrt{5}} = 3.020$$

Because $\Pr(U > 3.020) = 0.00126$, as in Example A4.1, the combined p value is highly significant.

Besides providing symmetric values for large and small p values (i.e., p and $1 - p$), a second advantage of the Z -score approach is that one can individually *weight* p values from different tests (Mosteller and Bush 1954; Liptak 1958), as the weighted sum of unit normals is itself a unit normal (while the weighted sum of χ^2 variables—the analog for Fisher’s test—is considerably more complex). The resulting weighted version becomes

$$Z_w = \frac{\sum_{i=1}^k w_i Z_i}{\sqrt{\sum_{i=1}^k w_i^2}} \quad (\text{A4.2c})$$

where $Z_w \sim N(0, 1)$. As expected, Z_w (Equation A4.2c) reduces to Z_s (Equation A4.2a) when all the weights are equal. One can either weight by the degrees of freedom or by the reciprocal of the standard error of the estimate. Whitlock (2005) showed that the weighted Z -score method is superior to either X^2 or Z_s when sample size varies over the data. Z_w has higher power and also a higher correlation between its predicted p value and the actual p value obtained if one was able to merge all the samples. As noted by Whitlock, many studies in evolutionary biology examine whether a hypothesis consistently holds over a collection of species. In such cases, the number of species is the number of replicates, and weighting p values for individual species is inappropriate.

As detailed at the end of this Appendix, combining p values is one of the *least powerful* meta-analysis approaches, as it leaves much of the information from a collection of studies underutilized. A formal meta-analysis requires that studies report standard errors for their estimates. Unfortunately, many studies do not, and simply report p values instead, and in this setting the proceeding methods are the only type of meta-analysis available.

BONFERRONI CORRECTIONS AND THEIR EXTENSIONS

We now turn to the complementary problem of determining the significance level, α , for individual tests required to control the overall false-positive rate over a collection of n tests. The typical setting is that a single study or experiment has gathered data and a number of different tests, usually on *different* hypotheses, are performed using these data. Let π denote our desired experiment-wide false-positive rate—the probability of one (or more) false positives *over the entire collection* of n tests being no greater than π . The traditional approach for determining the appropriate α , given n and π , is to use **Bonferroni corrections**.

Standard Bonferroni Corrections

The probability of not making any Type-I errors (false positives) over n independent tests, each at level α , is $(1 - \alpha)^n$. Hence, the probability, π , of having at least one false positive over the entire collection is simply one minus this or

$$\pi = 1 - (1 - \alpha)^n \quad (\text{A4.3a})$$

If we solve for the α value required for each test,

$$\alpha = 1 - (1 - \pi)^{1/n} \quad (\text{A4.3b})$$

This is often called the **Dunn-Šidák method**. If we note that $(1 - \alpha)^n \simeq 1 - n\alpha$, we obtain the **Bonferroni method** by taking

$$\alpha = \pi/n \quad (\text{A4.4})$$

Both Equations A4.3b and A4.4 are referred to as **Bonferroni corrections**. In the literature, π is the **family-wide error rate (FWER)**, while α is the **comparison-wise error rate (CWER)**, also referred to as the **point-wise significance level (PWSL)**.

Example A4.3. Suppose we have $n = 100$ independent tests and wish to obtain an overall π value of 0.05. What value of α should be used for each individual test to achieve an experiment-wide false-positive rate of 0.05? The Dunn-Šidák correction suggests

$$\alpha = 1 - (1 - 0.05)^{1/100} = 0.000512$$

while the Bonferroni correction is

$$\alpha = 0.05/100 = 0.0005$$

Note that using such small α values greatly reduces the power for any single test. For example, under a normal distribution, the 95% (two-sided) confidence interval(CI) for the true mean is $\bar{x} \pm 1.96\sqrt{\text{Var}}$, where Var denotes the variance of the sample mean. Moving to an α value of 0.0005 gives the associated CI as $\bar{x} \pm 3.48\sqrt{\text{Var}}$, as $\Pr(|z| \geq 3.48) = 0.0005$ for $z \sim N(0, 1)$.

Sequential Bonferroni Corrections

Under a strict Bonferroni correction, only those tests whose associated p values are $\leq \pi/n$ are rejected (**declared significant**); all others are **accepted** (or more formally, **fail to be rejected**). This results in a considerable reduction in power if two or more of the hypotheses are actually false. When we reject a hypothesis, one fewer test remains, and the multiple comparison correction should reflect this, resulting in **sequential Bonferroni corrections**. Sequential approaches have increased power compared to standard Bonferroni corrections, as illustrated below in Example A4.4. Shaffer (1995) reviewed these and other approaches. The basic structure is that one has a collection of multiple tests, with $H(i)$ denoting the null hypothesis for test i —for example, the test that marker i has a nonzero effect, in which case $H(i)$ is the null hypothesis of no effect. In this case, rejecting $H(i)$ suggests evidence for a nonzero effect for marker i .

Holm's Method

The simplest of these sequential adjustments is **Holm's method** (Holm 1979). The first step is to order the p values for the n hypotheses being tested from smallest to largest, $p(1) \leq p(2) \leq \dots \leq p(n)$, and let $H(i)$ be the hypothesis associated with $p(i)$. One proceeds with Holm's method as follows:

- (i) If $p(1) > \pi/n$, accept all n null hypotheses (i.e., none are declared significant).
- (ii) If $p(1) \leq \pi/n$, reject $H(1)$ [i.e., $H(1)$ is declared significant], and consider $H(2)$.
- (iii) If $p(2) > \pi/(n - 1)$, accept $H(i)$ (for $i \geq 2$).
- (iv) If $p(2) \leq \pi/(n - 1)$, reject $H(2)$ and move onto $H(3)$.
- (v) Proceed with rejecting hypotheses until reaching the first i such that $p(i) > \pi/(n - i + 1)$.

We can also apply Holm's method using Equation A4.3a—namely, $\alpha = 1 - (1 - \pi)^{1/n}$, the Dunn-Šidák correction—in place of $\alpha = \pi/n$.

Simes-Hochberg Method

With Holm's method, we stop once we fail to reject a hypothesis. An improvement on this approach is the **Simes-Hochberg correction** (Simes 1986; Hochberg 1988), which effectively starts backward, working with the largest p values first.

- (i) If $p(n) \leq \pi$, then all hypothesis are rejected.
- (ii) If not, $H(n)$ cannot be rejected, and we next examine $H(n - 1)$.
- (iii) If $p(n - 1) \leq \pi/2$, then all $H(i)$ for $i \leq n - 1$ are rejected.
- (iv) If not, $H(n - 1)$ cannot be rejected, and we compare $p(n - 2)$ with $\pi/3$.
- (v) In general, if $p(n - i) \leq \pi/(n - i + 1)$, then all $H(i)$ for $i \leq n - i$ are rejected.

While the Simes-Hochberg approach is more powerful than that of Holm's (see Example A4.4), it is only strictly applicable when the group of tests being jointly considered are independent, whereas Holm's approach does not have this restriction. Hence, the general strategy is to use Holm's method if one is concerned about potential dependencies between tests, and the Simes-Hochberg's method if the tests are independent.

Hommel's Method

Hommel's method (1988) is slightly more complicated, but it is more powerful than the Simes-Hochberg correction (Hommel 1989). Under Hommel's method, we reject all hypotheses whose p values are less than or equal to π/k^* , where

$$k^* = \max_i \left(p(n - i + j) > \pi \frac{j}{i} \right) \quad \text{for all } j = 1, \dots, i$$

Example A4.4 shows how all three of these methods are applied.

Example A4.4. Suppose for $n = 10$ tests, the (ordered) p values are as follows:

i	1	2	3	4	5	6	7	8	9	10
$p(i)$	0.0020	0.0045	0.0060	0.0080	0.0085	0.0090	0.0175	0.0250	0.1055	0.5350
$\frac{\pi}{n-i+1}$	0.0050	0.0056	0.0063	0.0071	0.0083	0.0100	0.0125	0.0167	0.0250	0.0500

For an experiment-wide level of significance of $\pi = 0.05$, the Bonferroni correction is $\alpha = 0.05/10 = 0.005$. Hence, using a strict Bonferroni, we reject hypotheses 1 and 2, and we fail to reject (i.e., we accept) 3 through 10. To apply sequential methods, we use the associated $\pi/(n - i + 1)$ values for $\pi = 0.05$, which are given above in the table. Under Holm's method, $p(i) \leq \pi/(n - i + 1)$ for $i \leq 3$, and hence we reject $H(1)$ through $H(3)$ and accept the others. Under Simes-Hochberg, we fail to reject $H(7)$ through $H(10)$ [as $p(i) > \pi/(n - i + 1)$], but because $p(6) = 0.009 \leq \pi/(n - i + 1) = 0.010$, we reject $H(6)$ through $H(1)$.

To apply Hommel's method, we reject all hypotheses whose p values are less than or equal to π/k^* , where

$$k^* = \max_i \left(p(n - i + j) > \pi \frac{j}{i} \right) \quad \text{for all } j = 1, \dots, i$$

Solving k^* requires an iterative approach, as follows. First, start with $i = 1$. Here, ($i = 1, j = 1$), $p(10) = 0.5350 > \pi \cdot (1/1) = 0.05$. Now let us try $i = 2$, which yields (for $j = 1, 2$), $p(9) = 0.1055 > \pi(1/2) = 0.025$ and (as above) $p(10) > \pi$. Hommel's condition still holds for $i = 3$, as $p(8) = 0.025 > \pi \cdot (1/3) = 0.0167$, $p(9) > \pi \cdot (2/3) = 0.033$, and $p(10) > \pi$. However, it fails for $i = 4$, as while it holds for $p(7) = 0.175 > \pi \cdot (1/4) = 0.0125$, it fails for ($i = 4, j = 2$) because $p(8) = 0.025 = \pi \cdot (1/2)$. Hence, $k^* = 3$ (because Hommel's condition holds for $k = 3$ but not for $k = 4$), and we reject all hypotheses whose p values are

$\leq 0.05/3 = 0.0167$, which means $H(1)$ through $H(6)$. Note that a strict Bonferroni rejected the fewest null hypotheses and Simes-Hochberg and Hommel's rejected the most null hypotheses (i.e., declared them to be significant), and all methods controlled the experiment-wide false-positive rate at 0.05.

Cheverud's Method and Other Approaches for Dealing with Dependence

When different tests share correlated data, it introduces dependency between the p values for these tests. How do we account for this? One approach (Cheverud 2001; Li and Ji 2005; Nyholt 2005) is to use the nature of the dependency structure of the data to estimate an **effective number of independent tests**, n_e . This value is then substituted for n in the above methods; e.g., Equation A4.3b becomes $\alpha = 1 - (1 - \pi)^{1/n_e}$. A classic application of this approach is correcting for correlations among tests of marker-trait associations over a set of linked markers in either a QTL mapping experiment or a GWAS (LW Chapters 15 and 16).

To proceed, we need to introduce a few facts about the eigenstructure of a *correlation matrix*, \mathbf{C} , whose eigenvalues are denoted (from largest to smallest) by $\lambda_1, \dots, \lambda_n$. First, because \mathbf{C} is a positive-semidefinite matrix, all $\lambda_i \geq 0$ (Appendix 5). Second, \mathbf{C} is an $n \times n$ matrix with ones on its diagonal, which makes its trace (the sum of its diagonal elements; Appendix 5) equal to a value of n . The importance of this result is that the trace of a matrix equals the sum of its eigenvalues (Equation A5.8), which demonstrates that the average eigenvalue of \mathbf{C} is

$$n^{-1} \sum_{i=1}^n \lambda_i = n^{-1} n = 1$$

When all of the underlying variables that generate \mathbf{C} are uncorrelated, then $\lambda_1 = \dots = \lambda_n = 1$, while when all of the observations are completely correlated, then $\lambda_1 = n$ and $\lambda_2 = \dots = \lambda_n = 0$. These two cases represent the extremes of n independent tests (the former) and one independent test (the latter). As with principal components (Appendix 5), the spread of the eigenvalues tells us about dependency. One metric of this is the variance in the eigenvalues, $\sigma^2(\lambda)$. If all of the eigenvalues are equal, then $\sigma^2(\lambda) = 0$, while if one eigenvalue is nonzero, then $\sigma^2(\lambda) = n$.

Motivated by the above eigenstructure observations, **Cheverud's method** (2001) computes the effective number of independent tests as

$$n_{e,Cheverud} = n \left(1 - \frac{(n-1)\sigma^2(\lambda)}{n^2} \right), \quad \text{where} \quad \sigma^2(\lambda) = \frac{1}{n-1} \sum_{i=1}^n (\lambda_i - 1)^2 \quad (\text{A4.5a})$$

This returns $n_e = n$ when $\sigma^2(\lambda) = 0$ and $n_e = 1$ when $\sigma^2(\lambda) = n$, which matches the expected results from the eigenvalue analysis for these extreme cases.

Li and Ji (2005) noted that Cheverud's method often returns an overly large value of n_e (and therefore, less power), especially when used with a large number of moderately correlated tests. While Cheverud's approach considered the two extreme cases (n vs. 1 independent test), Li and Ji noted that a set of c identical tests will result in an eigenvalue of $c > 1$, while tests that are only partially correlated with others will generate eigenvalues values < 1 . Hence, they partitioned an eigenvalue into two parts, its integer value and the remainder, where the integer part implies identical tests (and hence is counted as contributing one independent test), while the remainder represents partial correlations. Hence, if an eigensequence is 4.1, 3.5, 1, 0.5, 0.1, ..., then the first three eigenvalues correspond to independent tests, and with the total of their non-integer residuals ($0.1 + 0.5 + 0.5 + 0.1 = 1.2$) adding one additional test, giving (for this part of the sequence) an effective number of four independent tests. Formally, the **Li-Ji method** is coded as

$$n_{e,Li-Ji} = \sum_{i=1}^N I(\lambda_i \geq 1) + \sum_{i=1}^N (\lambda_i - \text{floor}[\lambda_i]) \quad (\text{A4.5b})$$

where the indicator function $I(x \geq 1)$ returns a value of one when $x \geq 1$, and otherwise returns a value of zero. Hence, the first sum in Equation A4.5b is the number of eigenvalues of \mathbf{C} that are ≥ 1 . The $\text{floor}[x]$ function in the second term corresponds to the largest integer $\leq x$, so the second sum is all of the remainder terms (the effects of partial correlations among tests). Additional corrections for dealing with correlated tests have been proposed (e.g., Owen 2005; Efron 2007; Leek and Storey 2007, 2008; Li et al. 2012).

DETECTING AN EXCESS NUMBER OF SIGNIFICANT TESTS

While Bonferroni corrections (and their sequential counterparts) are widely used, when the number of tests is modest to large, their application significantly erodes power, leading to very high **Type-II errors** (failing to declare a test significant when the null is false). This tradeoff of Type-I versus Type-II errors applies to most statistical tests (LW Appendix 5), and the error of more concern to the investigator determines how to proceed. In many cases, our initial experiment is simply an enrichment method: we wish to take a large number of possible hypotheses and extract a subset showing the most support for their alternative hypotheses for further consideration. In such cases, we are often more concerned with Type-II errors, as the cost of rejecting a hypotheses that is truly null (i.e., improperly including it as significant; i.e., Type-I error) may be less than the cost of excluding a hypotheses from the alternative (failure to reject; i.e., a Type II-error). In such settings, we would like to calculate the number of hypotheses (n_0 ; or equivalently, the fraction $\pi_0 = n_0/n$) of true nulls among the n tested hypotheses. The first step toward doing so is to ask if the observed number of significant tests is excessive under the **global null hypotheses** (all hypotheses are truly nulls).

How Many False Positives?

Suppose we perform n independent tests, each with a Type-I error rate of α . If all hypotheses are truly null, the number, j , of false positives follows a binomial distribution, with a “success” probability (a false positive) of α , and n trials (the number of tests), yielding

$$\Pr(j \text{ false positives}) = \frac{n!}{(n-j)! j!} (1-\alpha)^{n-j} \alpha^j \quad (\text{A4.6})$$

For n large and α small, this is closely approximated by the Poisson distribution, with Poisson parameter $n\alpha$ (the expected number of false positives), yielding

$$\Pr(j \text{ false positives}) \simeq \frac{(n\alpha)^j e^{-n\alpha}}{j!} \quad (\text{A4.7})$$

Example A4.5. Suppose 250 independent tests are performed, each with $\alpha = 0.025$ (a 2.5% chance of declaring a result from the null hypothesis to be significant), and 15 tests are declared significant by this criteria. Is this number greater than expected by chance? The expected number of significant tests under the global null hypothesis is $n\alpha = 250 \cdot 0.025 = 6.25$. From Equation A4.5, the probability of observing 15 (or more) significant tests is

$$\sum_{j=15}^{250} \Pr(j \text{ false positives}) = \sum_{j=15}^{250} \frac{250!}{(250-j)! j!} (1-0.025)^{250-j} 0.025^j$$

We could either sum this series directly or use the cumulative distribution function for a binomial. In R, the probability that a binomial with parameters n and p has a value of i or less is obtained by using the command `pbinom(i, n, p)`. The probability of 15 or greater is one minus the probability of 14 or less, or `1 - pbinom(14, 250, 0.025)`, for which R returns 0.0018. A similar calculation can use the Poisson approximation (Equation A4.7), with $1 -$

`ppois(14, 6.25)` returning a value of 0.0021. Given that there is only a 0.2% chance of seeing this many significant tests under the global null, we expect that some of these significant tests are true **discoveries** (those whose associated null hypothesis is incorrect), not false positives. The critical question, of course, is which ones?

Testing for an excessive number of significant tests is a rather crude indicator of the actual number (n_0) of the n tests that are true nulls. It is very possible that $n_0 < n$ and yet we would not detect an excess of significant tests by the above method. Likewise, if an excessive number is detected, what really can we say about n_0 other than $n_0 < n$? For instance, Example A4.5 shows an excess of 9 significant tests (observed 15, expected 6), but clearly assuming $n_0 = n - 9$ is a bit naive. Finally, the outcome varies with our choice of α . One could easily imagine an excess of significant tests using $\alpha = 0.05$, but not when using $\alpha = 0.01$. Ideally, we would like to have an estimate for n_0 that is independent of the choice of α .

Such estimators readily follow from one of the key ideas in this Appendix, namely that *if the null is correct, random draws of p values follow a uniform distribution over (0,1)*. A more careful examination of the empirical distribution of p values over our sample of tests, rather than simply how many we declare significant, is the key to obtaining estimates of n_0 .

Schweder-Spjøtvoll plots

A simple graphical approach using the empirical distribution of p values was suggested by Schweder and Spjøtvoll (1982). If one rank-orders the p values from the smallest $p(1)$ to the largest $p(n)$, a plot of $p(i)$ versus i is a straight line under a uniform. Because our interest is usually in detecting an excessive number of small p values (as would be expected if $n_0 < n$), Schweder and Spjøtvoll suggest plotting $1 - p(i)$ values on the horizontal axis, and the ranks of these values (which are the reverse of the ranks of the $p[i]$) on the vertical axis. For example, the first point is $(1 - p[n], 1)$, the second $(1 - p[n - 1], 2)$, \dots , and the n th $(1 - p[1], n)$. If all of the p values are indeed generated from null hypotheses, then these are drawn from a uniform, and the resulting plot will be a straight line (the solid triangles in Figure A4.1). Conversely, if some of the p values are drawn from hypotheses where the null is false, we expect an excess of small p values, and hence an over-abundance of $1 - p$ values near one (the open circles in Figure A4.1).

In addition to providing a quick visual check as to whether the p values follow a uniform, Schweder and Spjøtvoll suggest that these plots can also estimate n_0 . One fits the best straight line until the upturn (i.e., inflection point) near one appears, extrapolating this line to obtain the n value for $1 - p = 1$ estimates the number of true null hypotheses, n_0 . As shown in Figure A4.1, this gives a value very close to 80 (for the open circles), the correct number of true nulls used to generate this figure.

Estimating n_0 : Subsampling From a Uniform Distribution

As suggested by the Schweder-Spjøtvoll plot, the distribution of p values offers insight into the number of truly null hypotheses, n_0 . While this plot offers either a simple visual, or a more formal regression-based, estimator of n_0 , it tends to overestimate the number of nulls. Further, it can be difficult to specify exactly where the upturn in the plotted values begins. A number of other estimators have been suggested, again based on a uniform distribution of p values for those tests under the null. Recall that the histogram from a sufficiently large number of draws from a uniform distribution is flat, as all values are equally likely (Figure A4.2A). However, if the null is false for at least some of the tests, then the distribution of p values is shifted away from uniform, and usually with a skew toward smaller values (Figure A4.2B), but potentially also skewed toward one (for example, if one-tailed tests are used when a two-tailed test is appropriate; Figure A4.2C).

If the collection of tests contains some alternative hypotheses mixed in with true nulls,

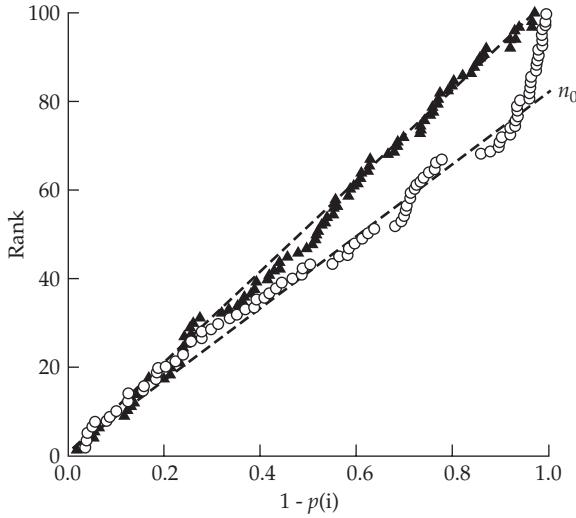

Figure A4.1 A Schweder-Spjøtvoll plot is one approach for detecting departures from a uniform distribution of p values. The p values are ordered from smallest, $p(1)$, to largest, $p(n)$, and one plots the rank of $1 - p(i)$ versus its value. These ranks are reversed from the ranks of $p(i)$, as the rank of $1 - p(n)$, being the smallest value, is 1. Under a uniform, the result is a straight line passing through the origin and the point $(1, n)$. The upper curve (solid triangles), generated by randomly sampling $n = 100$ values from a uniform $(0,1)$, fits this pattern. The lower curve (open circles), generated by simulating p values for 80 true nulls and 20 tests where the alternative was correct, shows an inflation of p values near zero ($1 - p$ values near one). This results in a strong departure from linearity near one. Ignoring this upturn and extrapolating the linear fit for the values below this inflection point gives an approximate value of 80 for the value of this projected line when $1 - p = 1$. This is the estimate of n_0 .

we expect the distribution to be a mixture, with fraction, $\pi_0 = n_0/n$, consisting of draws from a uniform and the remaining fraction, $(1 - n_0/n)$, from some other distribution. Figure A4.3 plots the empirical distribution of p values from a study by Mosig et al. (2001) on marker-trait associations. While the middle of the distribution appears to be consistent with random sampling around a flat average, there is a large excess of values near zero.

One simple approach for estimating n_0 is to use the average height for the middle range of the p -value histogram. Presumably, these p values are almost entirely drawn from null hypotheses, though this may not be the case for values near zero (and potentially one). Recall that the probability density function for a uniform over $(0,1)$ has a very simple form

$$\phi_u(p) = 1 \quad \text{for} \quad 0 \leq p \leq 1 \quad (\text{A4.8a})$$

If there are n_0 truly null tests, then the expected number of p values from these tests that fall within an interval $0 \leq a < b \leq 1$ is simply

$$n_0 \int_a^b \phi_u(p) dp = n_0 \int_a^b 1 \cdot dp = n_0(b - a) \quad (\text{A4.8b})$$

Hence

$$\hat{n}_0(a, b) = \frac{\text{Number of } p(i) \text{ values in } (a, b)}{b - a} \quad (\text{A4.8c})$$

Likewise, an estimate for the fraction $\pi_0 = n_0/n$ of true nulls is

$$\begin{aligned} \hat{\pi}_0(a, b) &= \frac{\text{Number of } p(i) \text{ values in } (a, b)}{n(b - a)} \\ &= \frac{\text{Fraction of } p(i) \text{ values in } (a, b)}{b - a} \end{aligned} \quad (\text{A4.8d})$$

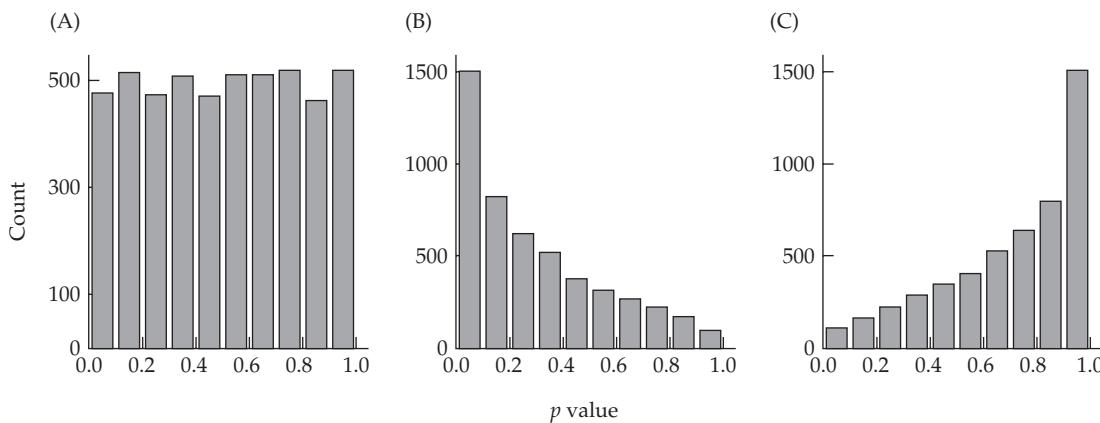

Figure A4.2 Simulated distribution of p values based on 5000 tests for samples of 25 draws from a normal distribution with a mean of μ and a variance of one. The null hypothesis is $H_0 : \mu \leq 0$. **A:** The distribution of p values when $\mu = 0$ (the null is correct) is uniform. **B:** The distribution when $\mu = 0.2$ is skewed toward an excess of values near zero. **C:** The distribution when $\mu = -0.2$ is skewed toward an excess of values near one.

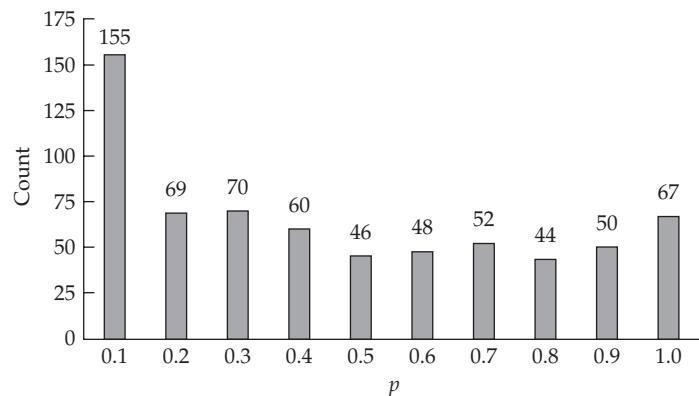

Figure A4.3 An empirical distribution of p values (for $n = 644$ tests) from Mosig et al. (2001). The number of p values in each of ten bins (of width 0.1) are given above the bars. Note the large excess of values near zero.

Example A4.6. According to the data in Figure A4.3, what is n_0 ? Consider the bins centered around $p = 0.5$. Based on the central three bins (0.4, 0.5, and 0.6), a total of $60 + 46 + 48 = 154$ tests have p values in this interval. From Equation A4.8b, $154 = n_0 \cdot 0.3$ or $n_0 = 154/0.3 = 513$, and hence a fraction, $\pi_0 = n_0/n = 513/644 = 0.80$, of the tests are true nulls. Using the bins from 0.3 to 0.8 yields $n_0 = 322/0.6 = 537$, or $\pi_0 = 537/644 = 0.83$. Hence, it appears that around 80% of the tests are consistent with true nulls. Mosig et al. (2001; also see Nettleton et al. 2006) used an iterative approach (also based on bin counts in the p -value histogram) and arrived at an estimate of $n_0 = 500$ (78%).

Storey and Tibshirani (2003) considered the number of p values exceeding some tunable parameter value, λ (taking $a = \lambda$ and $b = 1$ in Equation A4.8b), on the logic that for larger values of λ , most of these draws are from the uniform corresponding to draws from the null. Let $\hat{\pi}_0(\lambda)$ denote the estimated fraction of truly null hypotheses based on using a tuning

value of λ , then

$$\hat{\pi}_0(\lambda) = \frac{\text{Number of } p(i) \text{ values} > \lambda}{n(1 - \lambda)} \quad (\text{A4.9a})$$

and

$$\hat{n}_0(\lambda) = n \cdot \hat{\pi}_0(\lambda) = \frac{\text{Number of } p(i) \text{ values} > \lambda}{1 - \lambda} \quad (\text{A4.9b})$$

By focusing on the interval $(\lambda, 1)$, the **Storey-Tibshirani estimator** is potentially biased when there are an excess of p values near one. This can happen for a variety of reasons, such as inappropriate assumptions for the test statistic (e.g., the use of one-sided tests when two-sided tests are more appropriate). Both Equation A4.8c and the Storey-Tibshirani estimator (Equation A4.9b) rely on tuning parameters (a , b , and λ , respectively) which define the region of the distribution of p values assumed to be drawn from a uniform (i.e., almost all p values in this interval are assumed to be generated under the null). Nettleton et al. (2006) reviewed these and other approaches for estimating n_0 from sampling parts of a presumed uniform and elaborated on their strengths and weaknesses.

One significant concern is that correlated tests can result in either an under- or over-dispersion of p values under the global null hypothesis, resulting in significant departure from a uniform distribution (Efron 2007; Hu et al. 2011; Leek and Storey 2011). This in turn compromises estimates of n_0 .

Estimating n_0 : Mixture Models

Allison et al. (2002) suggested that π_0 can be estimated by treating the distribution of p values as a mixture, a fraction π_0 of which comes from a uniform (and hence a uniform distribution function, ϕ_u), while the remainder ($1 - \pi_0$) are from the distribution, $\phi_A(p)$, of p values when the alternative hypothesis is true (Figure A4.4). While the general form of $\phi_A(p)$ is unknown, a very flexible distribution to model it is by using the beta distribution (Appendix 2; Figure A2.3)

$$\phi_A(p) = \frac{\Gamma(a + b)}{\Gamma(a)\Gamma(b)} p^{a-1}(1-p)^{b-1} \quad (\text{A4.10a})$$

Under the alternative hypothesis, we expect an increase in p values near zero, which occurs when $a < 1$. Likewise, the beta distribution can easily accommodate an increase in p values near one ($b < 1$). When $a = b = 1$, this simply reduces to a uniform.

Allison et al. (2002) suggested fitting the actual shape by using the data to obtain ML estimates of a and b , as well as our desired parameter, the fraction of true nulls, π_0 . The resulting likelihood function for a single p value becomes

$$\ell(p) = (1 - \pi_0) \phi_A(p) + \pi_0 \phi_u(p) = (1 - \pi_0) \frac{\Gamma(a + b)}{\Gamma(a)\Gamma(b)} p^{a-1}(1-p)^{b-1} + \pi_0 \quad (\text{A4.10b})$$

with the resulting total likelihood over the n sampled p values (from independent tests) calculated by

$$\ell(\mathbf{p}) = \prod_{i=1}^n \ell(p_i) \quad (\text{A4.10c})$$

Standard ML methods (LW Appendix 2) are used to solve for a , b , and π_0 .

While hypothesis testing under a maximum likelihood framework is typically performed using the likelihood ratio (LR) test (LW Appendix 2), this is not appropriate for tests of the number of components in a mixture, as the LR does not approach a limiting χ^2 distribution, because π_0 is being tested against a boundary value, in this case a value of one (McLachlan 1987). While a modified LR test for mixtures can be constructed that behaves better (Chen et al. 2001), Allison et al. used a bootstrap approach (McLachlan 1987; Schork 1992). Here, one first uses the original distribution of p values to compute an LR test statistic for the null of a uniform versus the alternative of a mixture. One then generates **parametric**

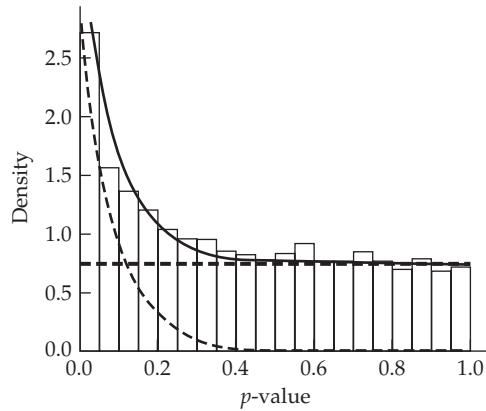

Figure A4.4 The empirical distribution of p values can be treated as a mixture model of a uniform plus a beta distribution (whose shape parameters, a and b , can be estimated via ML), see Equation A4.10b. In this hypothetical example, a weighted mixture of a uniform (horizontal dashed line) and a beta with ($a < 1, b = 1$; dashed curve), yields the mixture distribution (solid curve) that fits the empirical distribution of the p values.

bootstrap samples by drawing n values of p from the null distribution (here a uniform) and then using this simulated dataset to compute an LR test statistic for a mixture. This is done several thousand times to generate an approximate distribution of the LR statistic under the null, which is used to assess significance. For example, if only 0.25% of the bootstrap LR values are equal to (or exceed) the LR value for the original data, the significance is approximately 0.25%. Likewise, approximate standard errors for π_0 can be generated using a **conventional bootstrap** approach. One samples the *original* p values with replacement to generate a **bootstrap sample** of size n . This is then used to estimate π_0 (and the other parameters) under a standard ML framework. Several thousand bootstrap samples are generated, and the variation across estimates of π_0 (or any other parameter) over these samples provides an approximate estimate of the sampling variance for $\hat{\pi}_0$.

Finally, while a beta (or weighted sum of betas) can be used as the functional form for ϕ_A , another approach is to use a nonparametric estimator for this unknown density function. This can be done using a **kernel density estimator**, whereby the form of an unknown density is estimated by using the observed number of counts within a series of bins spanning the distribution in conjunction with an appropriate smoothing function. This approach was used by Robin et al. (2007) and Guedj et al. (2009).

FDR: THE FALSE-DISCOVERY RATE

As mentioned, Bonferroni corrections (and their extensions) are appropriate when we expect that only a very few of the many null hypotheses are false. An alternate setting is that in which some substantial fraction of the null hypotheses is *expected* to be false. In such cases, even sequential Bonferroni corrections are likely to be too stringent, resulting in too many false negatives (Type-II errors; i.e., a failure to reject a false hypothesis). A different approach is required in these settings, most notably the **false-discovery rate (FDR)**, introduced by Benjamini and Hochberg (1995).

The FDR is the fraction of false positives among all the tests that are declared to be significant. The motivation for using the FDR is that we may be conducting a very large number of tests, with those that are declared to be significant being subjected to further study. An example would be a search for differential expression over a huge set of genes. The goal of the initial analysis is to distill a large number of candidates down to a reduced set (for further analysis) that is highly enriched for true positives.

In such cases, we are more concerned with making sure all possible true alternatives are included in this reduced set, and we are willing to accept some false positives to ac-

complish this goal. However, we also don't want to be completely swamped with false positives. The goal is a statistical procedure that results in a significant *enrichment* of true positives (differentially expressed genes in our example), while controlling the fraction of false positives within this enriched set by specifying a value, δ , for the FDR. Choosing an FDR of 5% means that (on average) 5% of the genes that we declare to be significant are actually false positives. The flip side is that 95% of those genes (tests) that are declared to be significant do indeed have differential expression. Hence, screening genes with an FDR of 5% results in a significant enrichment of genes that are truly differentially expressed.

To formally motivate the concept of the FDR, suppose a total of n hypotheses are tested, S of which are judged significant (i.e., the p value for the test is \leq some threshold value, τ). If we had complete knowledge, we would know that n_0 of the hypotheses have the null true and $n_1 = n - n_0$ have the alternative true, and we might find that F of the true nulls were called significant, while T of the alternative trues were called significant, yielding the following table

	Called significant	Called not significant	Total
Null true	F	$n_0 - F$	n_0
Alternative true	T	$n_1 - T$	n_1
Total	S	$n - S$	n

For this experiment, the false-discovery rate is the fraction of tests called significant that are actually true nulls, $\text{FDR} = F/S$. (The term **discovery** follows in that a significant result can be considered as a discovery for future work.) As a point of contrast, the normal Type-I error (which we can also call the **false-positive rate [FPR]**), which is the fraction of true nulls that are called significant, is F/n_0 . Note the critical distinction between these two error rates. While the numerator of each is F , the denominators are considerably different—the total number, S , of tests called significant (for FDR), versus the number, n_0 , of hypotheses that are truly null (FPR). As the threshold value (τ) for significance is changed, so too is the fraction F/S . To obtain a FDR of δ over our experiment, τ is adjusted to find its largest value such that some expectation of F/S is bounded above by δ . Finally, Gadbury et al. (2004) defined the **expected discovery rate (EDR)** as T/n_1 (the fraction of all true discoveries declared to be significant), which is the analog of statistical power in this setting.

Another way to see the distinction between the false-positive rate and the false-discovery rate is to consider them as probability statements for a single test involving hypothesis i . For the FDR, we condition on the test as being significant,

$$\text{FDR} = \Pr(i \text{ is truly null} \mid i \text{ is deemed significant}) = \delta \quad (\text{A4.11a})$$

whereas for the false-positive rate, we condition on the hypothesis being null

$$\text{FPR} = \Pr(i \text{ is deemed significant} \mid i \text{ is truly null}) = \alpha \quad (\text{A4.11b})$$

Morton's Posterior Error Rate (PER) and the FDR

Table A4.1 reminds the reader of the various test parameters that arise when multiple comparisons are considered. We now show how these are related. First, the relationship between α , π , and F is as follows. Suppose we have set the false-positive rate (i.e., the Type-I error rate) for an individual test at α . Such a p -value threshold only guarantees that the expected number of false positives is bounded above by $E[F] \leq \alpha \cdot n$. For n independent tests, a π -level experiment-wide false-positive error (setting $\alpha = \pi/n$; namely, the Bonferroni correction) implies that $\Pr(F \geq 1) \leq \pi$, i.e., the probability of at least one false positive is no greater than π . To show how α , β , π_0 , and δ are related, we first need to introduce the concept of the posterior error rate.

Fernando et al. (2004) and Manly et al. (2004) both noted that FDR measures are closely

Table A4.1 Summary of the multiple comparisons parameters used in this Appendix. F denotes the number of false positives, namely, tests under the null that are declared significant.

Parameter	Definition
α	Comparison-wide Type-I error (false positive).
β	Type-II error (false negative); $1 - \beta = \text{power}$.
π	Family-wide Type-I error; $\Pr(F > 0) = \pi$.
δ	False-discovery rate.
π_0	Fraction of all hypotheses that are truly null.
p	Probability of the test statistic under the null.
$p(k)$	k th smallest p value of the n tests.

related to Morton's (1955) **posterior error rate (PER)**, originally introduced in the context of linkage analysis in humans (this is also referred to as the **false positive report probability [FPRP]**; Wacholder et al. 2004). Morton's PER is simply the probability that a single significant test is a false positive,

$$\text{PER} = \Pr(F = 1 | S = n = 1) \quad (\text{A4.12})$$

The connection between the FDR and the PER is that if we set the FDR to δ , then the PER for a randomly drawn significant test is also δ .

Framing tests in terms of the PER highlights the **screening paradox**: “Type-I error control may not lead to a suitably low PER” (Manly et al. 2004). For example, we might choose $\alpha = 0.05$, but the PER may be far higher, which means that a test that is *declared to be significant* may have a much larger probability than 5% of being a false positive. The key is that because we are *conditioning on the test being significant* (as opposed to conditioning on the hypothesis being a null, as occurs with α), S may include either false positives or true positives. The relative fractions of each (and hence the probability of a false positive) is a function of the single test parameters, α and β , and the fraction, π_0 , of hypotheses that are truly null. To see this, we apply Bayes' theorem (Equation A2.2a), which yields

$$\text{PER} = \Pr(F = 1 | S = n = 1) = \frac{\Pr(\text{false positive} | \text{null true}) \cdot \Pr(\text{null})}{\Pr(S = n = 1)} \quad (\text{A4.13})$$

Consider the numerator of Equation A4.13 first. Let $\pi_0 = n_0/n$ be the fraction of all hypotheses that are truly null. The probability that a null is declared significant is simply the Type-I error, α , hence

$$\Pr(\text{false positive} | \text{null true}) \cdot \Pr(\text{null}) = \alpha \cdot \pi_0 \quad (\text{A4.14a})$$

Turning to the denominator of Equation A4.13, what is the probability that a single (randomly chosen) test will be declared significant, $\Pr(S = n = 1)$? This event can occur because we choose to test a hypothesis that is truly null (π_0) and have a Type-I error (α), or because we choose to test a hypothesis that is truly false ($1 - \pi_0$) and avoid a Type-II error. For the latter, the power is simply T/n_1 , the fraction of all tests under the alternative that is declared to be significant. If we write the power as $1 - \beta$ (β is the Type-II error), the resulting probability that a single (randomly drawn) test is significant is

$$\Pr(S = n = 1) = \alpha\pi_0 + (1 - \beta)(1 - \pi_0) \quad (\text{A4.14b})$$

Substituting Equations A4.14a and A4.14b into Equation A4.13 yields

$$\text{PER} = \frac{\alpha \cdot \pi_0}{\alpha \cdot \pi_0 + (1 - \beta) \cdot (1 - \pi_0)} = \left(1 + \frac{(1 - \beta) \cdot (1 - \pi_0)}{\alpha \cdot \pi_0} \right)^{-1} \quad (\text{A4.15a})$$

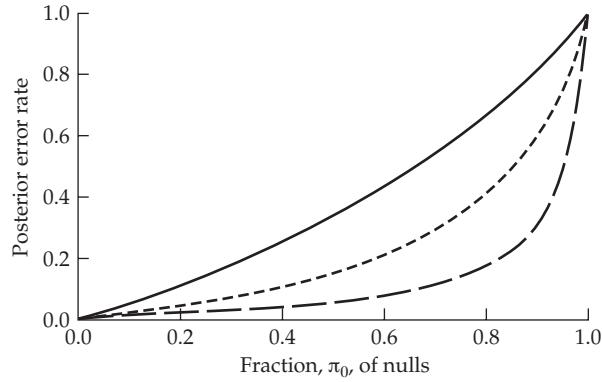

Figure A4.5 Plot of the posterior error rate (Equation A4.15a) for $\alpha = 0.05$, as a function of π_0 (the fraction of cases where the null hypothesis holds) and β (the Type-II error, which is one minus the power). The solid curve corresponds to $\beta = 0.9$ (10% power), the short-dashed curve corresponds to $\beta = 0.7$ (30% power), and the long-dashed (lower) curve corresponds to $\beta = 0$ (100% power).

Figure A4.5 plots Equation A4.15a for various values of π_0 and β .

Sham and Purcell (2014) noted that one can rearrange Equation A4.15a to find the α value to obtain a desired PER value of γ , with

$$\alpha = \left(\frac{\gamma}{1 - \gamma} \right) \left(\frac{1 - \pi_0}{\pi_0} \right) (1 - \beta) \quad (\text{A4.15b})$$

In particular, if there is complete power ($\beta = 0$) and only one of the n tested hypotheses departs from the null ($\pi_0 = n/[n + 1]$), Equation A4.15c reduces to

$$\alpha = \left(\frac{\gamma}{1 - \gamma} \right) \left(\frac{1}{n} \right) \simeq \frac{\gamma}{n} \quad (\text{A4.15c})$$

which recovers the Bonferroni correction (Equation A4.4).

The Type-I error rate, α , of a *random* test, and the PER for a *significant* test, which are often assumed to be the same, are actually very different. In addition to α , the PER also depends on the power, β , of a test and the fraction, π_0 , of tests that are truly null (as these latter parameters influence the probability that a test is declared to be significant). Manly et al. (2004) noted that the PER is acceptably low only if the fraction of alternative hypotheses ($1 - \pi_0$) is well above α .

Thinking in terms of the PER allows us to consider multiple comparisons in a continuum from Bonferroni-type corrections to using FDR to control the PER. If $\pi_1 = 1 - \pi_0$ is very small, most tests will truly be from the null hypothesis, and we can control the overall false-positive rate with a Bonferroni-type correction. However, if some fraction of the hypotheses is expected to be false (i.e., $1 - \pi_0$ is at least of modest value), then using FDR corrections makes more sense for controlling the PER.

Example A4.7. In Morton's original application, because there are 23 pairs of human chromosomes, he argued that two randomly chosen genes had a $1/23 \simeq 0.05$ prior probability of linkage, namely, $1 - \pi_0 = 0.05$, and thus $\pi_0 = 0.95$. Assuming a Type-I error rate of $\alpha = 0.05$ and 80% power to detect linkage ($\beta = 0.20$), applying Equation A4.15a yields a PER of

$$\frac{0.05 \cdot 0.95}{0.05 \cdot 0.95 + 0.80 \cdot 0.05} = 0.54$$

Hence, with a Type-I error control of $\alpha = 0.05$, a random test showing a significant result ($p \leq 0.05$) has a 54% chance of being a false positive. This occurs because most of the hypotheses are expected to be null—for example, if we draw 1000 random pairs of loci, 950 are expected to be unlinked and we expect $950 \cdot 0.05 = 47.5$ of these to show a false positive. Conversely, only 50 are expected to be linked, and we would declare $50 \cdot 0.80 = 40$ of these to be significant, so that $47.5/87.5 = 0.54$ of the significant results are due to false positives.

What value for α is needed under the above parameters to give a PER of 0.05? Solving for α in the expression

$$\frac{\alpha \cdot 0.95}{\alpha \cdot 0.95 + 0.80 \cdot 0.05} = 0.05$$

yields $\alpha = 0.0022$, and hence, setting this as the Type-I error gives a PER of 5%.

Example A4.8. Suppose we set $\alpha = 0.005$ for each test, and assume that the resulting power is essentially 1 (i.e., $\beta \simeq 0$). Consider 5000 tests under two different settings. First, suppose that the alternative is very rare, with $n_1 = 1$ ($\pi_0 = 0.9998$). Under this setting, we expect $4999 \cdot 0.005 = 24.995$ false positives and one true positive ($1 \cdot [1 - \beta] = 1$), yielding an expected PER of

$$\text{PER} = \frac{24.995}{24.995 + 1} = 0.961$$

Thus, a randomly chosen significant test has a 96.1% probability of being a false positive.

Now suppose that the alternative is not especially rare, for example $n_1 = 500$ ($\pi_0 = 0.9$). The expected number of false positives is $4500 \cdot 0.005 = 22.5$, while the expected number of true positives is 500, yielding a PER of

$$\text{PER} = \frac{22.5}{522.5} = 0.043$$

The PER is thus rather sensitive to π_0 , the fraction of all tests that are truly from the null hypothesis. If π_0 is essentially 1, a PER of δ is obtained using the Bonferroni correction, $\alpha = \delta/n$. However, if π_0 departs even slightly from one (i.e., more than a few of the alternative hypotheses are correct), then the per-test level of α to achieve a desired PER rate is considerably larger (i.e., less stringent) than that given by the Bonferroni correction, namely, $\alpha(\delta) > \delta/n$. For example, for a 0.04 experiment-wide error rate, $\alpha = 0.04/5000 = 8 \cdot 10^{-6}$, which is roughly 625 times smaller than the value of $\alpha = 0.005$ required for a 4% FDR, highlighting the greatly increased power under the FDR framework. This increased power arises because the FDR approach acknowledges that some fraction of the tests are not from the null.

A Technical Aside: Different Definitions of False-discovery Rate

While the false-discovery rate for any experiment is simply F/S , there are several subtly different ways to formally define the expectation of this ratio. The original notion of a false-discovery rate is due to Benjamini and Hochberg (1995), with modifications suggested by a number of other workers, most notable Storey (2002) and Fernando et al. (2004); see Table A4.2.

While the technical distinction between these different false-discovery rates is important, when actually estimating a false-discovery rate from a collection of p values, one is usually left with an expression of the form $E(F)/E(S)$, which consists of the expected number of false positives divided by the expected number of significant tests. Strictly speaking, this is the **proportion of false positives (PFP)**.

The main distinction between the different false-discovery rates are: (i) the original method of Benjamini and Hochberg (1995), which assumes $n = n_0$ (all hypotheses are nulls); and (ii) all other estimators, which assume n_0 is not necessarily n , and thus attempt to estimate either π_0 or n_0 , and then use either to estimate the false-discovery rate.

Table A4.2 Measures of false discovery. Here F is the number of false discoveries, S is the number of tests declared significant, and n is the total number of tests. (After Manly et al. 2004.)

	Name	Definition	Reference
FDR	False-discovery rate	$E(\frac{F}{S} S > 0) \Pr(S > 0)$	Benjamini and Hochberg (1995)
pFDR	Positive false-discovery rate	$E(\frac{F}{S} S > 0)$	Storey (2002)
PFP	Proportion of false positives	$E(F)/E(S)$	Fernando et al. (2004)
PER	Posterior error rate	$\Pr(F = 1 S = n = 1)$	Morton (1955)
FPR	False-positive rate	$\Pr(F > 0)$	

The Benjamini-Hochberg FDR Estimator

The original estimator for the FDR was introduced by Benjamini and Hochberg (1995). Suppose we declare a test to be significant if its p value is at or below some threshold value, $\tau = p(k)$, in which case k of the hypotheses will be declared significant (as $p[k]$ is the k th smallest p value), and $S = k$. Likewise, if all n of the hypotheses are null, then the expected value of F (the number of false positives) is just $n p(k)$. The resulting fraction of all rejected hypotheses that are false discoveries becomes $F/S = n p(k)/k$. Hence, the false-discovery rate, δ_k , for hypothesis k is bounded by

$$\frac{np(k)}{k} \leq \delta_k \quad (\text{A4.16a})$$

In particular, if we wish to obtain an FDR of δ for the entire experiment, then we reject (i.e., declare as significant) all hypotheses that satisfy

$$p(k) \leq \delta \frac{k}{n} \quad (\text{A4.16b})$$

This simple (heuristic) derivation shows why the original Benjamini-Hochberg estimate of the FDR is conservative, as in those settings in which one applies the FDR criteria, the expectation is that some fraction of the hypotheses are not null, and so $n_0 < n$. The correct estimator of the expected number of rejected null hypotheses is $n_0 p(k)$, which leads to a more generalized estimate of the FDR, where \hat{n}_0 (e.g., Equations A4.8–A4.10) replaces n . In this case, Equation A4.16a becomes

$$\hat{\delta}_k = \frac{\hat{n}_0 p(k)}{k} \quad (\text{A4.17})$$

Example A4.9. Consider again the 10 ordered p values from Example A4.4. Computing $n p(k)/k = 10 p(k)/k$, where k denotes the test with the k -th smallest p value, yields the following table:

k	1	2	3	4	5	6	7	8	9	10
$p(k)$	0.0020	0.0045	0.0060	0.0080	0.0085	0.0090	0.0175	0.0250	0.1055	0.5350
$n \frac{p(k)}{k}$	0.0200	0.0225	0.0200	0.0200	0.0170	0.0150	0.0250	0.0313	0.1172	0.5350

Thus, if we wish an overall FDR value of $\delta = 0.05$, we would reject hypotheses when $n p(k)/k \leq \delta = 0.05$, which is satisfied by H(1) through H(8). Notice that this procedure rejects more hypotheses (i.e., returns more discoveries) than any of the sequential Bonferroni methods (Example A4.4).

A (Slightly More) Formal Derivation of the Estimated FDR

Following Storey and Tibshirani (2003), we consider the expected FDR for an experiment where we declare a hypothesis to be significant if its p value is less than or equal to some threshold value, τ . Obviously, as τ becomes smaller, the FDR is smaller (as significant nulls become increasingly less likely). However, if τ is set too small, we lose power (e.g., suppose we set $\tau = \pi/n$; namely, the Bonferroni correction). What we would like to do is to find the expected value of the FDR as a function of the chosen threshold parameter, τ , to allow us to optimally tune this parameter to obtain the desired FDR. If we have a large number of tested hypotheses,

$$E[FDR(\tau)] = E\left[\frac{F(\tau)}{S(\tau)}\right] \simeq \frac{E[F(\tau)]}{E[S(\tau)]} \quad (\text{A4.18})$$

A simple estimate of $E[S(\tau)]$ is given by the observed number of significant tests when the threshold is τ .

To obtain an estimate for $E[F(\tau)]$, we again use the fact that the distribution of p values under the null follows a uniform $(0, 1)$ distribution. Hence,

$$\Pr(p \leq \tau \mid \text{null hypothesis}) = \int_0^\tau \phi_u(p) dp = \tau \quad (\text{A4.19})$$

where $\phi_u(p)$ is the uniform probability density function for p values under the null (Equation A4.8a). Hence, if n_0 of the n tests are truly null, then

$$E[F(\tau)] = n_0 \cdot \Pr(p \leq \tau \mid \text{null hypothesis}) \simeq n_0 \cdot \tau \quad (\text{A4.20})$$

Hence,

$$E[FDR(\tau)] = \frac{n_0 \cdot \tau}{S(\tau)} \quad (\text{A4.21})$$

Setting $\tau = p(k)$, then $S(\tau) = k$, and Equation A4.21 becomes $n_0 p(k)/k$, recovering Equation A4.17. Using the Storey-Tibshirani estimator for n_0 (Equation A4.9b), an estimated value for the FDR using threshold value, τ (and based on the tuning parameter, λ , in the Storey-Tibshirani estimator), becomes

$$\widehat{FDR}(\tau) = n_0 \cdot \frac{\tau}{S(\tau)} = \left(\frac{N[p(i) \text{ values} > \lambda]}{1 - \lambda} \right) \cdot \left(\frac{\tau}{N[p(i) \text{ values} \leq \tau]} \right) \quad (\text{A4.22})$$

where $N[x]$ is the number of occurrences of event x . Ideally, over a reasonable range of λ values, we expect this estimate be stable. If λ is set too large, the likelihood that almost all values correspond to draws from a null will be countered by the much smaller sample size (and hence a larger sampling error) from using such a small fraction of the total data.

Under a mixture-model setting (e.g., Equation A4.10), the false-discovery rate for a given a significance threshold (τ) is simply the fraction of all true positives that are declared significant divided by the fraction of all tests that are declared significant (i.e., those tests for which $p \leq \tau$). This can be estimated directly from the parameters of the mixture distribution,

$$\text{FDR}(\tau) = \frac{\pi_0 \text{cdf}_U(\tau)}{\pi_0 \text{cdf}_U(\tau) + (1 - \pi_0) \text{cdf}_A(\tau)} = \frac{\pi_0 \tau}{\pi_0 \tau + (1 - \pi_0) \text{cdf}_A(\tau)}, \quad (\text{A4.23})$$

where cdf denotes the cumulative distribution function, with

$$\text{cdf}_U(x) = \int_0^x \phi_U(p) dp = x \quad \text{cdf}_A(x) = \int_0^x \phi_A(p) dp$$

where ϕ_U is the uniform distribution under the null and ϕ_A is the distribution of p values under the alternative (for example, a fitted beta).

Storey's q Value

While we can control the FDR for an entire set of experiments, we would also like to have an indication of the FDR for any particular experiment (or test) within this family of tests. Intuitively, tests with smaller p values should also have smaller associated FDR values. To address this, Storey (2002; Storey and Tibshirani 2003) introduced the concept of a **q value** (as opposed to the p value) for a particular test, where q is the expected FDR rate for tests *within the current experiment* whose p values are at least as extreme as the test of interest. The estimated q value is a function of the p value for that test and the distribution of the entire set of p values from the family of tests being considered, namely,

$$\hat{q}[p(i)] = \min_{\tau \geq p(i)} \widehat{FDR}(\tau) \quad (\text{A4.24})$$

In words, the q value of a test is calculated by using the smallest FDR value over all significance threshold values (τ) such that this threshold is equal to, or greater than, the p value, $p(i)$ of the test.

To see why we used $\min_{\tau \geq p(i)}$ instead of simply setting $q_i = \widehat{FDR}[p(i)]$, recall Example A4.9. This example used the Benjamini-Hochberg estimator for FDR value (which differs from other FDR estimators by a constant, n_0/n). Notice that the smallest FDR occurs for hypothesis 6 (1.5%), and not for hypotheses with smaller p values. This reflects the tradeoff whereby increasing the threshold, τ , for significance results in the declaration of more tests as discoveries, so the ratio $\tau/S(\tau)$ need not monotonically increase as τ increases. As Example A4.9 shows, setting the threshold τ *above* the $p(i)$ value may actually result in a smaller q value, and hence Storey's definition.

Example A4.10. As an example of the interplay between the family-wide error rate (π), and the individual p and q values for a particular test, consider Storey and Tibshirani's (2003) analysis of a microarray dataset comparing *BRCA1* and *BRCA2* positive breast cancer tumors. A total of 3226 genes were examined. Setting a critical p value of $\alpha = 0.001$ detects 51 significant genes (i.e., those with differential expression between the two types of tumors). If we assume that the hypotheses being tested are independent (which is unlikely as expression can be highly correlated across sets of genes), the probability that there is at least one false positive is $\pi = 1 - (1 - .0001)^{3226} = 0.96$, while the expected number of false positives is $0.001 \cdot 3226 = 3.2$, or 6% (3.2/51) of the declared significant differences. After setting an FDR rate of $\delta = 0.05$, Storey and Tibshirani detected 160 genes that showed significant differences in expression. Of these 160, 8 (5%) are expected to be false positives. Compared to the Bonferroni correction (51 genes, 6% false positives), over three times as many genes were detected, and with a lower FDR rate. Further, Storey and Tibshirani estimated the fraction, π_0 , of nulls (genes with no difference in expression) at 67%, which suggests that 33% (or roughly 1000 of the 3226 genes) are likely to be differentially expressed between the two tumor types.

This dramatic difference in performance between Bonferroni and FDR control arises because the former enforces very strict control over *any* false positives, resulting in a much smaller set of discoveries. Conversely, FDR is more concerned with the *fraction* of discoveries that are false, and by including more true discoveries, that fraction can be made smaller than under Bonferroni. Because the fraction of null hypotheses that are false in this study is rather substantial, a lower significance threshold includes more of these true discoveries, thus decreasing the FDR.

To contrast the distinction between the p and q values, consider the *MSH2* gene, which has a q value of 0.013 and a p value of $5.50 \cdot 10^{-5}$. This p value implies that the probability of seeing at least this level of difference in expression for a randomly drawn gene from the null hypothesis (no difference in expression) is $5.50 \cdot 10^{-5}$. Conversely, $q = 0.013$ indicates that, *for this experiment*, 1.3% of genes that show differences in expression that are as, or more, extreme (i.e., whose p values are at least as small) as that for *MSH2* are expected to be false positives.

Closing Caveats in Using the FDR

While controlling the FDR is a very powerful approach for many multiple-comparison problems, it is not a panacea. One concern is correlations among tests. As mentioned, in this case the null distribution of p values can significantly depart from a uniform, giving biased estimates of π_0 (and thus FDR). Further, recall that FDR control is accomplished by controlling the *expected* value of the FDR (or some closely related measure, such as the PFP). The *variance* in the FDR across independent experiments can be considerable, especially when the tests are correlated (Owen 2005; Leek and Storey 2011). One approach for treating these concerns is to use Leek and Storey's (2007, 2008) surrogate variable analysis to account for dependencies among the data before the actual p values for individual tests are obtained.

A second issue is a bit more subtle. Consider a standard QTL mapping experiment (LW Chapter 15) wherein a controlled cross is made between two lines (which are typically inbred) and one looks for marker-trait associations in the resulting F_2 (or other) progeny by scanning for linkage signals across a number of linked markers that span each chromosome. For each marker, the null hypothesis is that there is no linkage to a QTL influencing the trait, while the alternative is that the marker is linked to a QTL. As noted by Chen and Storey (2006), the linkage signal from a QTL influences essentially all the markers on the chromosome arm on which it resides, and so *as a group* they all satisfy the same hypothesis. Either all are nulls (unlinked to a QTL) or all are failures of the null (linked to a QTL, albeit with differing degrees of a linkage signal). As such, investigators can arbitrarily obtain any FDR level they desire by simply adding or subtracting linked markers, and FDR control is not appropriate for this setting (Chen and Storey 2006). To a much lesser extent, the same issue occurs in genome-wide association studies among sets of extremely tightly linked SNPs. However, because the linkage signal in these cases is the persistence of linkage disequilibrium (LD) over a large number of generations, any common signal is restricted to a set of very tightly linked markers rather than an entire chromosome, and control of the FDR *among* such clusters is appropriate.

FORMAL META-ANALYSIS

Another class of analysis involving multiple comparisons considers comparison *across* studies, rather than trying to adjust for multiple comparisons *within* a single study. Such an analysis of analyses, coined **meta-analysis** (MA) by Glass (1976), is a tool of expanding importance in quantitative genetics. While multiple-comparison corrections involve isolating the significance of *separate* variables from a single large study containing many factors, a meta-analysis *combines* all information from a set of studies in order to increase the power and insight over any single study. While the roots of MA trace back to Fisher (1932b) and Cochran (1937), much of the field was developed in the social sciences. General overviews can be found in Hunter and Schmidt (2005), Borenstein et al. (2009a), and Cooper et al. (2009), and reviews with a specific focus on issues that can arise in evolution (and ecology) can be found in Harrison (2011), Nakagawa and Santos (2012), and Koricheva et al. (2013).

Informal, or Narrative, Meta-analysis

Table A4.3 shows the canonical structure of the data for a meta-analysis: one has a number of studies, either published or unpublished, dealing with a specific question (such as the average strength of natural selection; Chapter 30). Study i reports an estimate, T_i , of an effect whose true (and unknown) value is denoted by θ_i . Unfortunately, however, many studies report only T_i and perhaps, p_i , although the latter is often simply reported in binary form (whether they are significant at some level or not) rather than as an actual value.

In settings where studies simply report T_i (and perhaps p_i), only an **informal, or narrative**, MA can be performed. Here, one simply presents the statistics on the collection of T_i values, such as a histogram of effects or some metric on their overall distribution (such as their mean, median, or variance). Often these summary statistics are compared over different

Table A4.3 The potential data available for a meta-analysis of k studies. One has reported values for the estimated effect, T_i , for each study. A study may also have m reported **moderator variables** (cofactors such as sex, laboratory, species, etc.). In the simplest setting, the study only reports a p value for whether the effect is significant. In such cases, an overall p -value can be obtained from the methods discussed earlier in this Appendix. If the study also reported the standard errors (SE) of the estimates, or (under the assumption of a constant error per observation over all studies) the sample size, then a formal (i.e., model-based) meta-analysis may be performed (as detailed in the text).

Study	Effect		Sample size	SE	p value	Moderator variables
	Actual	Estimate				
1	θ_1	T_1	n_1	s_1	p_1	$M_{11}, M_{12}, \dots, M_{1m}$
2	θ_2	T_2	n_2	s_2	p_2	$M_{21}, M_{22}, \dots, M_{2m}$
3	θ_3	T_3	n_3	s_3	p_3	$M_{31}, M_{32}, \dots, M_{3m}$
\vdots	\vdots	\vdots	\vdots	\vdots	\vdots	\vdots
k	θ_k	T_k	n_k	s_k	p_k	$M_{k1}, M_{k2}, \dots, M_{km}$

values of any **moderator variables** (cofactors) associated with the data. For example, a comparison of whether the distribution of reported selection gradient (β) values vary between the sexes or over different episodes of selection.

If the p values are only reported in a binary fashion (e.g., significant or nonsignificant), a **vote-counting** (Light and Smith 1971) scheme is used, which details the number of significant differences out of a collection of tests. Again, these results might be contrasted over different moderator variables, such as those over males versus females. If the actual p values are published, then the methods given earlier in this Appendix for combining the (presumably independent) p values can be used. Both the vote-counting and combined p value approaches are examples of the **null hypothesis significance testing (NHST)** framework, and represent the *least powerful* form of MA (Hedges and Olkin 1980). Stewart (2010) bemoaned the fact that these approaches have “a long history that lingers beyond its sell-by date.” Unfortunately, many published studies in quantitative genetics only present p_i values (either actual values or values coded as significant or not significant), thus limiting the meta-analyst to these least-powerful approaches.

Furthermore, most MAs are not simply concerned about whether an effect is significant, as the usual assumption is that it is indeed. Rather, their motivation is in determining the *size of the effect* and whether it varies over cofactors of interest (for example, whether selection is stronger in males than females). If we focus only on p values, this information will be lost. When a study also reports standard errors for the test statistics (the s_i in Table A4.3), then a **formal MA** can proceed, which allows the meta-analyst to combine estimates of effect sizes, weighted by their precision, over the studies. This exploits the full power of an MA but critically depends on full transparency in reported studies (at a minimum, reporting values of s_i^2), something that is, surprisingly, often lacking.

Standardizing Effect Sizes

A formal meta-analysis proceeds by averaging over the standardized effect sizes for each study. As we will detail below, this weights each study by the strength (precision) of the evidence it provides. We will briefly review a few of the common standardizations here, pointing the reader to the general references cited at the start of this section, as well as to Nakagawa and Cuthill (2007), for more details.

The simplest setting is when study i estimates the mean of a quantity of interest, yielding

$$T_i = \bar{z}_i, \quad \text{with} \quad s_i^2 = \frac{1}{n_i - 1} \sum_{j=1}^{n_i} (z_{ij} - \bar{z}_i)^2 \quad (\text{A4.25})$$

Another common setting is that in which the study contrasts the means of two different groups, which we will call the treatment (t) versus control (c),

$$T_i = \bar{z}_{i,t} - \bar{z}_{i,c} \quad (\text{A4.26a})$$

Several slightly different standardizations exist in the literature for this case; they are of the form

$$D_i = \frac{T_i}{s_{i,p}} \quad (\text{A4.26b})$$

where $s_{i,p}$ is the pooled standard error for study i . Different standardizations arise from slightly different estimates of this pooled standard error. **Cohen's d statistic** uses Equation A4.26b with

$$s_{i,p}^2 = \frac{(n_{i,t} - 1)s_{i,t}^2 + (n_{i,c} - 1)s_{i,c}^2}{n_{i,c} + n_{i,t}} \quad (\text{A4.27})$$

Here, $n_{i,t}$ and $s_{i,t}$ (the latter from Equation A4.25 with $n_i = n_{i,t}$) are the sample size and standard error (respectively) for the treatment group, with similar expressions for the control group, c . This corresponds to the ML estimate of the pooled standard error (and hence is slightly biased; LW Chapter 27, LW Appendix 4).

Another common standardization in the literature is **Hedge's g** , which uses

$$g_i = \frac{\bar{z}_{i,t} - \bar{z}_{i,c}}{s_{i,p}}, \quad \text{where} \quad s_{i,p}^2 = \frac{(n_{i,t} - 1)s_{i,t}^2 + (n_{i,c} - 1)s_{i,c}^2}{n_{i,c} + n_{i,t} - 2} \quad (\text{A4.28a})$$

which is the unbiased OLS estimate (and hence the REML estimate) of the pooled standard error. One further correction is often applied to g_i , in that the ratio given by Equation A4.28a is a biased estimator of $(\mu_t - \mu_c)/\sigma_p$, which can be adjusted by using

$$g_i \left(1 - \frac{3}{4(n_{i,c} + n_{i,t}) - 9} \right) \quad (\text{A4.28b})$$

Besides comparisons of means, a meta-analysis often examines studies measuring the association between two variables, in which case the Pearson correlation coefficient, r_i , is the initial summary statistic. This is a slightly biased estimator of the true correlation coefficient (ρ), but a simple correction returns an unbiased estimate,

$$r_i^* = r_i + \frac{r_i(1 - r_i^2)}{2(n_i - 3)} \quad (\text{A4.29a})$$

Fisher's z -transformation is used to both stabilize the variance and remove some of the skew:

$$z_{i,r} = \frac{1}{2} \ln \left(\frac{1 + r_i}{1 - r_i} \right), \quad \text{with} \quad s_i^2 = \frac{1}{n_i - 3} \quad (\text{A4.29b})$$

Typically the unbiased estimate (r^*) is used in place of r in the transformed data, and we use $T_i = z_{i,r}$ as the study effect (i.e., the value in Table A4.3). Note that the standard error of the transformed sample correlation is now simply a function of the sample size. Likewise, any estimates based on z can be back-converted to inferences of ρ by using Fisher's z -to- r transform

$$r = \frac{e^{2z_r} - 1}{e^{2z_r} + 1} \quad (\text{A4.29c})$$

Other standardizations exist for other classes of comparisons, such as the log of the odds ratio.

Fixed-effects, Random-effects, and Mixed-model Meta-analysis

Once an appropriate summary statistic, along with its standard error, has been chosen, the next step is to decide if a fixed, random, or mixed meta-analysis should be used. For questions of interest to quantitative geneticists, a mixed-model analysis is likely the most appropriate. This is also the most general model, with the fixed-effects and random-effects models following as special cases. However, it will be useful to first consider the structure of these simpler models.

Under a **fixed-effects meta-analysis** (also called the **common-effect model**), we assume that the actual effect size is the *same* over all studies ($\theta_i = \theta$), which yields

$$T_i = \theta + e_i \quad (\text{A4.30a})$$

where we assume that the residuals are independent but heteroscedastic, as $\sigma^2(e_i) = s_i^2$. Under the fixed-effects model, our interest is in combining studies to obtain a better estimate of the common (fixed) effect, θ . This simply involves generalized least-squares (GLS; LW Chapter 8), with the resulting meta-analysis global estimate of θ (given the k studies) being

$$\bar{T} = \frac{\sum_{i=1}^k w_i T_i}{\sum_{i=1}^k w_i}, \quad \text{where } w_i = \frac{1}{s_i^2} \quad (\text{A4.30b})$$

In other words, we use a weighted average, with each study weighted by its precision (studies with smaller standard errors receive larger weights). The meta-analysis standard error, $s_{\bar{T}}$, for the global estimate, \bar{T} , is

$$s_{\bar{T}}^2 = \frac{1}{\sum_{i=1}^k w_i} \quad (\text{A4.30c})$$

For the situation where we assume that each individual observation in a given study has the same variance, so $\sigma^2(T_i) = \sigma^2/n_i$, then for k studies, each of size n ,

$$\sigma^2(\bar{T}) = \frac{\sigma^2}{nk} \quad (\text{A4.30d})$$

An obvious next line of inquiry is whether the assumption of a common effect over all studies is reasonable. This can be examined using the **Cochran Q test** of heterogeneity,

$$Q = \sum_{i=1}^k \frac{(T_i - \bar{T})^2}{s_i^2} \quad (\text{A4.31})$$

where (under the null of $\theta_1 = \dots = \theta_k$, and assuming that the values of T_i are normally distributed), the distribution of Q is χ^2 with $(k - 1)$ degrees of freedom.

One potential reason for a significant Q is that the study consists of different subsets of groups (say, males versus females), with a common effect that was the same in each group but differed among groups. In this case, we can extend the basic model by including a regression on moderator variables,

$$T_i = \theta + \sum_{j=1}^m b_j M_{ij} + e_i \quad (\text{A4.32})$$

Often the values of M_{ij} are simply zero-one indicator variables (e.g., 0 for male, 1 for female), but they can be more general regression slopes as well. For example, M_{1j} could be the age of individuals within study j , with a significantly nonzero value of b_1 in Equation A4.32 indicating that the treatment mean varies with age. Again Equation A4.32 is simply a GLS regression, and one can test for moderator-variable effects ($b_j \neq 0$) in the standard regression fashion.

In most biological settings, the assumption of a single common value for the treatment mean over all studies is unrealistic. For example, in a meta-analysis of the strength of selection, we expect θ_i to vary over studies, and our interest shifts to the variance *among* the actual effects. This leads to the **random-effects meta-analysis** model

$$T_i = \mu + u_i + e_i \quad (\text{A4.33a})$$

where $\mu_i \sim (0, \sigma_u^2)$. Typically, the effect sizes ($\theta_i = \mu + u_i$) are assumed to be drawn from a normal, $\theta_i \sim N(\mu, \sigma_u^2)$, and are independent of the residuals (which remain heteroscedastic). Under a random-effects analysis, our interest is the variation, σ_u^2 , among the realized effects, in addition to their overall grand mean, μ . The estimate for the latter is also of the form of Equation A4.30b, but with a critical difference. Under a random-effects model, the weights are now given by

$$w_i = \frac{1}{s_i^2 + \hat{\sigma}_u^2} \quad (\text{A4.33b})$$

where $\hat{\sigma}_u^2$ is the estimate of σ_u^2 . One option for obtaining this variance is the **DerSimonian-Laird estimator**, which is based on Cochran's Q value (Equation A4.31),

$$\hat{\sigma}_u^2 = \frac{Q - (k - 1)}{S_1 - (S_2/S_1)}, \quad \text{where } S_j = \sum_{i=1}^k s_i^{-2j} \quad (\text{A4.33c})$$

which is set to zero if it is negative (DerSimonian and Laird 1986), although other approaches (e.g., REML) could also be used.

This difference in weighting schemes under fixed effects (Equation A4.30b) versus random effects (Equation A4.33b) can have profound implications (a nice review was presented by Borenstein et al. 2010b). In particular, the presence of $\hat{\sigma}_u^2$ makes the random-effect weights more equal over studies, especially when $\hat{\sigma}_u^2$ is of the same order as an average value of s_i^2 . Under a fixed-effects setting, larger studies (i.e., those with smaller values of s_i^2) are given more weight than smaller studies. In a random-effects setting, this difference in weights is reduced such that larger studies lose influence and smaller studies gain influence. In the extreme when $\hat{\sigma}_u^2$ is large relative to all of the s_i^2 values, all studies are given roughly equal weight, independent of their sample size.

To see why this occurs, assume we are using the same design that led to Equation A4.30d, namely, k studies all of size n , and all with a common residual variance (σ^2) for each observation. In this case, the variance of the estimate of μ becomes

$$\sigma^2(\bar{T}) = \frac{\sigma^2}{nk} + \frac{\sigma_u^2}{k} \quad (\text{A4.34})$$

showing (unlike the fixed-effects case; Equation A4.30d) that the actual number (k) of studies is at least as important as the total number (nk) of observations over all studies. Under a fixed-effects design, all that matters is nk , as the only error is in estimating the common mean, with the contribution from any particular study being proportional to its sample size. Under a random-effects model, there is an *additional error* from the among-study variance, in that the mean realization for each study, $\theta_i = \mu + u_i$, differs, with each new study providing additional information on the among-study variance. This leads to the second important consideration for a random-effects model: power is as much a function of the number of studies (k) as it is of the precision of any particular study (n_i). Indeed, if θ_i is measured without error in any particular study, one still needs a reasonable number of θ_i values to estimate their variance with any precision. Hence, not surprisingly, random-effects models have lower power than fixed-effects models.

Given the lower power of a random-effects model, one might be tempted to start with a fixed-effects analysis and only consider random-effects when the fixed-effects model generates a significant Q value (Equation A4.31). Borenstein et al. (2010b) strongly caution against this approach. First, if the number of studies is small to moderate, Q can have poor

power, so a failure to reject homogeneity among studies could simply be due to low power, and not an absence of among-study variation. Second, although there are costs (lower power) with a random-effects model, this arises because such models make a less stringent assumption: they allow the effect size to vary over studies. This is generally closer to reality, as the assumption of a constant θ value over all studies is unlikely to be correct.

Finally, in many settings, we might expect the grand mean to vary over different categories, as when the selection gradient differs between males and females. Similarly, we may wish to examine whether the strength of selection varies between life-history versus morphological traits. The potential of different means over different major categories can be accommodated in a meta-analysis model by the use of moderator variables (cofactors). These adjust the mean for a particular class, leading to a **mixed-model meta-analysis**. Suppose that there are $m \ll k$ moderators. The resulting mixed-model is

$$T_i = \mu + \sum_{j=1}^m b_j M_{ij} + u_i + e_i \quad (\text{A4.35a})$$

where b_j is the effect of a moderator, j , which has a value of M_{ij} in study i . Equations A4.32 and A4.33a are special cases of Equation A4.35a, which we can write in general-linear-model form (LW Chapter 8) as

$$\mathbf{y} = \mathbf{Mb} + \mathbf{u} + \mathbf{e} \quad (\text{A4.35b})$$

where $y_i = T_i$, and the i th row of the $k \times m$ matrix, \mathbf{M} , contains the values of the moderator variables associated with study i . The vectors, \mathbf{u} and \mathbf{e} , of random effects are assumed uncorrelated, with $\mathbf{e} \sim (\mathbf{0}, \mathbf{R})$ and $\mathbf{u} \sim (\mathbf{0}, \mathbf{G})$, where \mathbf{R} is a known diagonal matrix, $\text{diag}(s_1^2, s_2^3, \dots, s_k^2)$, and $\mathbf{G} = \sigma_u^2 \mathbf{C}$, where \mathbf{C} is a matrix of known constants.

While typically it is assumed that $\mathbf{C} = \mathbf{I}$ (i.e., effects are uncorrelated and homoscedastic), we can easily incorporate \mathbf{C} matrices that account for phylogenetic relationships (i.e., correlations) when comparisons are made between species (Hadfield and Nakagawa 2010; Nakagawa and Santos 2012). In such settings, one could use either a Brownian-motion model (Equation A1.31) for the elements of \mathbf{C} (divergence under drift) or an Ornstein-Uhlenbeck model (Equation A1.33) (divergence under drift and stabilizing selection). The bottom line is that our previous discussions on the great flexibility of mixed models (Chapters 19 and 20; LW Chapters 26 and 27) also hold when we conduct a meta-analysis using a mixed-model framework.

Publication and Other Sources in Bias

The most common concern of a meta-analysis is the issue of **publication bias**, whereby the chosen sample of studies is nonrandom with respect to all of the actual studies that have been done. Before addressing this, we need to stress that the most serious MA problem is simply **poor data reporting** (Gurevitch and Hedges 1999). The lack of inclusion of standard errors in many studies relegates their data to the lower status of a narrative MA. Ideally, *all* of the individual data, and not just summary statistics, should be readily available to the research community.

A second concern is **research bias** (Gurevitch and Hedges 1999). For example, in searching for signals of selection on traits, investigators are unlikely to choose a random set of characters. Rather, at least some of the traits will be explicitly chosen because an investigator feels that they are likely to be under selection. This introduces nonrandom sampling, and such a collection of estimates is not an unbiased sample of the nature of selection on a random trait. A related issue is **study bias**, in that human nature is such that investigators will often seek to make their task easier by nonrandomly choosing systems in which is it easier to measure quantities of interest.

These important concerns aside, meta-analysts worry about publication bias, such as the so-called **file-drawer effect**, whereby studies that do not achieve significance are not published but rather are simply left in the file drawer (Rosenthal 1979; Rosenberg 2005). Likewise, studies showing significant effects are more likely to be published in higher-profile

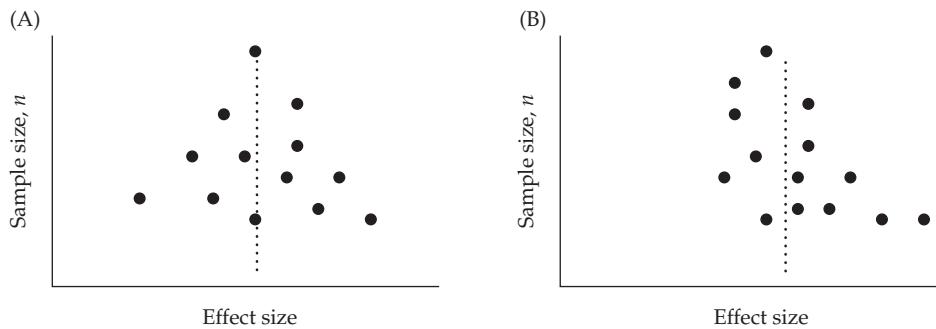

Figure A4.6 A funnel plot contrasts the estimated effect size (on the horizontal axis) of a study versus a measure of its precision (such as the sample size or $1/s_i^2$) on the vertical axis. **A:** An idealized funnel plot showing symmetry about the grand mean (dotted line). **B:** A funnel plot showing asymmetry, in this case an excess of larger effect-size estimates in studies with lower precision.

and more widely disseminated journals. Given this concern, a number of heuristic approaches for detecting the potential of publication bias have been proposed (a nice introduction can be found in Møller and Jennions 2001). Perhaps the best way to start any discussion of publication bias, and attempts to adjust for it, is with the comment by Copas and Shi (2000) that “correcting for publication bias is only possible if we are prepared to make unverifiable assumptions.”

Methods for treating publication bias consist either of approaches that attempt to detect it (funnel plots, rank-correlation tests, Egger regressions) or that attempt to assess its impact (fail-safe numbers, trim-and-fill, model selection). Nice reviews of publication bias issues as they relate to evolutionary and ecological studies can be found in Møller and Jennions (2001) and Nakagawa and Santos (2012). While any serious meta-analysis should examine publication bias, it is often ignored. In a survey of 100 evolutionary and ecologically related meta-analyses, Nakagawa and Santos found that only 49% attempted to assess publication bias. Among those studies that did, only 45% searched for signals of bias, only 14% attempted to assess the impact of bias, and 41% attempted to do both.

A number of tests for the potential presence of publication bias are constructed around the notion of a **funnel plot** (Light and Pillemer 1984). As shown in Figure A4.6, for each study, one plots the estimated effect size on the horizontal axis and some measure of precision, such as s_i^{-2} or the sample size, on the vertical axis. Under a fixed-effects model, the scatter of points should be broad at the base (reflecting spread about the true mean due to larger standard errors in the estimate), and then narrowing as one moves vertically up in the plot (larger studies). This generates a plot that looks like an inverted funnel, hence the name. Under a fixed-effects model, data high on the vertical axis (i.e., studies with very large sample sizes) should show essentially no spread about the grand mean. Under a random-effects interpretation, even when sampling error is entirely removed (due to very large sample size), there will still be a spread of values around the grand mean, reflecting the random effect of sampling the mean for a particular realization. One will still see a funnel, but it will only narrow down (for large n) to a spread given by σ_u^2 , namely, the funnel will taper up to a cylinder whose width is a function of σ_u^2 .

Figure A4.6A shows an idealized setting, with estimates that are symmetrically distributed about the grand mean. Figure A4.6B shows a situation in which there is asymmetry in the funnel. In this case, there is an excess of large-effect estimates for studies with less precision (i.e., smaller samples). Publication bias can generate such an asymmetry, as studies whose estimated effects are smaller (and therefore either not significant, or only marginally so) are less likely to be published. However, other sources of bias can also generate such an asymmetry, so that its presence does not automatically guarantee that publication

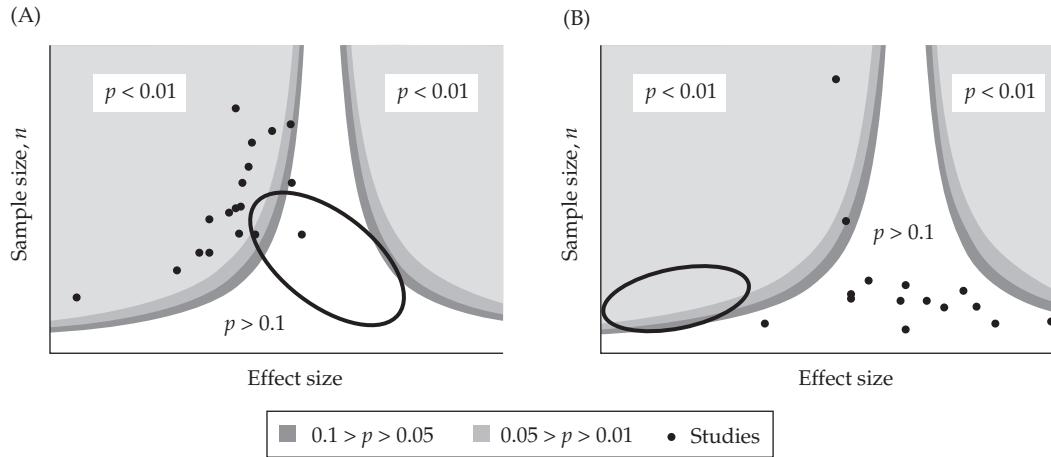

Figure A4.7 Contour-enhanced funnel plots help in the interpretation of asymmetry. Both of the plots show asymmetry, with the open ellipse showing the area of “missing” studies that generates the asymmetry. Such missing values would be added under the trim-and-fill method. The contours (showing regions of statistical significance) show the expected likelihood of study values under the null of no effect. **A:** The “missing” studies are in a region where they are likely to occur by chance ($p > 0.1$), suggesting they are absent due to publication bias. **B:** Here, these studies will all fall into regions unlikely to be seen under the null ($p < 0.05$), and hence may be missing for reasons other than publication bias. (After Peters et al. 2008.)

bias has occurred. For example, effect sizes could be correlated with their standard errors, as might occur in settings where the realization of a effect size is expected to be small (say, a selection gradient on what is regarded as a minor trait), and so the study collects a larger sample size in order to try to achieve sufficient power (Gurevitch and Hedges 1999).

While funnel asymmetry is essentially an informal visual judgment, the basic idea has been used for more formal tests. The **Begg-Mazumdar** (1994) **rank correlation test** looks for associations between the ranks of the standard errors (s_i) and study estimates (T_i). The **Egger regression test** (Egger et al. 1997) performs the regression

$$y_i = a + bs_i + e, \quad \text{where} \quad y_i = (T_i - \bar{T}) \quad (\text{A4.36})$$

Under a symmetric funnel plot, the data are distributed symmetrically around zero, and the resulting intercept (a) should be zero. An a value that is significantly different from zero indicates asymmetry. Both of these tests suffer from low power, and they are not recommended when the number of studies is small (ten or fewer). Indeed, Sterne et al. (2011) recommended that these tests “should be used in only a minority of meta-analysis.” Further, even a highly significant result does not imply publication bias, and a negative result does not imply that the study is free from such bias (especially if k is relatively small). Another indicator of the potential of publication bias is **time-lag bias**. Here, the initial studies report larger effects than are seen in follow-up studies. This can be tested by simply including the year of publication as a moderator variable in the original analysis (Nakagawa and Santos 2012).

While detecting publication bias can be problematic, *correcting* for it can be even more so. One approach is the **trim-and-fill** method of Duval and Tweedie (2000a, 2000b). Again, this method is based on funnel-plot asymmetry. In step one, smaller (i.e., lower-precision) studies are excluded in order to achieve a more symmetric plot, while step two replaces these excluded studies with “missing” studies whose values are imputed from the retained studies. Again, factors other than publication bias can result in asymmetric funnel plots, which compromises this approach.

The use of **contour funnel plots** (Figure A4.7) may provide some additional guidance (Peter et al. 2008). These are funnel plots enhanced by overlaying significance contours, which provides a visual test of whether “missing” studies occur in high- or low-probability

regions. The former suggests bias, and the latter suggests simple sampling. Figure A4.7 shows two situations of asymmetry, and the region of the funnel plot with “missing” studies that might be imputed under a trim-and-fill approach. The contour plots show that in Figure A4.7A the missing studies were quite likely to have been seen had there been no publication bias. However, in Figure A4.7B, the missing values are in regions of high significance (and hence could be absent simply by chance, given their low probability under the null), even with a full ascertainment of all studies.

A metric for assessing the impact of publication bias is the **fail-safe number** for an analysis (Rosenthal 1979; Rosenberg 2005). This is simply the number of additional studies (i.e., missed studies with no significance) that would have to be added to the analysis to invalidate (i.e., remove the significance of) the current analysis. The rough rule of thumb is that if this number exceeds $5k + 10$, then the study is fairly robust (Rosenthal 1979; Rosenberg 2005). Despite often being reported, there are issues with this metric. The most obvious one is that a meta-analysis is usually concerned with the average effect size (or the variance in true effect sizes), rather than whether an effect is significant. Hence, even if the fail-safe number indicates that the current study is robust, it is simply robust to overall *significance* and not necessarily to overall *effect size*. Second, as we stressed above, a random effects meta-analysis is generally the most appropriate (which extends to a mixed model if moderator variables are added). Fail-safe numbers in random-effects setting are much smaller than their fixed-effects counterparts and are much more delicate to obtain. Rosenberg (2005) cited a meta-analysis based on 71 studies where the fixed-effects fail-safe number (based on slightly different methods) ranged from 7500 to 8500, while the fail-safe number under a random-effects model was approximately 9.

The most powerful, and also the most delicate, methods to both detect and adjust for publication bias are model-based approaches. These require a model of the ascertainment scheme. For example, Copas and Shi (2000) proposed an ascertainment model that is very much like the model for a threshold trait (Chapter 14), wherein some underlying latent variable determines whether a study is published or not. In their model, this variable is a function of the standardized effect size, which means that studies with smaller standardized effects, and therefore less significance, are less likely to be published. An excellent example of a model-based ascertainment scheme in quantitative-genetics was the study by Hersch and Phillips (2004). To obtain the bias in estimates of selection gradients, they simulated each study as a random draw of five gradients from a known distribution, for which the results were only reported when one (or more) of the values was significant. Figure 30.7 shows the results of their analysis, which found that such ascertained gradients were overestimated.

Bias When Estimating Magnitudes

Finally, consider a random-effects setting, in which the parameter of interest, θ_i , in a given study (i) is drawn from normal distribution with a mean of μ and a variance of σ_u^2 , so $\theta_i \sim N(\mu, \sigma_u^2)$. Suppose we assume the observed effect, T_i , for this study is also normal, but with an additional sampling error, σ_e^2 , so that $T_i \sim N(\mu, \sigma_u^2 + \sigma_e^2)$. This additional variance has no effect on our estimate of the desired mean, μ , as $E[T_i] = \mu$. However, in many setting in quantitative genetics (as well as ecology and evolution), our interest may be in the absolute magnitude, $|\theta|$, of the effect, rather than its mean value. An important example of this type of inquiry is the estimation of the average strength of selection, $|\beta|$, on a trait (Chapters 29 and 30). As noted by Hereford et al. (2004) and Morrissey (2016), $E[|T|] > E[|\theta|]$ when $\sigma_e^2 > 0$, which will result in an overestimate of the expected absolute value of the effect. In particular, if $\mu = 0$, then (Example A4.11),

$$E[|\theta|] = \sigma_u \sqrt{2/\pi}, \quad \text{while} \quad E[|T|] = \sqrt{\sigma_u^2 + \sigma_e^2} \cdot \sqrt{2/\pi} \quad (\text{A4.37a})$$

which yields a relative error of

$$\frac{E[|T|] - E[|\theta|]}{E[|\theta|]} = \sqrt{\frac{\sigma_e^2}{\sigma_u^2} + 1} - 1 \quad (\text{A4.37b})$$

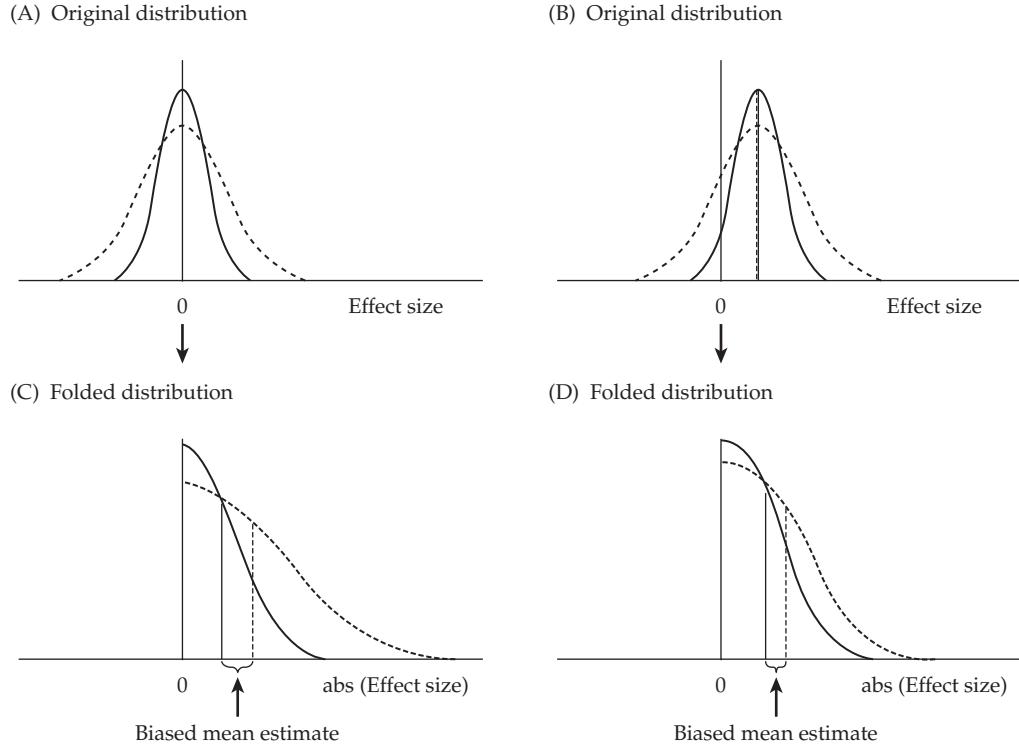

Figure A4.8 The consequences of considering the absolute value, $|\theta|$, of an effect. Here, the true size effect (θ) is normally distributed with a variance of σ^2 , whose distribution is indicated by the solid curves. Of course, we do not observe the true value, but rather an estimate, T , which has the same mean as θ , but an additional sampling error, σ_e^2 , so that while $\theta \sim N(\mu, \sigma^2)$, $T \sim N(\mu, \sigma^2 + \sigma_e^2)$, which (dashed curves) has a larger total variance. In (A) and (C), $\mu = 0$, while $\mu > 0$ in (B) and (D). The distribution of $|\theta|$ is given by **folding** the distribution about zero, with $\Pr(|\theta|) = \Pr(\theta) + \Pr(-\theta)$ for $\theta > 0$, as shown in panels (C) and (D). While the sampling variance (σ_e^2) does not translate into bias when estimating the mean, as $E[T] = E[\theta]$, it introduces bias when the absolute value of θ is of interest, with $E[|T|] > E[|\theta|]$ when $\sigma_e^2 > 0$, as shown in (C) and (D). (After Nakagawa and Lagisz 2016.)

which can be a significant overestimation of the average magnitude of an effect if the error variance is large relative to the effect variance (Figure A4.8). Morrissey (2016) presented several additional examples where the concern of a meta-analysis is in some measure of dispersion about a mean, in which case the error variance associated with using an estimate (T_i) will result in an upwardly biased estimator. Morrissey showed how the use of appropriate mixed models helps to resolve this concern.

Example A4.11. Hereford et al. (2004) and Morrissey (2016) presented general expressions for $E[|x|]$ when $x \sim N(\mu, \sigma^2)$. As shown in Figure A4.8, the distribution of $|x|$ is given by a folded normal distribution, from which it follows that

$$E[|x|] = \sigma \sqrt{\frac{2}{\pi}} \exp\left(-\frac{\mu^2}{2\sigma^2}\right) + |\mu| \cdot \operatorname{erf}\left(\frac{|\mu|}{\sigma\sqrt{2}}\right) \quad (\text{A4.38a})$$

where

$$\operatorname{erf}(x) = \frac{2}{\sqrt{\pi}} \int_0^x \exp(-t^2) dt$$

is the error function. Taking $\mu = 0$, Equation A4.38a reduces to Equation A4.37a. Likewise,

when $\mu \gg \sigma^2$, Equation A4.38a reduces to

$$E[|x|] \sim |\mu| \quad (\text{A4.38b})$$

which follows because for large values of x , $e^{-x} \rightarrow 0$ and $\text{erf}(x) \rightarrow 1$.

Appendix 5

The Geometry of Vectors and Matrices: Eigenvalues and Eigenvectors

Much of the presentation that follows is in matrix notation, and for this I offer no apology as this has rapidly become an essential tool of any serious student of animal breeding.

Henderson (1973)

The basic concepts of matrix algebra were introduced in LW Chapter 8 and LW Appendix A3, and we assume the reader has this level of understanding (which includes matrix multiplication, inverses, and determinants). If not, a quick review of LW Chapter 8 before proceeding will be helpful. A deeper understanding of multivariate issues in quantitative genetics requires an appreciation of matrix *geometry*. Our primary intent here is to introduce the reader to the idea of vectors and matrices as **geometric structures**, and thus viewing matrix operations as transformations converting one vector into another by a change in geometry (rotation and scaling), which is completely summarized by the **eigenvalues** (scaling), and their associated **eigenvectors** (rotation), of a matrix.

THE GEOMETRY OF VECTORS AND MATRICES

As there are numerous excellent texts on matrix algebra, we made little effort to prove most of the results given below. For statistical applications, concise introductions can be found in the chapters on matrix methods in Johnson and Wichern (1988) and Morrison (1976), while Dhrymes (1978) and Searle (1982) provided more extended treatments. Wilf's (1978) short chapter on matrix methods provides a very nifty review of methods useful in applied mathematics. Franklin (1968), Horn and Johnson (1985), and Gantmacher (1960), respectively, presented increasingly sophisticated treatments of matrix analysis.

Comparing Vectors: Lengths and Angles

As Figure A5.1A shows, a vector, \mathbf{x} , can be treated as a geometric object, consisting of an arrow leading from the origin to an n -dimensional point whose coordinates are given by the elements of \mathbf{x} . By changing coordinate systems, we change the resulting vector, potentially changing both its direction (**rotating** the vector) and length (**scaling** the vector). This geometric interpretation suggests several ways for comparing vectors, such as the **angle** between two vectors and the **projection** of one vector onto another.

Consider first the length (or **norm**) of a vector. The most common measure of length is the Euclidean distance of the vector from the origin, $\|\mathbf{x}\|$, defined as

$$\|\mathbf{x}\| = \sqrt{x_1^2 + x_2^2 + \cdots + x_n^2} = \sqrt{\mathbf{x}^T \mathbf{x}} \quad (\text{A5.1a})$$

For any scalar a , $\|a\mathbf{x}\| = |a|\|\mathbf{x}\|$. Similarly, the squared Euclidean distance between the vectors \mathbf{x} and \mathbf{y} is

$$\|\mathbf{x} - \mathbf{y}\|^2 = \sum_{i=1}^n (x_i - y_i)^2 = (\mathbf{x} - \mathbf{y})^T (\mathbf{x} - \mathbf{y}) = (\mathbf{y} - \mathbf{x})^T (\mathbf{y} - \mathbf{x}) \quad (\text{A5.1b})$$

Vectors can differ by length, direction, or both. The angle, θ , between two vectors (\mathbf{x} and \mathbf{y}) provides a measure of how much they differ in direction (Figure A5.1C). If the vectors

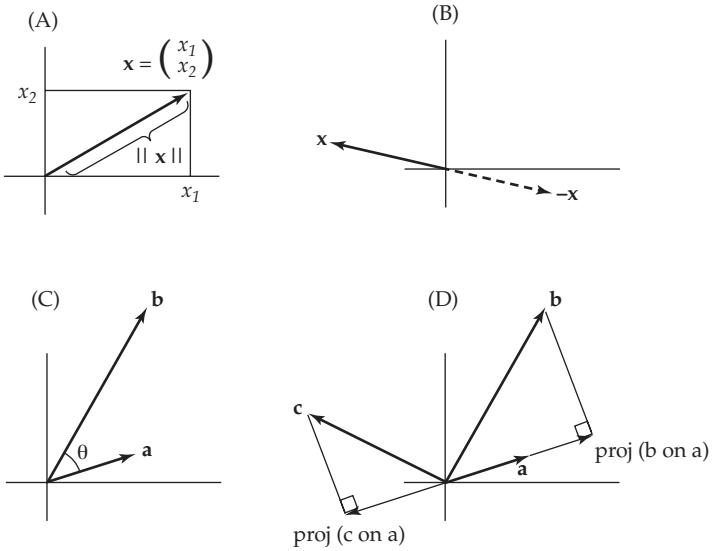

Figure A5.1 Some basic geometric concepts of vectors. While we use examples from two dimensions, these concepts easily extend to n dimensions. **A:** A vector \mathbf{x} can be thought of as an arrow from the origin to a point in space whose coordinates are given by the elements of \mathbf{x} . **B:** Multiplying a vector by -1 results in a *reflection* about the origin. **C:** One measure of the difference in direction between two vectors is the angle (θ) between them. **D:** $\text{Proj}(\mathbf{b} \text{ on } \mathbf{a})$ is the vector resulting from the projection of \mathbf{b} onto \mathbf{a} . Note that the resulting projection vector is either in the same direction as \mathbf{a} or in the direction of the reflection of \mathbf{a} , as seen for $\text{Proj}(\mathbf{c} \text{ on } \mathbf{a})$.

satisfy $a\mathbf{x} = \mathbf{y}$, they both point in exactly the same direction ($\theta = 0$; they are **codirectional**) when $a > 0$. If $a < 0$, they are exactly 180 degrees apart and differ in direction only by a **reflection** about the origin (Figure A5.1B). At the other extreme, two vectors can be at right angles to each other ($\theta = 90^\circ$ or 270°), in which case they are said to be **orthogonal**. Orthogonal vectors of unit length are further said to be **orthonormal**. For any two n -dimensional vectors, θ satisfies

$$\cos(\theta) = \frac{\mathbf{x}^T \mathbf{y}}{\|\mathbf{x}\| \|\mathbf{y}\|} = \frac{\mathbf{y}^T \mathbf{x}}{\|\mathbf{x}\| \|\mathbf{y}\|} \quad (\text{A5.2a})$$

Hence,

$$\theta = \cos^{-1} \left(\frac{\mathbf{y}^T \mathbf{x}}{\|\mathbf{x}\| \|\mathbf{y}\|} \right) \quad (\text{A5.2b})$$

If both \mathbf{x} and \mathbf{y} are of unit length, then $\theta = \cos^{-1}(\mathbf{y}^T \mathbf{x})$, which reveals the close connection between vector angles and inner products. Note that because $\cos(90^\circ) = \cos(270^\circ) = 0$, **two vectors are orthogonal if, and only if, their inner product is zero**, $\mathbf{x}^T \mathbf{y} = 0$.

Another way to compare two vectors is to consider the **projection** vector of one onto the other. $\text{Proj}(\mathbf{x} \text{ on } \mathbf{y})$, the projection of \mathbf{x} on \mathbf{y} , is a vector in the direction of \mathbf{y} , whose length is given by how much of the vector \mathbf{x} lies along the direction of \mathbf{y} . For any two n -dimensional vectors, the projection of \mathbf{x} on \mathbf{y} is defined by

$$\text{Proj}(\mathbf{x} \text{ on } \mathbf{y}) = \frac{\mathbf{x}^T \mathbf{y}}{\mathbf{y}^T \mathbf{y}} \mathbf{y} = \frac{\mathbf{x}^T \mathbf{y}}{\|\mathbf{y}\|^2} \mathbf{y} = \left(\cos(\theta) \frac{\|\mathbf{x}\|}{\|\mathbf{y}\|} \right) \mathbf{y} \quad (\text{A5.3a})$$

The term in the parentheses (which follows from Equation A5.2a) is a scalar, representing the length that \mathbf{x} projects in the direction of \mathbf{y} , which means that $\text{Proj}(\mathbf{x} \text{ on } \mathbf{y})$ is a scaled version of the vector \mathbf{y} onto which we are projecting. If $\|\mathbf{y}\| = 1$, then

$$\text{Proj}(\mathbf{x} \text{ on } \mathbf{y}) = (\mathbf{x}^T \mathbf{y}) \mathbf{y} = (\cos(\theta) \|\mathbf{x}\|) \mathbf{y} \quad (\text{A5.3b})$$

The vector resulting from the projection of \mathbf{x} on \mathbf{y} is in the same direction as \mathbf{y} unless $90^\circ < \theta < 270^\circ$, in which case $\cos(\theta) < 0$ and the projection vector is in exactly the opposite direction (the reflection of \mathbf{y} about the origin). The length of the projection vector is

$$\|\text{Proj}(\mathbf{x} \text{ on } \mathbf{y})\| = |\cos(\theta)| \|\mathbf{x}\| \leq \|\mathbf{x}\| \quad (\text{A5.3c})$$

If two vectors lie in exactly the same direction ($\theta = 0$), the projection of one on the other simply recovers the vector (i.e., $\text{Proj}(\mathbf{x} \text{ on } \mathbf{y}) = \mathbf{x}$). Conversely, if two vectors are orthogonal, the projection of one on the other yields a vector of length zero.

An important property of projection vectors is that if $\mathbf{y}_1, \mathbf{y}_2, \dots, \mathbf{y}_n$ is any set of mutually orthogonal n -dimensional vectors, then any n -dimensional vector \mathbf{x} can be represented as the sum of projections of \mathbf{x} onto the members of this set, namely,

$$\mathbf{x} = \sum_{i=1}^n \text{Proj}(\mathbf{x} \text{ on } \mathbf{y}_i) \quad (\text{A5.4})$$

One way to think about such a decomposition is as the transformation from one set of axes (or coordinates) into another (defined by the vectors, \mathbf{y}_i , that **span**, or completely cover, the vector space). We can also consider the projection of a vector into some **subspace** of a matrix (say $\mathbf{y}_1, \dots, \mathbf{y}_k$, where $k < n$), namely, the projection onto some subset of the vectors that span the space of the original matrix. For example, one might consider the subspace of a covariance matrix imposed by (say) its three largest factors (eigenvalues). The notion of a subspace of the genetic covariance matrix \mathbf{G} will prove useful in describing the constraints caused by the genetic covariance structure (Volume 3).

Matrices Describe Vector Transformations

When we multiply a vector, \mathbf{x} , by a matrix, \mathbf{A} , to create a new vector, $\mathbf{y} = \mathbf{Ax}$, \mathbf{A} rotates and *scales* the original vector, \mathbf{x} , into the new vector, \mathbf{y} . \mathbf{A} therefore describes a *transformation* of the original coordinate system of \mathbf{x} into a new coordinate system, \mathbf{y} (which has a different dimension from \mathbf{x} unless \mathbf{A} is square).

Example A5.1. Consider the Lande version of the multivariate breeder's equation, $\mathbf{R} = \mathbf{G}\beta$ (Equation 13.26a). Here \mathbf{R} is the change in the vector of phenotypic means resulting from selection, \mathbf{G} is the covariance matrix of additive-genetic values (breeding values) of the characters, and β is the directional selection gradient (the direction of change in character means that results in the greatest increase in mean population fitness; Chapters 13 and 30). Suppose

$$\mathbf{G} = \begin{pmatrix} 4 & -2 \\ -2 & 2 \end{pmatrix} \quad \text{and} \quad \beta = \begin{pmatrix} 1 \\ 3 \end{pmatrix}, \quad \text{yielding} \quad \mathbf{R} = \mathbf{G}\beta = \begin{pmatrix} -2 \\ 4 \end{pmatrix}$$

The resulting direction of change in character means is different from that most favored by natural selection. Selection (β) favors an increase in trait one (z_1), but when the genetic covariance structure is taken into account, the resulting change in the mean of z_1 is negative. If we take the appropriate inner products, we find $\|\beta\| = \sqrt{10}$, $\|\mathbf{R}\| = \sqrt{20}$, and $\beta^T \mathbf{R} = 10$. Equation A5.2a returns

$$\cos(\theta) = \frac{\beta^T \mathbf{R}}{\|\mathbf{R}\| \|\beta\|} = \frac{1}{\sqrt{2}}$$

The resulting angle between the selection gradient and response vector is $\cos^{-1}(1/\sqrt{2}) = 45^\circ$, implying that the constraints introduced by the genetic covariance matrix rotate the response vector considerably away from the direction most favored by natural selection (Figure A5.2).

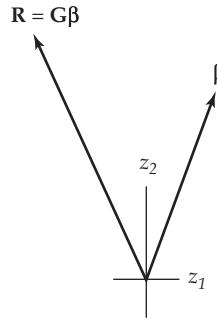

Figure A5.2 If we use the values of β and G from Example A5.1, observe that G translates the directional selection gradient vector (β) into the response vector (R) in a counterintuitive fashion. While β shows that fitness is maximized by increasing both traits 1 and 2, the resulting response vector, R , increases trait 2 but *decreases* trait 1. This behavior results from the strong negative additive-genetic covariance between z_1 and z_2 , as will become more obvious shortly, when we consider the eigenvectors of G (Figure A5.3). As shown in Example A5.1, the angle between the vectors β and R is 45 degrees.

Orthonormal Matrices: Rigid Rotations

A key building block on our way to the partitioning of a matrix into its rotational and scaling components is the idea of an **orthonormal matrix**. Writing a square $n \times n$ matrix, U , as a row vector whose n elements are $1 \times n$ column vectors, $U = (u_1, u_2, \dots, u_n)$, then U is said to be orthonormal if

$$u_i^T u_j = \begin{cases} 1 & \text{if } i = j \\ 0 & \text{if } i \neq j \end{cases}$$

Namely, each column of U is of unit length and is orthogonal to every other column. Matrices with this property are also referred to as **unitary** and satisfy

$$U^T U = U U^T = I \quad (\text{A5.5a})$$

As a result, the inverse of a unitary matrix is simply its transpose,

$$U^T = U^{-1} \quad (\text{A5.5b})$$

The coordinate transformation induced by an orthonormal matrix has a very simple geometric interpretation: it is a **rigid rotation** of the original coordinate system—axes of the original coordinates are all rotated by the same angle to create the new coordinate system. To see this, first note that **orthonormal matrices preserve all inner products**. Taking $y_1 = Ux_1$ and $y_2 = Ux_2$

$$y_1^T y_2 = x_1^T (U^T U) x_2 = x_1^T x_2 \quad (\text{A5.5c})$$

Thus, orthonormal matrices do not change (scale) the length of vectors, as $\|y_1\| = y_1^T y_1 = x_1^T x_1 = \|x_1\|$. Using these results, note that if θ is the angle between the vectors x_1 and x_2 , then following transformation by an orthonormal matrix

$$\cos(\theta | y_1, y_2) = \frac{y_1^T y_2}{\sqrt{\|y_1\| \|y_2\|}} = \frac{x_1^T x_2}{\sqrt{\|x_1\| \|x_2\|}} = \cos(\theta | x_1, x_2) \quad (\text{A5.5d})$$

which shows that the angle between the two vectors remains unchanged following their transformation by the same orthonormal matrix.

Eigenvalues and Eigenvectors

The eigenvalues, and their associated eigenvectors, of a square matrix describe its transformational geometry. Eigenvalues describe how the original coordinate axes are *scaled* in the

new coordinate system that is described by the eigenvectors (i.e., how the original axes are *rotated*).

To more formally introduce eigenvalues and eigenvectors, suppose, for a square matrix \mathbf{A} , that the vector \mathbf{y} satisfies the matrix equation

$$\mathbf{Ay} = \lambda\mathbf{y} \quad (\text{A5.6})$$

for some scalar value, λ . Geometrically, this means that the new vector resulting from transformation of \mathbf{y} by \mathbf{A} points in the same direction as \mathbf{y} (or is exactly reflected about the origin if $\lambda < 0$). For such vectors, the only action of the matrix transformation is to scale them by some amount, λ . These vectors thus represent the *inherent axes associated with the transformation given by \mathbf{A}* , and the set of all such vectors, along with their corresponding scalar multipliers, completely describes the geometry of this transformation. Vectors that satisfy Equation A5.6 are referred to as **eigenvectors**, and their associated scaling factors are **eigenvalues**, and together they jointly describe the **eigenstructure** (the intrinsic geometry) of the square matrix, \mathbf{A} . If \mathbf{y} is an eigenvector, then $a\mathbf{y}$ is also an eigenvector, as $\mathbf{A}(a\mathbf{y}) = a(\mathbf{Ay}) = \lambda(a\mathbf{y})$. Note, however, that the associated eigenvalue, λ , remains unchanged. Hence, we typically scale eigenvectors to be of unit length to yield **unit** or **normalized** eigenvectors. In particular, if \mathbf{y}_i is any eigenvector associated with the i th eigenvalue, then the associated normalized eigenvector is $\mathbf{e}_i = \mathbf{y}_i/\|\mathbf{y}_i\|$.

The eigenvalues of an n -dimensional square matrix, \mathbf{A} , are solutions of Equation A5.6, which can be written as $(\mathbf{A} - \lambda \mathbf{I})\mathbf{y} = 0$. This implies that the determinant of $(\mathbf{A} - \lambda \mathbf{I})$ must equal zero, which gives rise to the **characteristic equation**, $|\mathbf{A} - \lambda \mathbf{I}| = 0$, whose solution yields the eigenvalues of \mathbf{A} . This equation can be also be expressed using the **Laplace expansion**,

$$|\mathbf{A} - \lambda \mathbf{I}| = (-\lambda)^n + S_1(-\lambda)^{n-1} + \cdots + S_{n-1}(-\lambda)^1 + S_n = 0 \quad (\text{A5.7})$$

where $|\mathbf{A}|$ denotes the determinant of \mathbf{A} and S_i is the sum of all **principal minors** (minors including diagonal elements of the original matrix) of order i (minors, which are subsets of the full matrix, were defined in LW Chapter 8). Finding the eigenvalues thus requires solving a polynominal equation of order n , implying that there are exactly n eigenvalues (some of which may be identical, i.e., **repeated**). In practice, for $n > 2$ this is accomplished numerically, and most statistical analysis packages offer routines to accomplish this task.

Two of these principal minors are easily obtained and provide information on the nature of the eigenvalues. The only principal minor having the same order of the matrix is the full matrix itself, which means that $S_n = |\mathbf{A}|$, the determinant of \mathbf{A} . S_1 is also related to an important matrix quantity, the **trace**. This is denoted by $\text{tr}(\mathbf{A})$, and is the sum of the diagonal elements of the matrix, namely,

$$\text{tr}(\mathbf{A}) = \sum_{i=1}^n A_{ii}$$

Observe that $S_1 = \text{tr}(\mathbf{A})$, as the only principal minors of order one are the diagonal elements themselves, the sum of which equals the trace. Both the trace and determinant can be expressed as functions of the eigenvalues, with

$$\text{tr}(\mathbf{A}) = \sum_{i=1}^n \lambda_i \quad \text{and} \quad |\mathbf{A}| = \prod_{i=1}^n \lambda_i \quad (\text{A5.8})$$

Hence \mathbf{A} is *singular* ($|\mathbf{A}| = 0$) if, and only if, at least one eigenvalue is zero. As we will see, if \mathbf{A} is a covariance matrix, then its trace (the sum of its eigenvalues) measures its total amount of variation, as the eigenvalues of a covariance matrix are nonnegative ($\lambda_i \geq 0$).

Let \mathbf{e}_i be the (unit-length) eigenvector associated with eigenvalue λ_i . If the eigenvectors of \mathbf{A} can be chosen to be mutually orthogonal, namely, $\mathbf{e}_i^T \mathbf{e}_j = 0$ for $i \neq j$, then we can express \mathbf{A} as

$$\mathbf{A} = \lambda_1 \mathbf{e}_1 \mathbf{e}_1^T + \lambda_2 \mathbf{e}_2 \mathbf{e}_2^T + \cdots + \lambda_n \mathbf{e}_n \mathbf{e}_n^T \quad (\text{A5.9a})$$

This is called the **spectral decomposition** of \mathbf{A} , and it is derived below in Equation A5.10d. Because $\|\mathbf{e}_i\| = 1$, Equation A5.3b gives the projection of \mathbf{x} on \mathbf{e}_i as $(\mathbf{x}^T \mathbf{e}_i)\mathbf{e}_i$. Note that $\mathbf{e}_i(\mathbf{e}_i^T \mathbf{x}) = (\mathbf{e}_i^T \mathbf{x})\mathbf{e}_i = (\mathbf{x}^T \mathbf{e}_i)\mathbf{e}_i$, as $\mathbf{e}_i^T \mathbf{x}$ is a scalar, which implies that $\mathbf{e}_i^T \mathbf{x} = (\mathbf{e}_i^T \mathbf{x})^T = \mathbf{x}^T \mathbf{e}_i$. Hence, from Equation A5.3b, we have

$$\begin{aligned}\mathbf{Ax} &= \lambda_1 \mathbf{e}_1 \mathbf{e}_1^T \mathbf{x} + \lambda_2 \mathbf{e}_2 \mathbf{e}_2^T \mathbf{x} + \cdots + \lambda_n \mathbf{e}_n \mathbf{e}_n^T \mathbf{x} \\ &= \lambda_1 (\mathbf{e}_1^T \mathbf{x}) \mathbf{e}_1 + \lambda_2 (\mathbf{e}_2^T \mathbf{x}) \mathbf{e}_2 + \cdots + \lambda_n (\mathbf{e}_n^T \mathbf{x}) \mathbf{e}_n \\ &= \lambda_1 \text{Proj}(\mathbf{x} \text{ on } \mathbf{e}_1) + \lambda_2 \text{Proj}(\mathbf{x} \text{ on } \mathbf{e}_2) + \cdots + \lambda_n \text{Proj}(\mathbf{x} \text{ on } \mathbf{e}_n)\end{aligned}\quad (\text{A5.9b})$$

If we again apply Equation A5.3b, we can express this decomposition as

$$\mathbf{Ax} = \|\mathbf{x}\| \sum_{i=1}^n [\lambda_i \cdot \cos(\theta|\mathbf{x}, \mathbf{e}_i|)] \mathbf{e}_i \quad (\text{A5.9c})$$

where $\theta|\mathbf{x}, \mathbf{e}_i|$ denotes the angle between the vectors \mathbf{x} and \mathbf{e}_i . Thus, one can view a matrix as a series of vectors that form the **projection space** (the eigenvectors), so when a vector is multiplied by this matrix, the resulting vector is the weighted (by the eigenvalues) sum of projections over all of the vectors (the \mathbf{e}_i) that span the space defined by the matrix.

Example A5.2. Determine the eigenstructure of the genetic covariance matrix \mathbf{G} shown in Example A5.1. Writing the characteristic equation, and recalling the expression for the determinant of a 2×2 matrix (LW Equation 8.12a), yields

$$\begin{aligned}|\mathbf{G} - \lambda \mathbf{I}| &= \left| \begin{pmatrix} 4 - \lambda & -2 \\ -2 & 2 - \lambda \end{pmatrix} \right| \\ &= (4 - \lambda)(2 - \lambda) - (-2)^2 = \lambda^2 - 6\lambda + 4 = 0\end{aligned}$$

Alternatively, if we use the Laplace expansion (Equation A5.7), and note that $\text{tr}(\mathbf{G}) = 4+2 = 6$ and $|\mathbf{G}| = 4 \cdot 2 - (-2)^2 = 4$, we will also recover the characteristic equation, which has solutions

$$\lambda_1 = 3 + \sqrt{5} \approx 5.236 \quad \lambda_2 = 3 - \sqrt{5} \approx 0.764$$

The associated unit eigenvectors (which are easily obtained, along with the eigenvectors, by using the R command `eigen`) are

$$\mathbf{e}_1 \approx \begin{pmatrix} -0.851 \\ 0.526 \end{pmatrix} \quad \mathbf{e}_2 \approx \begin{pmatrix} 0.526 \\ 0.851 \end{pmatrix}$$

These are orthogonal as $\mathbf{e}_1^T \mathbf{e}_2 = 0$.

The eigenstructure of \mathbf{G} shows why the vector of responses, \mathbf{R} , is rotated away from the direction of the vector that corresponds to the direction of selection, β . From Example A5.1, $\|\beta\| = \sqrt{10}$, while $\mathbf{e}_1^T \beta \approx 0.727$ and $\mathbf{e}_2^T \beta \approx 3.079$. Because $\|\mathbf{e}_1\| = \|\mathbf{e}_2\| = 1$, Equation A5.2a simplifies to

$$\cos(\theta|\mathbf{e}_1, \beta|) \approx \frac{0.727}{\sqrt{10}} \approx 0.230 \quad \text{and} \quad \cos(\theta|\mathbf{e}_2, \beta|) \approx \frac{3.079}{\sqrt{10}} \approx 0.974$$

giving the angle between \mathbf{e}_1 and β as $\theta(\mathbf{e}_1, \beta) \approx 76.7^\circ$, while $\theta(\mathbf{e}_2, \beta) \approx 13.2^\circ$. Applying Equation A5.3b, the corresponding scaled projections of β on these eigenvectors are

$$\begin{aligned}\lambda_1 \text{Proj}(\beta \text{ on } \mathbf{e}_1) &= \lambda_1 \cos(\theta|\mathbf{e}_1, \beta|) \|\beta\| \mathbf{e}_1 = (5.236 \cdot 0.230 \cdot \sqrt{10}) \mathbf{e}_1 \\ &= 3.803 \begin{pmatrix} -0.851 \\ 0.526 \end{pmatrix} = \begin{pmatrix} -3.236 \\ 2 \end{pmatrix}\end{aligned}$$

$$\begin{aligned}\lambda_2 \text{Proj}(\beta \text{ on } \mathbf{e}_2) &= \lambda_2 \cos(\theta|\mathbf{e}_2, \beta|) \|\beta\| \mathbf{e}_2 = (0.764 \cdot 0.974 \cdot \sqrt{10}) \mathbf{e}_2 \\ &= 2.353 \begin{pmatrix} 0.526 \\ 0.851 \end{pmatrix} = \begin{pmatrix} 1.236 \\ 2 \end{pmatrix}\end{aligned}$$

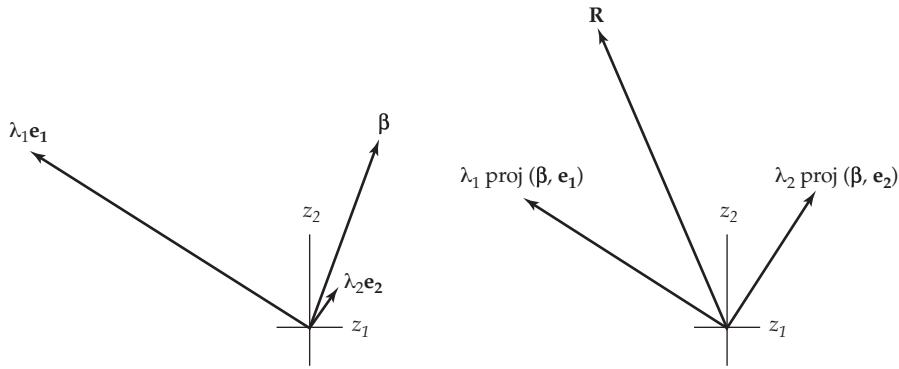

Figure A5.3 **Left:** The scaled eigenvectors associated with the covariance matrix, \mathbf{G} , from Example A5.1, plotted along with the selection gradient, β . Note that \mathbf{e}_1 and \mathbf{e}_2 are orthogonal and hence can be thought of as describing a new coordinate system. Because $\lambda_1 \gg \lambda_2$, the leading eigenvector, \mathbf{e}_1 , largely dominates the transformation. **Right:** This is shown by taking the projections of β on each of these eigenvectors (shown here on a magnified scale relative to the left figure). Even though β is nearly parallel to \mathbf{e}_2 ($\theta|\mathbf{e}_1, \beta = 13.2^\circ$), the projection of β on \mathbf{e}_1 yields a vector of greater length than the projection of β on \mathbf{e}_2 (3.803 versus 2.353). From Equation A5.9b, the vector of responses to selection, \mathbf{R} , is the sum of these two projections.

From Equation A5.9b, we can express the response, \mathbf{R} , as the sum of the projections of β onto the eigenvalues of \mathbf{G} , returning

$$\begin{aligned}\mathbf{R} &= \mathbf{G}\beta = \lambda_1 \text{Proj}(\beta \text{ on } \mathbf{e}_1) + \lambda_2 \text{Proj}(\beta \text{ on } \mathbf{e}_2) \\ &= \begin{pmatrix} -3.236 \\ 2 \end{pmatrix} + \begin{pmatrix} 1.236 \\ 2 \end{pmatrix} = \begin{pmatrix} -2 \\ 4 \end{pmatrix}\end{aligned}$$

As Figure A5.3 shows, the eigenstructure of \mathbf{G} explains the unusual behavior of the selection response seen in Figure A5.2. The eigenvector associated with the **leading eigenvalue**, λ_1 , accounts for most of the variation inherent in \mathbf{G} (87%, as $\lambda_1/(\lambda_1 + \lambda_2) = 0.87$), and this eigenvector corresponds to a strong negative correlation between the additive-genetic values of z_1 and z_2 . Hence, even though β points in very much the same direction as \mathbf{e}_2 , because $\lambda_1 \gg \lambda_2$, the projection of β on \mathbf{e}_1 yields a vector of greater length than the projection of β on \mathbf{e}_2 (3.803 versus 2.353), and it is this \mathbf{e}_1 projection vector that results in the decrease in μ_{z_1} .

PROPERTIES OF SYMMETRIC MATRICES

Many of the matrices encountered in quantitative genetics are **symmetric**, satisfying $\mathbf{A} = \mathbf{A}^T$ (and therefore necessarily square). Examples include covariance matrices and the γ matrix of quadratic coefficients in the Pearson-Lande-Arnold fitness regression (Chapter 30). Symmetric matrices have a number of useful properties (proofs of which can be found in Dhrymes 1978; Horn and Johnson 1985; and Wilf 1978):

1. If \mathbf{A} is symmetric, then if \mathbf{A}^{-1} exists, it is also symmetric.
2. The eigenvalues and eigenvectors of a symmetric matrix are all real.
3. For any n -dimensional symmetric matrix, a corresponding set of n orthonormal eigenvectors can be constructed, namely, we can obtain a set of eigenvalues \mathbf{e}_i for $1 \leq i \leq n$ that satisfies

$$\mathbf{e}_i^T \mathbf{e}_j = \begin{cases} 1 & \text{if } i = j \\ 0 & \text{if } i \neq j \end{cases}$$

In particular, this guarantees that a spectral decomposition of \mathbf{A} exists (Equation A5.9a).

4. A symmetric matrix \mathbf{A} can be **diagonalized** as

$$\mathbf{A} = \mathbf{U}\Lambda\mathbf{U}^T \quad (\text{A5.10a})$$

where Λ is a diagonal matrix and \mathbf{U} is an orthonormal matrix ($\mathbf{U}^{-1} = \mathbf{U}^T$). If λ_i and \mathbf{e}_i are the i th eigenvalue and its associated unit eigenvector of \mathbf{A} , then

$$\Lambda = \text{diag}(\lambda_1, \lambda_2, \dots, \lambda_n) = \begin{pmatrix} \lambda_1 & 0 & \cdots & 0 \\ 0 & \lambda_2 & \cdots & 0 \\ \vdots & & \ddots & \vdots \\ 0 & \cdots & \cdots & \lambda_n \end{pmatrix} \quad (\text{A5.10b})$$

and

$$\mathbf{U} = (\mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_n) \quad (\text{A5.10c})$$

Geometrically, \mathbf{U} is a unity matrix and thus describes a rigid rotation of the original coordinate system to a new coordinate system given by the eigenvectors of \mathbf{A} , while the diagonal elements of Λ give the amount by which vectors of unit length in the original coordinate system are scaled in the transformed system. If we use the decomposition $\mathbf{A} = \sum_{i=1}^n \Lambda_i$, where Λ_i is a diagonal matrix whose elements are all zero, except for λ_i , then Equation A5.10a becomes

$$\mathbf{A} = \mathbf{U} \left(\sum_{i=1}^n \Lambda_i \right) \mathbf{U}^T = \sum_{i=1}^n \mathbf{U} \Lambda_i \mathbf{U}^T = \sum_{i=1}^n \lambda_i \mathbf{e}_i \mathbf{e}_i^T \quad (\text{A5.10d})$$

recovering the spectral decomposition (Equation A5.9a). The last step in Equation A5.10d follows because $\mathbf{e}_i^T \mathbf{e}_j = 0$ for $i \neq j$. Because of this feature, Equation A5.10a is also called the **spectral factorization** or **eigendecomposition** of \mathbf{A} .

Using Equation A5.10a, it is easy to show that

$$\mathbf{A}^{-1} = \mathbf{U}\Lambda^{-1}\mathbf{U}^T \quad (\text{A5.11a})$$

To see this, note that

$$\mathbf{A}^{-1}\mathbf{A} = (\mathbf{U}\Lambda^{-1}\mathbf{U}^T)(\mathbf{U}\Lambda\mathbf{U}^T) = \mathbf{U}\Lambda^{-1}(\mathbf{U}^T\mathbf{U})\Lambda\mathbf{U}^T = \mathbf{U}\Lambda^{-1}\Lambda\mathbf{U}^T = \mathbf{U}\mathbf{U}^T = \mathbf{I}$$

Similar logic yields

$$\mathbf{A}^{1/2} = \mathbf{U}\Lambda^{1/2}\mathbf{U}^T \quad (\text{A5.11b})$$

$$\mathbf{A}^{-1/2} = \mathbf{U}\Lambda^{-1/2}\mathbf{U}^T \quad (\text{A5.11c})$$

$$\mathbf{A}^k = \mathbf{U}\Lambda^k\mathbf{U}^T \quad \text{for any integer } k \quad (\text{A5.11d})$$

where the **square root matrix**, $\mathbf{A}^{1/2}$, satisfies $\mathbf{A}^{1/2}\mathbf{A}^{1/2} = \mathbf{A}$, and $\mathbf{A}^{-1/2}$ satisfies $\mathbf{A}^{-1/2}\mathbf{A} = \mathbf{A}\mathbf{A}^{-1/2} = \mathbf{A}^{1/2}$, as well as $\mathbf{A}^{-1/2}\mathbf{A}^{1/2} = \mathbf{A}^{1/2}\mathbf{A}^{-1/2} = \mathbf{I}$.

Because Λ is diagonal, the i th diagonal elements of \mathbf{A}^{-1} , $\mathbf{A}^{1/2}$, $\mathbf{A}^{-1/2}$, and \mathbf{A}^k are λ_i^{-1} , $\lambda_i^{1/2}$, $\lambda_i^{-1/2}$, and λ_i^k , respectively, implying that if λ_i is an eigenvalue of \mathbf{A} , then λ_i^{-1} , $\lambda_i^{1/2}$, $\lambda_i^{-1/2}$, and λ_i^k , respectively, are eigenvalues of the matrices \mathbf{A}^{-1} , $\mathbf{A}^{1/2}$, $\mathbf{A}^{-1/2}$, and \mathbf{A}^k . Note that Equations A5.11a–A5.11d further imply that the matrices \mathbf{A} , \mathbf{A}^{-1} , $\mathbf{A}^{1/2}$, $\mathbf{A}^{-1/2}$, and \mathbf{A}^k all have the same eigenvectors, namely the columns of \mathbf{U} . Finally, using Equation A5.10a, we see that premultiplying \mathbf{A} by \mathbf{U}^T and then postmultiplying by \mathbf{U} gives a diagonal matrix whose elements are the eigenvalues of \mathbf{A}

$$\mathbf{U}^T\mathbf{A}\mathbf{U} = \mathbf{U}^T(\mathbf{U}\Lambda\mathbf{U}^T)\mathbf{U} = (\mathbf{U}^T\mathbf{U})\Lambda(\mathbf{U}^T\mathbf{U}) = \Lambda \quad (\text{A5.12})$$

5. The **Rayleigh-Ritz** theorem gives useful bounds on quadratic products associated with the symmetric matrix \mathbf{A} . It states that if the eigenvalues of \mathbf{A} are ordered as $\lambda_{\max} = \lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_n = \lambda_{\min}$, then for any vector of constants \mathbf{c} (for $\|\mathbf{c}\| > 0$)

$$\lambda_1 \|\mathbf{c}\| \geq \mathbf{c}^T \mathbf{A} \mathbf{c} \geq \lambda_n \|\mathbf{c}\| \quad (\text{A5.13a})$$

If \mathbf{c} is of unit length, then all quadratic products are bounded by

$$\lambda_1 \geq \mathbf{c}^T \mathbf{A} \mathbf{c} \geq \lambda_n \quad (\text{A5.13b})$$

The maximum and minimum quadratic products occur, respectively, when $\mathbf{c} = \mathbf{e}_1$ and $\mathbf{c} = \mathbf{e}_n$, the eigenvectors associated with λ_1 and λ_n . This is a useful result for bounding variances. Consider a univariate random variable, $y = \mathbf{c}^T \mathbf{x}$, formed by a linear combination of the elements of a random vector, \mathbf{x} . Recall from LW Equation 8.19 that the variance of a sum $y = \mathbf{c}^T \mathbf{x}$ is $\sigma^2(y) = \mathbf{c}^T \mathbf{V}_{\mathbf{x}} \mathbf{c}$, where $\mathbf{V}_{\mathbf{x}}$ is the covariance matrix for \mathbf{x} . If we apply Equation A5.13a we obtain

$$\lambda_1 \|\mathbf{c}\|^2 \geq \sigma^2(y) \geq \lambda_n \|\mathbf{c}\|^2 \quad (\text{A5.14})$$

where λ_1 is the largest (leading or **dominant**) eigenvalue and λ_n is the smallest eigenvalue of the covariance matrix $\mathbf{V}_{\mathbf{x}}$.

Example A5.3. Consider the additive-genetic covariance matrix \mathbf{G} from Examples A5.1 and A5.2. Recalling the results from Example A5.2 and using Equation A5.10a, we can express \mathbf{G} as $\mathbf{U} \Lambda \mathbf{U}^T$, where

$$\Lambda = \begin{pmatrix} 5.241 & 0 \\ 0 & 0.765 \end{pmatrix} \quad \text{and} \quad \mathbf{U} = (\mathbf{e}_1 \ \mathbf{e}_2) = \left(\begin{pmatrix} -0.851 \\ 0.526 \end{pmatrix} \quad \begin{pmatrix} 0.526 \\ 0.851 \end{pmatrix} \right)$$

From Equation A5.11a, the eigenvalues of \mathbf{A}^{-1} are $(5.241)^{-1} \simeq 0.191$ and $(0.765)^{-1} \simeq 1.307$, while from Equation A5.11b, the eigenvalues of $\mathbf{A}^{1/2}$ are $\sqrt{5.241} \simeq 2.289$ and $\sqrt{0.765} \simeq 0.875$.

Correlations Can Be Removed by a Matrix Transformation

A powerful use of diagonalization is that it allows one to extract a set of n uncorrelated variables for any $n \times n$ nonsingular covariance matrix, $\mathbf{V}_{\mathbf{x}}$. Consider the transformation

$$\mathbf{y} = \mathbf{U}^T \mathbf{x} \quad (\text{A5.15a})$$

where $\mathbf{U} = (\mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_n)$ contains the normalized eigenvectors of $\mathbf{V}_{\mathbf{x}}$. Because \mathbf{U} is an orthonormal matrix, this transformation is a rigid rotation of the axes of the original (x_1, \dots, x_n) coordinate system to a new system given by (e_1, \dots, e_n) . Applying LW Equation 8.21b and Equation A5.12, respectively, the covariance matrix for \mathbf{y} is

$$\mathbf{V}_{\mathbf{y}} = \mathbf{U}^T \mathbf{V}_{\mathbf{x}} \mathbf{U} = \Lambda \quad (\text{A5.15b})$$

where Λ is a diagonal matrix whose elements are the eigenvalues of $\mathbf{V}_{\mathbf{x}}$,

$$\sigma(y_i, y_j) = \begin{cases} \lambda_i & \text{if } i = j \\ 0 & \text{if } i \neq j \end{cases}$$

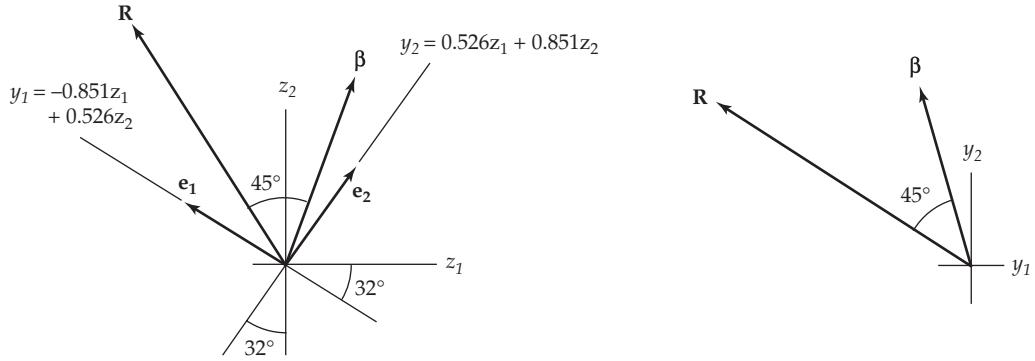

Figure A5.4 The transformation (Equation A5.15a) generating a set of independent variables for the covariance matrix \mathbf{G} from Example A5.4 results in a rigid rotation of axes of the original traits onto the new, uncorrelated set. **Left:** The direction of the new axes are given by the eigenvectors \mathbf{e}_1 and \mathbf{e}_2 . The angle between the new axis, \mathbf{e}_1 , and the original \mathbf{z}_1 axis is given by the angle between \mathbf{e}_1 and $\mathbf{z}_1 = (1, 0)^T$. Here, $\|\mathbf{e}_1\| = \|\mathbf{z}_1\| = 1$ and $\mathbf{e}_1^T \mathbf{z}_1 = 0.851$, giving $\theta = \cos^{-1}(0.851) \simeq 32^\circ$. As this transformation is a rigid rotation, the angle between \mathbf{e}_2 and the $\mathbf{z}_2 = (0, 1)^T$ axis is also 32° . **Right:** On the (y_1, y_2) coordinates, the angle between \mathbf{R} and β remains unchanged. See Example A5.4 for further details.

The rigid rotation introduced by \mathbf{U} creates a set of n uncorrelated variables, the i th of which is

$$y_i = \mathbf{e}_i^T \mathbf{x} \quad (\text{A5.15c})$$

Because the \mathbf{e}_i are of unit length, from Equation A5.3b we have that $y_i = \mathbf{e}_i^T \mathbf{x}$ is the length of the projection of \mathbf{x} onto the i th eigenvector of \mathbf{V}_x , which implies that the axes of the new coordinate system are given by the orthogonal set of eigenvectors of \mathbf{V}_x .

Defining the matrix \mathbf{B} as

$$\mathbf{B} = \mathbf{U} \Lambda^{-1/2} \quad (\text{A5.15d})$$

the vector $\mathbf{y} = \mathbf{B}^T \mathbf{x}$ has a covariance matrix of $\mathbf{V}_y = \mathbf{I}$, which means that this transformation creates a set of uncorrelated variables, each with unit variance. To see this, note that

$$\begin{aligned} \mathbf{V}_y &= \mathbf{B}^T \mathbf{V}_x \mathbf{B} = \left(\mathbf{U} \Lambda^{-1/2} \right)^T \left(\mathbf{U} \Lambda \mathbf{U}^T \right) \left(\mathbf{U} \Lambda^{-1/2} \right) \\ &= \Lambda^{-1/2} \left(\mathbf{U}^T \mathbf{U} \right) \Lambda \left(\mathbf{U}^T \mathbf{U} \right) \Lambda^{-1/2} \\ &= \Lambda^{-1/2} \Lambda \Lambda^{-1/2} = \mathbf{I} \end{aligned} \quad (\text{A5.15e})$$

An alternative to Equation A5.15d is the **Cholesky decomposition**, $\mathbf{A} = \mathbf{C}^T \mathbf{C}$, of a square, symmetric matrix \mathbf{A} , where \mathbf{C} is an **lower triangular matrix** (all elements above the diagonal are zero). If \mathbf{C} is the Cholesky decomposition for \mathbf{V}_x , then $\mathbf{y} = \mathbf{C}^{-1} \mathbf{x}$ also returns a covariance matrix of \mathbf{I} .

Example A5.4. If we apply the change of variables suggested by Equation A5.15a to the vector, \mathbf{z} , of characters with associated \mathbf{G} matrix used in Example A5.1 and using the eigenvalues and vectors obtained in Example A5.2 yields

$$\begin{aligned} \mathbf{y} &= \mathbf{U}^T \mathbf{z} = \begin{pmatrix} \mathbf{e}_1^T \\ \mathbf{e}_2^T \end{pmatrix} \begin{pmatrix} z_1 \\ z_2 \end{pmatrix} \\ &= \begin{pmatrix} -0.851 & 0.526 \\ 0.526 & 0.851 \end{pmatrix} \begin{pmatrix} z_1 \\ z_2 \end{pmatrix} \\ &= \begin{pmatrix} -0.851z_1 + 0.526z_2 \\ 0.526z_1 + 0.851z_2 \end{pmatrix} \end{aligned}$$

From Equation A5.15b, $\mathbf{V}_y = \Lambda$ as given in Example A5.3, showing that y_1 and y_2 are uncorrelated with $\sigma^2(y_1) = \lambda_1 = 5.241$ and $\sigma^2(y_2) = \lambda_2 = 0.765$. Hence, by considering the new coordinate system with

$$y_1 = \mathbf{e}_1^T \mathbf{z} = -0.851z_1 + 0.526z_2 \quad \text{and} \quad y_2 = \mathbf{e}_2^T \mathbf{z} = 0.526z_1 + 0.851z_2$$

we can transform the original coordinate system into a new system on which there are no additive-genetic correlations between these new characters. Figure A5.4 shows that this transformation is simply a rigid rotation of the axes.

Likewise, from Equation A5.15d, the transformation that yields uncorrelated variables with unit variance is

$$\begin{aligned} \mathbf{y} &= \Lambda^{-1/2} \mathbf{U}^T \mathbf{z} = \begin{pmatrix} 1/\sqrt{\lambda_1} & 0 \\ 0 & 1/\sqrt{\lambda_2} \end{pmatrix} \begin{pmatrix} \mathbf{e}_1^T \\ \mathbf{e}_2^T \end{pmatrix} \begin{pmatrix} z_1 \\ z_2 \end{pmatrix} \\ &= \begin{pmatrix} 1/\sqrt{5.236} & 0 \\ 0 & 1/\sqrt{0.764} \end{pmatrix} \begin{pmatrix} -0.851 & 0.526 \\ 0.526 & 0.851 \end{pmatrix} \begin{pmatrix} z_1 \\ z_2 \end{pmatrix} \\ &= \begin{pmatrix} -0.372 & 0.230 \\ 0.602 & 0.974 \end{pmatrix} \begin{pmatrix} z_1 \\ z_2 \end{pmatrix} \end{aligned}$$

Hence, the transformed variables $y_1 = -0.372z_1 + 0.230z_2$ and $y_2 = 0.602z_1 + 0.974z_2$ are uncorrelated, and each has unit variance.

An alternative set of uncorrelated random variables follows from the Cholesky decomposition, which can be compute in R using the `chol` command. (As an aside, `chol` returns the upper-triangular version of the decomposition, which is simply the transpose of the lower-triangular version). The resulting decomposition is

$$\mathbf{G} = \begin{pmatrix} 4 & -2 \\ -2 & 2 \end{pmatrix} = \mathbf{C} \mathbf{C}^T = \begin{pmatrix} 2 & 0 \\ -1 & 1 \end{pmatrix} \begin{pmatrix} 2 & -1 \\ 0 & 1 \end{pmatrix}$$

yielding

$$\mathbf{y} = \mathbf{C}^{-1} \mathbf{z} = \begin{pmatrix} 0.5 & 0 \\ 0.5 & 1 \end{pmatrix} \begin{pmatrix} z_1 \\ z_2 \end{pmatrix}$$

or

$$y_1 = z_1/2 \quad \text{and} \quad z_2 = z_1/2 + z_2$$

as a new set of uncorrelated variables , each with unit variance. One nice feature about using a Cholesky decomposition is that we can always isolate a given variable of interest (simply by putting first in the vector). Because \mathbf{C} is lower-triangular, it always returns the first new uncorrelated variable as a scalar times the first original variable (rather than some linear combination of all the variables, as was the case for the first decomposition in this example).

Simultaneous Diagonalization

An extension of the notion of diagonalization is the **simultaneous diagonalization** of two symmetric matrices, \mathbf{P} and \mathbf{G} , of the same dimension. There exists a matrix \mathbf{T} such that

$$\mathbf{T}^T \mathbf{P} \mathbf{T} = \mathbf{I} \quad \text{and} \quad \mathbf{T}^T \mathbf{G} \mathbf{T} = \mathbf{D} \tag{A5.16}$$

where \mathbf{D} is a diagonal matrix, whose elements are the eigenvalues of $\mathbf{P}^{-1} \mathbf{G}$. Hence, the same transformation simultaneously diagonalizes both \mathbf{P} and \mathbf{G} . If one has a series of traits with both genetic (\mathbf{G}) and phenotypic (\mathbf{P}) covariances, they can be transformed to a scale where the new traits (based on linear combinations of the original traits) are genetically and phenotypically uncorrelated, where the elements of \mathbf{D} correspond to the heritabilities of these new traits.

Example A5.5. To find the matrix, \mathbf{T} , that simultaneously diagonalizes both \mathbf{P} and \mathbf{G} , we first use Equation A5.10a to write

$$\mathbf{P} = \mathbf{U}\Lambda\mathbf{U}^T$$

where Λ is a diagonal matrix and $\mathbf{U}^T\mathbf{U} = \mathbf{U}\mathbf{U}^T = \mathbf{I}$. Defining $\mathbf{B} = \mathbf{U}\Lambda^{-1/2}$, Equation A5.15e showed that $\mathbf{B}^T\mathbf{P}\mathbf{B} = \mathbf{I}$. Next, note for $\mathbf{M} = \mathbf{B}^T\mathbf{G}\mathbf{B}$, that $\mathbf{M} = \mathbf{M}^T$ (i.e., \mathbf{M} is symmetric), as

$$\mathbf{M}^T = (\mathbf{B}^T\mathbf{G}\mathbf{B})^T = \mathbf{B}^T\mathbf{G}^T\mathbf{B} = \mathbf{B}^T\mathbf{G}\mathbf{B} = \mathbf{M}$$

Hence, we can also diagonalize \mathbf{M} ,

$$\mathbf{C}^T\mathbf{M}\mathbf{C} = \mathbf{D}$$

where \mathbf{D} is a diagonal matrix and $\mathbf{C}^T\mathbf{C} = \mathbf{C}\mathbf{C}^T = \mathbf{I}$. Thus,

$$\mathbf{C}^T\mathbf{M}\mathbf{C} = \mathbf{C}^T(\mathbf{B}^T\mathbf{G}\mathbf{B})\mathbf{C} = (\mathbf{B}\mathbf{C})^T\mathbf{G}(\mathbf{B}\mathbf{C}) = \mathbf{D}$$

Defining

$$\mathbf{T} = \mathbf{B}\mathbf{C} = \mathbf{U}\Lambda^{-1/2}\mathbf{C}$$

we have from the previous expression that

$$\mathbf{T}^T\mathbf{G}\mathbf{T} = \mathbf{D}$$

Likewise,

$$\mathbf{T}^T\mathbf{P}\mathbf{T} = (\mathbf{B}\mathbf{C})^T\mathbf{P}(\mathbf{B}\mathbf{C}) = \mathbf{C}^T(\mathbf{B}^T\mathbf{P}\mathbf{B})\mathbf{C} = \mathbf{C}^T\mathbf{C} = \mathbf{I}$$

showing that the matrix \mathbf{T} satisfies Equation A5.16.

CANONICAL AXES OF QUADRATIC FORMS

The transformation $\mathbf{y} = \mathbf{U}^T\mathbf{x}$ given by Equation A5.15a applies to any symmetric matrix, and is referred to as its **canonical transformation**. This simplifies the interpretation of the quadratic form $\mathbf{x}^T\mathbf{A}\mathbf{x}$, as rotation of the original axes to align them with the eigenvectors of \mathbf{A} removes all cross-product terms ($x_i x_j$ for $i \neq j$) on this new coordinate system. Recall (Equation A5.5b) that \mathbf{U} is a unitary matrix and hence $\mathbf{U}^T = \mathbf{U}^{-1}$. Thus,

$$\mathbf{U}\mathbf{y} = \mathbf{U}\mathbf{U}^T\mathbf{x} = \mathbf{x}$$

Applying Equations A5.15a and A5.12 transforms a quadratic form to one in which the square matrix is diagonal, which greatly simplifies the resulting quadratic product, as

$$\begin{aligned} \mathbf{x}^T\mathbf{A}\mathbf{x} &= (\mathbf{U}\mathbf{y})^T\mathbf{A}\mathbf{U}\mathbf{y} = \mathbf{y}^T(\mathbf{U}^T\mathbf{A}\mathbf{U})\mathbf{y} \\ &= \mathbf{y}^T\Lambda\mathbf{y} \\ &= \sum_{i=1}^n \lambda_i y_i^2, \quad \text{with } y_i = \mathbf{e}_i^T\mathbf{x} \end{aligned} \tag{A5.17a}$$

where λ_i and \mathbf{e}_i are the eigenvalues and associated (normalized, i.e., $\|\mathbf{e}_i\| = 1$) eigenvectors of \mathbf{A} . The new axes defined by the \mathbf{e}_i vectors are the **canonical** (or **principal**)

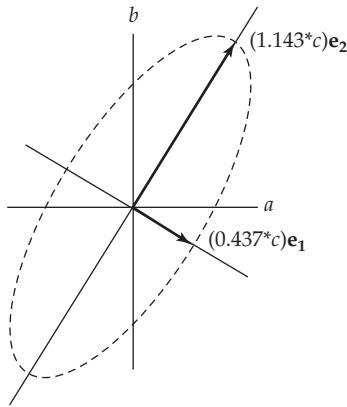

Figure A5.5 The general shape of surfaces of constant variance for the additive-genetic covariance matrix, \mathbf{G} , given in Example A5.1. Defining a new composite character $y = az_1 + bz_2$, the rotated ellipse represents the set of weights (a, b) that give y the same additive-genetic variance, c^2 . The major axis of the ellipse is along \mathbf{e}_2 , the eigenvector associated with the smallest eigenvalue of \mathbf{G} , where $\lambda_2 \simeq 0.765$, giving $1/\sqrt{\lambda_2} \simeq 1.143$. The minor axis of the ellipse is along \mathbf{e}_1 , the eigenvector associated with the largest eigenvalue of \mathbf{G} , where $\lambda_1 \simeq 5.241$, giving $1/\sqrt{\lambda_1} \simeq 0.437$.

axes of \mathbf{A} . Because $y_i^2 \geq 0$, Equation A5.17a immediately shows the connection between the signs of the eigenvalues of a matrix and whether that matrix is positive definite, negative definite, or indefinite.

If all eigenvalues are positive (all $\lambda_i > 0$), then any quadratic form is always positive (unless all the y_i are zero) and hence \mathbf{A} is **positive definite**. If one or more of the eigenvalues are zero, while the rest are positive, then \mathbf{A} is said to be **positive semidefinite**, implying that quadratic products are either zero (corresponding to $\lambda_i = 0$) or positive. If all eigenvalues are negative (all $\lambda_i < 0$), then \mathbf{A} is **negative definite** as any quadratic form is always negative, while \mathbf{A} is said to be **negative semidefinite** if the eigenvalues are either zero or negative. If \mathbf{A} has both positive and negative eigenvalues it is said to be **indefinite**, as quadratic products can be either positive or negative.

Equations of the form

$$\mathbf{x}^T \mathbf{A} \mathbf{x} = \sum_{i=1}^n \sum_{j=1}^n A_{ij} x_i x_j = c^2 \quad (\text{A5.17b})$$

arise fairly frequently in quantitative genetics. For example, they describe surfaces of constant variance (Figure A5.5) or constant fitnesses in quadratic fitness regressions (Chapter 30). Solutions to Equation A5.17b describe **quadratic surfaces**—for two dimensions, these are the familiar conic sections (ellipses, parabolas, or hyperbolas). Equation A5.17a greatly simplifies the interpretation of these surfaces by removing all cross product terms, yielding

$$\mathbf{x}^T \mathbf{A} \mathbf{x} = \sum_{i=1}^n \lambda_i y_i^2 = c^2 \quad (\text{A5.17c})$$

Because $(y_i)^2$ and $(-y_i)^2$ have the same value, the canonical axes of \mathbf{A} are also the **axes of symmetry** for the quadratic surface generated by quadratic forms involving \mathbf{A} . When all eigenvalues of \mathbf{A} are positive (as occurs with nonsingular covariance and other positive-definite matrices), Equation A5.17c describes an ellipsoid whose axes of symmetry are given by the eigenvectors of \mathbf{A} . The distance from the origin to the surface along the \mathbf{e}_i axis is $\lambda_i y_i^2 = c^2$ or $y_i = c\lambda_i^{-1/2}$, as can be seen by setting all the y_k equal to zero except for y_i , which yields

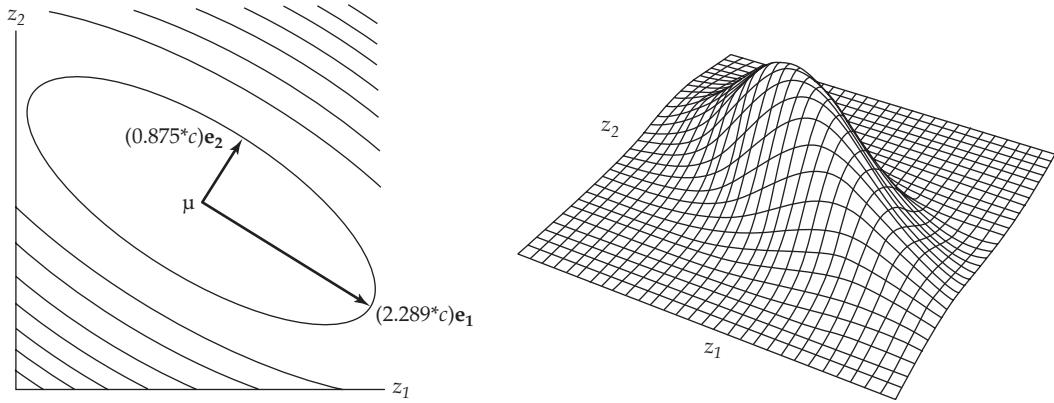

Figure A5.6 Surfaces for a multivariate normal (MVN) distribution. **Left:** Surfaces of equal probability assuming that the additive-genetic values associated with the characters z_1 and z_2 in Example A5.1 are $\sim \text{MVN}(\boldsymbol{\mu}, \mathbf{G})$. These surfaces are ellipses centered at $\boldsymbol{\mu}$, with the major axis of the ellipse along \mathbf{e}_1 and the minor axis along \mathbf{e}_2 , whose lengths (for a fixed c) are, respectively, $\sqrt{\lambda_1} = 2.289$ and $\sqrt{\lambda_2} = 0.875$. **Right:** A plot of the associated probability density. Slicing along either the major or minor axis gives a normal curve. Because the variance in the major axis is greater, the curve is much broader along this axis. The covariance between the breeding values of z_1 and z_2 rotates the distribution so that the principal axes ($\mathbf{e}_1, \mathbf{e}_2$) do not coincide with the original (z_1, z_2) axes.

$$\mathbf{x}^T \mathbf{A} \mathbf{x} = \lambda_i y_i^2 = c^2.$$

Consider a new variable (y) that is a weighted combination $y = ax_1 + bx_2 = \mathbf{b}^T \mathbf{x}$ of the original vector (\mathbf{x}) of random variables, where $\mathbf{b}^T = (a, b)$. Its resulting variance is

$$\sigma^2(y) = a^2 \sigma^2(x_1) + 2ab\sigma(x_1, x_2) + b^2 \sigma^2(x_2) = \mathbf{b}^T \mathbf{V}_{\mathbf{x}} \mathbf{b}$$

As shown in Figure A5.5, the collection of a, b values that result in the same variance (c^2) is the ellipse given by $c^2 = \mathbf{b}^T \mathbf{V}_{\mathbf{x}} \mathbf{b}$. Variables with a large amount of variance require smaller weights to achieve the constant value (c^2) than do variables with lower variances. Thus, on a **constant-variance surface**, minor axes correspond to directions with *the most* variance, while major axes correspond to the directions with *the least* variability. This is in contrast to **surfaces of equal probability** (Figure A5.6), where major axes correspond to directions with the most variance. The reason for this reversal of roles is that constant-variance surfaces are functions of $\lambda_i^{-1/2}$, whereas constant-probability surfaces are functions of $\lambda_i^{1/2}$.

Implications for the Multivariate Normal Distribution

Recall the probability density function for the multivariate normal distribution (LW Chapter 8)

$$\phi(\mathbf{x}) = (2\pi)^{-n/2} |\mathbf{V}_{\mathbf{x}}|^{-1/2} \exp \left[-\frac{1}{2} (\mathbf{x} - \boldsymbol{\mu})^T \mathbf{V}_{\mathbf{x}}^{-1} (\mathbf{x} - \boldsymbol{\mu}) \right] \quad (\text{A5.18a})$$

Because only the quadratic product in the exponential varies with \mathbf{x} , surfaces of equal probability for MVN distributed vectors satisfy

$$(\mathbf{x} - \boldsymbol{\mu})^T \mathbf{V}_{\mathbf{x}}^{-1} (\mathbf{x} - \boldsymbol{\mu}) = c^2 \quad (\text{A5.18b})$$

From the discussion following Equation A5.17c, these surfaces are n -dimensional ellipsoids centered at $\boldsymbol{\mu}$ whose axes of symmetry are given by the principal components (the eigenvectors) of the covariance matrix, $\mathbf{V}_{\mathbf{x}}$. The length of the ellipsoid along the i th axis is $c\sqrt{\lambda_i}$ where λ_i is the eigenvalue associated with the eigenvector \mathbf{e}_i (Figure A5.6).

Equation A5.18b motivates the **Mahalanobis distance**

$$D = \sqrt{(\mathbf{x} - \boldsymbol{\mu})^T \mathbf{V}_{\mathbf{x}}^{-1} (\mathbf{x} - \boldsymbol{\mu})} \quad (\text{A5.19})$$

which measures the distance of a point from its mean μ , correcting for its covariance structure, \mathbf{V}_x (Mahalanobis 1938). As we detail shortly, D provides one metric for tests of multivariate normality.

Applying the canonical transformation (Equation A5.15a), we can change coordinate systems by a rigid rotation to remove any correlations between the variables in x . If $x \sim MVN(\mu, \mathbf{V}_x)$, then for $y = \mathbf{U}^T(x - \mu)$, it follows that

$$y \sim MVN(\mathbf{0}, \Lambda) \quad (\text{A5.20a})$$

where Λ and \mathbf{U} are the matrices defined by Equations A5.10b and A5.10bc for the diagonalization of \mathbf{V}_x . In particular,

$$y_i = \mathbf{e}_i^T(x - \mu) \quad \text{where } y_i \sim N(0, \lambda_i) \quad (\text{A5.20b})$$

Note from Equation A5.20a that because the y_i are uncorrelated, they are also independent as the joint probability density is the product of n individual univariate normal densities. We can further transform the original vector by taking

$$z_i = \frac{\mathbf{e}_i^T(x - \mu)}{\sqrt{\lambda_i}} \quad \text{giving } z_i \sim N(0, 1) \quad (\text{A5.20c})$$

Applying the transformation

$$\mathbf{z} = \Lambda^{-1/2} \mathbf{U}^T(x - \mu) \quad (\text{A5.20d})$$

results in $\mathbf{z} \sim MVN(\mathbf{0}, \mathbf{I})$, namely that the n elements of the vector y are each independent unit normal random variables.

Principal Components of the Variance-Covariance Matrix

We are often interested in how the variance of a random vector can be decomposed into independent components. For example, even though we may be measuring n variables, only one or two of these may account for the majority of the variation. If this is the case, we may wish to exclude those variables contributing very little variation from further analysis. More generally, if random variables are correlated, then certain **linear combinations** of the elements of x may account for most of the variance. The procedure of **principal component analysis (PCA)** extracts these combinations by decomposing the variance of x into the contributions from a series of orthogonal vectors, the first of which explains the most variation possible for any single vector, the second the next possible amount, and so on until we account for the entire variance of x .

Consider Figure A5.5. Because the set of points comprising the ellipse represents the set of linear combinations (i.e., the set of weights) of the random variables of \mathbf{z} that yield **equal** variance, a little thought shows that the closer a point on this curve is to the origin, the more variance there is in that direction. The points closest to the origin are those that lie along the axis defined by \mathbf{e}_1 , while those furthest away lie along the axis defined by \mathbf{e}_2 . Here \mathbf{e}_1 and \mathbf{e}_2 are the principal components of \mathbf{G} , with the first principal component accounting for most of the variation of \mathbf{G} . In particular, the ratio of additive variances for the characters $y_1 = \mathbf{e}_1^T \mathbf{z}$ and $y_2 = \mathbf{e}_2^T \mathbf{z}$ is $\sigma^2(y_1)/\sigma^2(y_2) = \sigma^2(\mathbf{e}_1^T \mathbf{z})/\sigma^2(\mathbf{e}_2^T \mathbf{z}) = \mathbf{e}_1^T \mathbf{G} \mathbf{e}_1 / \mathbf{e}_2^T \mathbf{G} \mathbf{e}_2 = \lambda_1 / \lambda_2 \simeq 5.241 / 0.765 \simeq 6.85$, so that a character in the direction of \mathbf{e}_1 has almost seven times as much additive variance as a character lying in the direction of \mathbf{e}_2 .

In general, suppose we have an n -dimensional covariance matrix, \mathbf{V}_x . If we order the eigenvalues of \mathbf{V}_x as $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_n$, then Equation A5.13b gives the maximum variance for any linear combination of the elements of x ($y = \mathbf{c}_1^T x$, subject to the constraint that $\|\mathbf{c}_1\| = 1$), as

$$\max \sigma^2(y) = \max_{\|\mathbf{c}_1\|=1} \sigma^2(\mathbf{c}_1^T x) = \mathbf{c}_1^T \mathbf{V}_x \mathbf{c}_1 = \lambda_1$$

which occurs when $\mathbf{c}_1 = \mathbf{e}_1$ (the normalized eigenvector associated with the leading eigenvalue λ_1). This vector is the **first principal component** (often abbreviated as **PC1**), and

accounts for the fraction $\lambda_1/\text{tr}(\mathbf{V}_x)$ of the total variation in x . We can partition the remaining variance in x after the removal of PC1 in a similar fashion. For example, the vector \mathbf{c}_2 , that is orthogonal to PC1 ($\mathbf{c}_2^T \mathbf{c}_1 = 0$) and maximizes the remaining variance can be shown to be \mathbf{e}_2 , which accounts for a fraction $\lambda_2/\text{tr}(\mathbf{V}_x)$ of the total variation in x (e.g., Morrison 1976; Johnson and Wichern 1988). By proceeding in this fashion, we can see that the i th PC is given by \mathbf{e}_i , and that the amount of variation it accounts for is

$$\lambda_i / \sum_{k=1}^n \lambda_k = \frac{\lambda_i}{\text{tr}(\mathbf{V}_x)} \quad (\text{A5.21})$$

Hence $\sum \lambda_i = \text{tr}(\mathbf{V}_x)$ is the total variance of the vector x , while $\lambda_i/\text{tr}(\mathbf{V}_x)$ is the fraction of that total variance explained by the linear combination $\mathbf{e}_i^T \mathbf{x}$.

Example A5.6. Again let us consider the additive-genetic covariance matrix, \mathbf{G} , as shown in Examples A5.1 and A5.2. Because $\lambda_1 \approx 5.241$, $\lambda_2 \approx 0.765$, and $\text{tr}(\mathbf{G}) = 4 + 2 = 6$, the first PC explains $5.241/6 \approx 0.8735$, or 87% of the variance in \mathbf{G} . While the first PC accounts for the majority of variation over the entire space of the variables (x), the amount of variation explained by PC1 for any *particular* weighted combination, $y = \mathbf{b}^T \mathbf{x}$, of the original variables depends on the projection of \mathbf{b} onto PC1. For example, if $\mathbf{b} = \mathbf{e}_2$ (the weight vector corresponds to the second eigenvector), then the projection of \mathbf{b} onto PC1 has a length of zero, because PC1 is orthogonal to \mathbf{e}_2 , and hence PC1 explains none of the variation of this new variable.

Example A5.7 serves as a brief introduction to the important field of **morphometrics**, which is concerned with quantification and comparison of sizes and shapes of organisms. The reader is referred to Pimentel (1979), Reyment et al. (1984), Elewa (2004), Claude (2008) and especially Bookstein et al. (1985), Rohlf and Bookstein (1990), Reyment (1991), Bookstein (1997), Slice (2005), and Zelditch et al. (2012) for detailed treatments.

Example A5.7. Jolicoeur and Mosimann (1960) measured three carapace characters in 24 males of the painted turtle (*Chrysemys picta marginata*). Letting z_1 be the carapace length, z_2 be the maximum carapace width, and z_3 be the carapace height, the resulting sample covariance matrix (\mathbf{S}_z , the sample estimate of \mathbf{V}_z) for these data was found to be

$$\mathbf{S}_z = \begin{pmatrix} 138.77 & 79.15 & 37.38 \\ 79.15 & 50.04 & 21.65 \\ 37.38 & 21.65 & 11.26 \end{pmatrix}$$

Hence, $\text{tr}(\mathbf{S}_z) = 138.77 + 50.04 + 11.26 = 200.07$. Using R, the eigenvalues of \mathbf{S}_z are found to be

$$\lambda_1 = 195.280, \quad \lambda_2 = 3.687, \quad \lambda_3 = 1.103$$

which (as expected) sum to the value of the trace, 200.07. The associated (normalized) eigenvectors are similarly found to be

$$\mathbf{e}_1 = \begin{pmatrix} 0.840 \\ 0.492 \\ 0.229 \end{pmatrix}, \quad \mathbf{e}_2 = \begin{pmatrix} 0.488 \\ -0.870 \\ 0.079 \end{pmatrix}, \quad \mathbf{e}_3 = \begin{pmatrix} 0.213 \\ 0.043 \\ -0.971 \end{pmatrix}$$

PC1 accounts for 97.6% of the variation ($195.281/200.07 = 0.976$), while PC2 and PC3 account for 1.84% and 0.55%, respectively. Jolicoeur and Mosimann interpret PC1 as measuring overall size, as the new variable

$$y_1 = \mathbf{e}_1^T \mathbf{z} = 0.840z_1 + 0.492z_2 + 0.229z_3$$

corresponds to a simultaneous change in all three variables in the same direction, as is expected as individuals change their overall size. Likewise, PC2 and PC3 are

$$\begin{aligned}y_2 &= \mathbf{e}_2^T \mathbf{z} = 0.488z_1 - 0.870z_2 + 0.079z_3 \\y_3 &= \mathbf{e}_3^T \mathbf{z} = 0.213z_1 + 0.043z_2 - 0.971z_3\end{aligned}$$

which Jolicoeur and Mosimann interpreted as measures of shape. Because the coefficient on z_3 is small relative to the others in PC2, they interpret PC2 as measuring the tradeoff between length (z_1) and width (z_2). Thus, after removing the variation in size, 1.84% of the remaining variation can be accounted for by differences in the shape measured by length versus width. Likewise, because the PC3 coefficient for z_2 is very small, PC3 mainly measures shape differences due to length (z_1) versus height (z_3).

This example points out some of the advantages, and possible pitfalls, of using principal component analysis for dimensional reduction of the data. Namely, replacing the n -component vector \mathbf{z} by an $m < n$ component vector \mathbf{y} composed of linear combinations of the \mathbf{z} , i.e., $\mathbf{y}_{m \times 1} = \mathbf{M}_{m \times n} \mathbf{z}_{n \times 1}$, where $\mathbf{M} = (\mathbf{e}_1, \dots, \mathbf{e}_m)^T$, with $y_i = \mathbf{e}_i^T \mathbf{z}$. Essentially all (over 97%) of the variance in the three measured characters is accounted for by variation in overall size, with the remaining variation accounted for by differences in shape. While the temptation is strong to simply consider overall size and ignore all shape information, it might be the case that selection is largely ignoring variation in size and instead focusing on (size-independent) shape differences. In this case, an analysis ignoring shape (as would occur if only the new character generated by PC1 were considered) would be very misleading. A further complication with principal component analysis is that it can often be difficult to give biological interpretations to the new characters resulting from the rotation of the coordinate system.

TESTING FOR MULTIVARIATE NORMALITY

Multivariate normality is often assumed in statistical procedures, but it is less often tested. In LW Chapter 11 we briefly discussed two approaches for testing univariate normality, one graphical and the other based on deviations of observed skewness and/or kurtosis from Gaussian expectations. As we now demonstrate, both of these approaches can be extended to testing for multivariate normality. Additional methods are reviewed by Malkovich and Afifi (1973), Gnanadesikan (1977), Cox and Small (1978), Seber (1984), Looney (1995), and Henze (2002).

Graphical Tests: Chi-square Plots

A fairly simple graphical test can be developed by extending the notion of the normal probability plot that is used to check univariate normality (LW Chapter 11), where observations were ranked and then plotted against their ranked expected values under normality. Departures from linearity signify departures from normality, and we can apply this same approach to check for multivariate normality. From Equation A5.20d, if $\mathbf{z} \sim \text{MVN}(\boldsymbol{\mu}, \mathbf{V}_z)$, then each element of the vector

$$\mathbf{y} = \mathbf{A}^{-1/2} \mathbf{U}^T (\mathbf{z} - \boldsymbol{\mu})$$

is an independent unit normal, so that $\mathbf{y} \sim \text{MVN}(\mathbf{0}, \mathbf{I})$. Recalling that $\mathbf{U}^{-1} = \mathbf{U}^T$, we can rearrange this expression to yield

$$(\mathbf{z} - \boldsymbol{\mu}) = \mathbf{U} \mathbf{A}^{1/2} \mathbf{y}$$

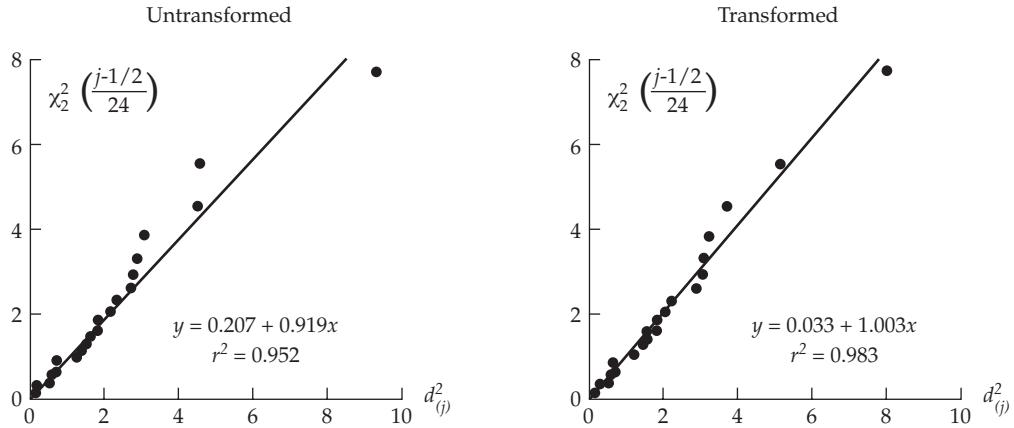

Figure A5.7 Plots of ranked distance data ($d_{(j)}^2$ being the j th smallest distance) versus the expected corresponding χ^2 value for the data of Jolicoeur and Mosimann from Example A5.8. **Left:** The untransformed data do not appear to depart significantly from linearity, although they depart slightly from the intercept (0) and slope (1) of the expected regression under multivariate normality. **Right:** Log-transforming the data gives a slightly better linear fit ($r^2 = 0.983$ versus $r^2 = 0.952$), with the best-fitting line passing through the origin as expected if the distance data follow a χ^2 distribution, and has a slope of essentially one. See Example A5.8 for more details.

Using this result and recalling Equation A5.11a, we have that

$$\begin{aligned} (\mathbf{z} - \boldsymbol{\mu})^T \mathbf{V}_{\mathbf{z}}^{-1} (\mathbf{z} - \boldsymbol{\mu}) &= \left(\mathbf{U} \boldsymbol{\Lambda}^{1/2} \mathbf{y} \right)^T \left(\mathbf{U} \boldsymbol{\Lambda}^{-1} \mathbf{U}^T \right) \left(\mathbf{U} \boldsymbol{\Lambda}^{1/2} \mathbf{y} \right) \\ &= \mathbf{y}^T \boldsymbol{\Lambda}^{1/2} \left(\mathbf{U}^T \mathbf{U} \right) \boldsymbol{\Lambda}^{-1} \left(\mathbf{U}^T \mathbf{U} \right) \boldsymbol{\Lambda}^{1/2} \mathbf{y} \\ &= \mathbf{y}^T \mathbf{y} = \sum_{i=1}^n y_i^2 \end{aligned} \quad (\text{A5.22})$$

Thus if $\mathbf{z} \sim \text{MVN}$, the quadratic form given by Equation A5.22 is the sum of n independent squared unit normal random variables. By definition, this sum is a χ^2 random variable with n degrees of freedom (LW Appendix 5), suggesting that one test for multivariate normality is to compare the goodness of fit of the scaled distances

$$d_i^2 = (\mathbf{z}_i - \bar{\mathbf{z}})^T \mathbf{S}_{\mathbf{z}}^{-1} (\mathbf{z}_i - \bar{\mathbf{z}}) \quad (\text{A5.23})$$

to those generated by n (rank-ordered) draws from a χ_n^2 . Here \mathbf{z}_i is the vector of observations from the i th individual, $\bar{\mathbf{z}}$ the vector of sample means, and $\mathbf{S}_{\mathbf{z}}^{-1}$ the inverse of the sample covariance matrix. Note that the d_i are simply the squared Mahalanobis distances (Equation A5.19). We use the term *distance* because when \mathbf{z} is transformed to \mathbf{y} , $\mathbf{V}\mathbf{y} = \mathbf{I}$, giving the variance of the linear combination $\mathbf{c}^T \mathbf{y}$ as $\mathbf{c}^T \mathbf{V} \mathbf{y} \mathbf{c} = \mathbf{c}^T \mathbf{I} \mathbf{c} = \|\mathbf{c}\|^2$. Thus, regardless of orientation, any two \mathbf{y} vectors having the same length also have the same variance, which equals their squared Euclidean distance.

The regression test for multivariate normality is based on *ordered* distances. Hence, we first order the distances generated by Equation A5.23 from smallest to largest,

$$d_{(1)}^2 \leq d_{(2)}^2 \leq \cdots \leq d_{(m)}^2$$

where m is the number of individuals sampled. Note that we use the subscription notation where $d_{(j)}^2$ denotes the j th smallest *distance* (the j th smallest value of Equation A5.23), whereas d_i^2 is the distance associated with the vector of observations for the i th *observation*.

Let $\chi_n^2(\alpha)$ correspond to the value of a chi-square random variable, X , with n degrees of freedom that satisfies $\text{Prob}[X \leq \chi_n^2(\alpha)] = \alpha$. Under multivariate normality, we expect the points

$$\left(d_{(i)}^2, \chi_n^2 \left[\frac{i - 1/2}{m} \right] \right) \quad \text{for } 1 \leq i \leq m$$

to fall along a line with a slope of one and an intercept of zero, as the i th ordered distance has i/m observations less than or equal to it (the factor of $1/2$ is added as a correction for continuity). As with univariate normal probability plots, departures from multivariate normality are indicated by departures from linearity. More formally, one can use a standard **Kolmogorov-Smirnov test** (Conover 1999) for comparing two distributions to compare the goodness-of-fit of these ordered distances with a χ_n^2 .

Example A5.8. Consider again the data of Jolicoeur and Mosimann (1960) on carapace characters in 24 male turtles. Are the characters z_1 (carapace length) and z_2 (maximum carapace width) jointly bivariate normally distributed? Here $n = 2$ and $m = 24$ and

$$\bar{\mathbf{z}} = \begin{pmatrix} 113.13 \\ 88.29 \end{pmatrix}, \quad \mathbf{S}_Z = \begin{pmatrix} 138.77 & 79.15 \\ 79.15 & 50.04 \end{pmatrix}, \quad \mathbf{S}_Z^{-1} = \begin{pmatrix} 0.0737 & -0.1165 \\ -0.1165 & 0.2043 \end{pmatrix}$$

where \mathbf{S}_Z is the sample covariance matrix. A partial list of the 24 vectors of observations is

$$\mathbf{z}_1 = \begin{pmatrix} 93 \\ 74 \end{pmatrix}, \quad \dots, \quad \mathbf{z}_{11} = \begin{pmatrix} 113 \\ 88 \end{pmatrix}, \quad \dots, \quad \mathbf{z}_{24} = \begin{pmatrix} 135 \\ 106 \end{pmatrix}$$

Applying Equation A5.23, these observations translate into the distances

$$d_1^2 = 4.45, \quad \dots, \quad d_{11}^2 = 0.002, \quad \dots, \quad d_{24}^2 = 9.277$$

After rank ordering, these correspond to $d_{(23)}^2$, $d_{(1)}^2$, and $d_{(24)}^2$, respectively. For $d_{(23)}^2$, the matching value when distances are χ^2 -distributed is

$$\chi_2^2 \left(\frac{23 - 1/2}{24} \right) = \chi_2^2 (0.9375)$$

The R command `qchisq(0.9375, 2)` returns a value of $x = 5.545$, which satisfies $\text{Pr}(\chi_2^2 \leq x) = 0.9375$, and calculates the point generated from \mathbf{z}_1 as $(4.45, 5.545)$. Likewise, the χ^2 values for $d_{(1)}^2$ and $d_{(24)}^2$ are 0.043 and 7.742, respectively. Proceeding similarly for the other values, we obtain the regression plotted in Figure A5.7. This departs somewhat from linearity. Further, under the assumption of multivariate normality, the best-fitting linear regression is expected to have a slope of one and to pass through the origin, while the best linear fit of these data shows slight departures from these values. Transforming the data by taking logs results in a slightly better fit (Figure A5.7).

Mardia's Test: Multivariate Skewness and Kurtosis

As was the case for univariate normality, we can test for multivariate normality by examining the sample skewness and kurtosis. Mardia (1970, 1974) proposed multivariate extensions of skewness and kurtosis measures and suggested a large-sample test based on the asymptotic distribution of these statistics. If there are m vectors of observations (with each vector measuring n characters), then the multivariate skewness is estimated by

$$b_{1,n} = \frac{1}{m^2} \sum_{i=1}^m \sum_{j=1}^m \left[(\mathbf{z}_i - \bar{\mathbf{z}})^T \mathbf{S}_Z^{-1} (\mathbf{z}_j - \bar{\mathbf{z}}) \right]^3 \quad (\text{A5.24a})$$

while the multivariate kurtosis is estimated by

$$b_{2,n} = \frac{1}{m} \sum_{i=1}^m \left[(\mathbf{z}_i - \bar{\mathbf{z}})^T \mathbf{S}_{\mathbf{z}}^{-1} (\mathbf{z}_i - \bar{\mathbf{z}}) \right]^2 \quad (\text{A5.24b})$$

If $\mathbf{z} \sim \text{MVN}$, then $b_{1,n}$ and $b_{2,n}$ have expected values 0 and $n(n+2)$. For large values of m , Mardia showed that the (scaled) multivariate skewness is asymptotically distributed as a chi-square random variable with f degrees of freedom, with

$$\frac{m}{6} b_{1,n} \sim \chi_f^2, \quad \text{where } f = \frac{n(n+1)(n+2)}{6} \quad (\text{A5.25a})$$

Likewise for large values of m , the multivariate kurtosis (following appropriate scaling) is distributed as a unit-normal, with

$$\frac{b_{2,n} - n(n+2)}{\sqrt{8n(n+2)/m}} \sim N(0, 1) \quad (\text{A5.25b})$$

If either Equation A5.25a or A5.25b is significant, then multivariate normality is rejected.

Example A5.9. Do the data considered in Example A5.8 display significant skewness or kurtosis? Here $n = 2$ and $m = 24$. Applying Equations A5.25a and A5.25b gives $b_{1,2} = 0.6792$ and $b_{2,2} = 7.6043$. Considering skewness first, from Equation A5.25a it follows that the value

$$\frac{m}{6} b_{1,2} = \frac{24}{6} 0.6792 = 2.717$$

is (under MVN) a draw from a chi-square distribution with $f = 2(2+1)(2+2)/6 = 4$ degrees of freedom. Because $\text{Prob}(\chi_4^2 \geq 2.717) \simeq 0.606$, this is not significant. Turning to kurtosis, Equation A5.25b yields

$$\frac{b_{2,n} - n(n+2)}{\sqrt{8n(n+2)/m}} = \frac{7.6043 - 8}{1.633} \simeq -0.2423$$

which is also not significant as $\text{Prob}(|N(0, 1)| \geq 0.2423) \simeq 0.81$. Transforming the data by taking logs gives $b_{1,2} = 0.2767$ and $b_{2,2} = 7.1501$, and hence showing a slight decrease in skewness and a slight increase in kurtosis relative to the untransformed data. Reymert (1971) presented a number of other biological examples using Mardia's test.

Appendix 6

Derivatives of Vectors and Vector-valued Functions

Mathematics is a collection of cheap tricks and dirty jokes. Lipman Bers

Quantitative genetics often deals with vector-valued functions, and here we provide a brief review of the calculus of such functions. In particular, we review common expressions for derivatives of vectors and vector-valued functions, introduce the gradient vector and Hessian matrix (for first and second partials, respectively), and use this machinery in multidimensional Taylor series for approximating functions around a specific value. We apply these results to several problems in selection theory and evolution.

DERIVATIVES OF VECTORS AND VECTOR-VALUED FUNCTIONS

Suppose we let $f(\mathbf{x})$ be a scalar (single-dimension) function of a column vector, $\mathbf{x} = (x_1, \dots, x_n)^T$, of n variables. The **gradient** (or **gradient vector**) of f with respect to \mathbf{x} is obtained by taking partial derivatives of the function with respect to each variable. In matrix notation, the gradient operator is denoted by

$$\nabla_{\mathbf{x}}[f] = \frac{\partial f}{\partial \mathbf{x}} = \begin{pmatrix} \frac{\partial f}{\partial x_1} \\ \vdots \\ \frac{\partial f}{\partial x_n} \end{pmatrix}$$

The gradient at a point, \mathbf{x}_o , corresponds to a vector indicating the direction of local steepest ascent of the function at that point (the multivariate slope of f at \mathbf{x}_o).

Example A6.1. For an $n \times 1$ column vector, \mathbf{x} , compute the gradient for

$$f(\mathbf{x}) = \sum_{i=1}^n x_i^2 = \mathbf{x}^T \mathbf{x}$$

Because $\partial f / \partial x_i = 2x_i$, the gradient vector is just $\nabla_{\mathbf{x}}[f(\mathbf{x})] = 2\mathbf{x}$. At the point \mathbf{x}_o , $\mathbf{x}^T \mathbf{x}$ locally increases most rapidly if we change \mathbf{x} in the same direction as the vector going from point \mathbf{x}_o to point $\mathbf{x}_o + 2\delta \mathbf{x}_o = (1 + 2\delta) \mathbf{x}_o$, where δ is a small positive value.

Now consider an $m \times n$ matrix, \mathbf{A} , of constants. What is the derivative of the $n \times 1$ column vector \mathbf{Ax} with respect to \mathbf{x} ? Recall from the definition of matrix multiplication that the i th element of \mathbf{Ax} is

$$(\mathbf{Ax})_i = \sum_{j=1}^n A_{ij} x_j, \quad \text{yielding} \quad \partial(\mathbf{Az})_i / \partial x_k = A_{ik}$$

Hence, the i th element of $\nabla_{\mathbf{x}}[\mathbf{Ax}]_k$ is $(A_{1k} \ A_{2k} \ \dots \ A_{mk})$, namely the transpose of the k th column of \mathbf{A} , which yields $\nabla_{\mathbf{x}}[\mathbf{Ax}] = \mathbf{A}^T$.

For a vector (\mathbf{a}) and a matrix (\mathbf{A}) of constants, using the same logic as in Example A6.1, it can be shown (e.g., Morrison 1976; Graham 1981; Searle 1982) that

$$\nabla_{\mathbf{x}} [\mathbf{a}^T \mathbf{x}] = \nabla_{\mathbf{x}} [\mathbf{x}^T \mathbf{a}] = \mathbf{a} \quad (\text{A6.1a})$$

$$\nabla_{\mathbf{x}} [\mathbf{A}\mathbf{x}] = \mathbf{A}^T \quad (\text{A6.1b})$$

Turning to quadratic forms, if \mathbf{A} is symmetric ($\mathbf{A} = \mathbf{A}^T$), then

$$\nabla_{\mathbf{x}} [\mathbf{x}^T \mathbf{A}\mathbf{x}] = 2\mathbf{A}\mathbf{x} \quad (\text{A6.1c})$$

$$\nabla_{\mathbf{x}} [(\mathbf{x} - \mathbf{a})^T \mathbf{A}(\mathbf{x} - \mathbf{a})] = 2\mathbf{A}(\mathbf{x} - \mathbf{a}) \quad (\text{A6.1d})$$

$$\nabla_{\mathbf{x}} [(\mathbf{a} - \mathbf{x})^T \mathbf{A}(\mathbf{a} - \mathbf{x})] = -2\mathbf{A}(\mathbf{a} - \mathbf{x}) \quad (\text{A6.1e})$$

Taking $\mathbf{A} = \mathbf{I}$, Equation A6.1c implies

$$\nabla_{\mathbf{x}} [\mathbf{x}^T \mathbf{x}] = \nabla_{\mathbf{x}} [\mathbf{x}^T \mathbf{I}\mathbf{x}] = 2\mathbf{I}\mathbf{x} = 2\mathbf{x} \quad (\text{A6.1f})$$

as was found in Example A6.1. Two other useful identities follow from the chain rule of differentiation, namely,

$$\nabla_{\mathbf{x}} [\exp\{f(\mathbf{x})\}] = \exp[f(\mathbf{x})] \nabla_{\mathbf{x}} [f(\mathbf{x})] \quad (\text{A6.1g})$$

$$\nabla_{\mathbf{x}} [\ln[f(\mathbf{x})]] = \frac{1}{f(\mathbf{x})} \cdot \nabla_{\mathbf{x}} [f(\mathbf{x})] \quad (\text{A6.1h})$$

Finally, the product rule also applies to a gradient, with

$$\nabla_{\mathbf{x}} [f(\mathbf{x}) g(\mathbf{x})] = \nabla_{\mathbf{x}} [f(\mathbf{x})] g(\mathbf{x}) + f(\mathbf{x}) \nabla_{\mathbf{x}} [g(\mathbf{x})] \quad (\text{A6.1i})$$

Example A6.2. The density function $\varphi(\mathbf{x}, \boldsymbol{\mu}, \mathbf{V})$ for a multivariate normal (MVN) distribution returns a scalar value and is a function of the data vector, \mathbf{x} , the vector of means, $\boldsymbol{\mu}$, and the covariance matrix, \mathbf{V} ,

$$\varphi(\mathbf{x}, \boldsymbol{\mu}, \mathbf{V}) = a \exp\left(-\frac{1}{2} \cdot (\mathbf{x} - \boldsymbol{\mu})^T \mathbf{V}^{-1} (\mathbf{x} - \boldsymbol{\mu})\right)$$

where the constant $a = \pi^{-n/2} |\mathbf{V}|^{-1/2}$, and $|\mathbf{V}|$ denotes the determinant of \mathbf{V} . To compute the gradient of the MVN with respect to the data vector, \mathbf{x} , first apply Equation A6.1g to yield

$$\nabla_{\mathbf{x}} [\varphi(\mathbf{x}, \boldsymbol{\mu}, \mathbf{V})] = \varphi(\mathbf{x}, \boldsymbol{\mu}, \mathbf{V}) \cdot \nabla_{\mathbf{x}} \left[\left(-\frac{1}{2}\right) \cdot (\mathbf{x} - \boldsymbol{\mu})^T \mathbf{V}^{-1} (\mathbf{x} - \boldsymbol{\mu}) \right]$$

Using this result along with Equation A6.1d returns

$$\nabla_{\mathbf{x}} [\varphi(\mathbf{x}, \boldsymbol{\mu}, \mathbf{V})] = -\varphi(\mathbf{x}, \boldsymbol{\mu}, \mathbf{V}) \cdot \mathbf{V}^{-1} (\mathbf{x} - \boldsymbol{\mu}) \quad (\text{A6.2a})$$

Similarly, Equation A6.1e implies that the gradient of the MVN with respect to the vector of means $\boldsymbol{\mu}$ is

$$\nabla_{\boldsymbol{\mu}} [\varphi(\mathbf{x}, \boldsymbol{\mu}, \mathbf{V})] = \varphi(\mathbf{x}, \boldsymbol{\mu}, \mathbf{V}) \cdot \mathbf{V}^{-1} (\mathbf{x} - \boldsymbol{\mu}) \quad (\text{A6.2b})$$

Example A6.3. Recall (Equations 13.27c and 30.5a) that when the distribution of phenotypes is multivariate normal, the directional selection gradient, $\boldsymbol{\beta} = \mathbf{P}^{-1}\mathbf{S}$, equals the gradient

of log mean fitness with respect to the vector of trait means, $\nabla_{\boldsymbol{\mu}}[\ln \bar{W}(\boldsymbol{\mu})]$ (Lande 1979a). Hence, the increase in the mean population fitness is maximized if mean character values change in the same direction as the vector $\boldsymbol{\beta}$. To see this, first note that applying Equation A6.1h yields

$$\nabla_{\boldsymbol{\mu}}[\ln \bar{W}(\boldsymbol{\mu})] = \bar{W}^{-1} \nabla_{\boldsymbol{\mu}}[\bar{W}(\boldsymbol{\mu})] \quad (\text{A6.2c})$$

If we write mean fitness as $\bar{W}(\boldsymbol{\mu}) = \int W(\mathbf{z}) \varphi(\mathbf{z}, \boldsymbol{\mu}) d\mathbf{z}$ and take the gradient through the integral, we obtain

$$\nabla_{\boldsymbol{\mu}}[\ln \bar{W}(\boldsymbol{\mu})] = \bar{W}^{-1} \nabla_{\boldsymbol{\mu}} \left[\int W(\mathbf{z}) \varphi(\mathbf{z}, \boldsymbol{\mu}) d\mathbf{z} \right] = \bar{W}^{-1} \int W(\mathbf{z}) \nabla_{\boldsymbol{\mu}} [\varphi(\mathbf{z}, \boldsymbol{\mu})] d\mathbf{z}$$

The last identity follows from the assumption that $W(\mathbf{z})$ is not a function of the vector of trait means, $\boldsymbol{\mu}$, that is, the fitnesses are *frequency-independent* ($\nabla_{\boldsymbol{\mu}} [W(\mathbf{z})] = 0$). If the trait vector $\mathbf{z} \sim \text{MVN}(\boldsymbol{\mu}, \mathbf{P})$, Equation A6.2b yields

$$\nabla_{\boldsymbol{\mu}} [\varphi(\mathbf{z}, \boldsymbol{\mu})] = \varphi(\mathbf{z}, \boldsymbol{\mu}) \mathbf{P}^{-1} (\mathbf{z} - \boldsymbol{\mu}) \quad (\text{A6.2d})$$

Hence,

$$\begin{aligned} \bar{W}^{-1} \int W(\mathbf{z}) \nabla_{\boldsymbol{\mu}} [\varphi(\mathbf{z}, \boldsymbol{\mu})] d\mathbf{z} &= \int w(\mathbf{z}) \varphi(\mathbf{z}, \boldsymbol{\mu}) \mathbf{P}^{-1} (\mathbf{z} - \boldsymbol{\mu}) d\mathbf{z} \\ &= \mathbf{P}^{-1} \left(\int \mathbf{z} w(\mathbf{z}) \varphi(\mathbf{z}, \boldsymbol{\mu}) d\mathbf{z} - \boldsymbol{\mu} \int w(\mathbf{z}) \varphi(\mathbf{z}, \boldsymbol{\mu}) d\mathbf{z} \right) \\ &= \mathbf{P}^{-1}(\boldsymbol{\mu}^* - \boldsymbol{\mu}) = \mathbf{P}^{-1}\mathbf{S} = \boldsymbol{\beta} \end{aligned} \quad (\text{A6.2e})$$

which follows because the first integral (in the second line above) is the mean character value after selection, $\boldsymbol{\mu}^*$, while the second integral equals one by definition, as $E[w] = 1$.

If individual fitnesses are *frequency-dependent* (changing with $\boldsymbol{\mu}$), then, according to the product rule (Equation A6.1i), a second integral appears, and $\nabla_{\boldsymbol{\mu}}[\ln \bar{W}(\boldsymbol{\mu})]$ now becomes

$$\bar{W}^{-1} \int W(\mathbf{z}) \nabla_{\boldsymbol{\mu}} [\varphi(\mathbf{z}, \boldsymbol{\mu})] d\mathbf{z} + \bar{W}^{-1} \int \nabla_{\boldsymbol{\mu}} [W(\mathbf{z})] \varphi(\mathbf{z}, \boldsymbol{\mu}) d\mathbf{z}$$

which yields

$$\nabla_{\boldsymbol{\mu}}[\ln \bar{W}(\boldsymbol{\mu})] = \boldsymbol{\beta} + \bar{W}^{-1} \int \nabla_{\boldsymbol{\mu}} [W(\mathbf{z})] \varphi(\mathbf{z}, \boldsymbol{\mu}) d\mathbf{z} \quad (\text{A6.2f})$$

Example A6.4. Consider the ordinary least-squares solution for the general linear model, $\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{e}$, where $\boldsymbol{\beta}$ is the vector that minimizes the sum of squared residual errors, $\sum e_i^2$. In matrix form, this sum becomes

$$\begin{aligned} \sum_{i=1}^n e_i^2 &= \mathbf{e}^T \mathbf{e} = (\mathbf{y} - \mathbf{X}\boldsymbol{\beta})^T (\mathbf{y} - \mathbf{X}\boldsymbol{\beta}) \\ &= \mathbf{y}^T \mathbf{y} - \boldsymbol{\beta}^T \mathbf{X}^T \mathbf{y} - \mathbf{y}^T \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\beta}^T \mathbf{X}^T \mathbf{X}\boldsymbol{\beta} \\ &= \mathbf{y}^T \mathbf{y} - 2\boldsymbol{\beta}^T \mathbf{X}^T \mathbf{y} + \boldsymbol{\beta}^T \mathbf{X}^T \mathbf{X}\boldsymbol{\beta} \end{aligned} \quad (\text{A6.3a})$$

and the last step follows because the matrix product $\boldsymbol{\beta}^T \mathbf{X}^T \mathbf{y}$ yields a scalar, and hence equals its transpose,

$$\boldsymbol{\beta}^T \mathbf{X}^T \mathbf{y} = (\boldsymbol{\beta}^T \mathbf{X}^T \mathbf{y})^T = \mathbf{y}^T \mathbf{X}\boldsymbol{\beta} \quad (\text{A6.3b})$$

To find the vector $\boldsymbol{\beta}$ that minimizes $\mathbf{e}^T \mathbf{e}$, we take the derivative with respect to $\boldsymbol{\beta}$ and use Equations A6.1a–A6.1c, which yields

$$\nabla_{\boldsymbol{\beta}} [\mathbf{e}^T \mathbf{e}] = \frac{\partial \mathbf{e}^T \mathbf{e}}{\partial \boldsymbol{\beta}} = -2\mathbf{X}^T \mathbf{y} + 2\mathbf{X}^T \mathbf{X}\boldsymbol{\beta} \quad (\text{A6.3c})$$

Setting this equal to zero yields $\mathbf{X}^T \mathbf{X} \boldsymbol{\beta} = \mathbf{X}^T \mathbf{y}$, which (provided the inverse of $\mathbf{X}^T \mathbf{X}$ exists) has a solution of

$$\boldsymbol{\beta} = (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{y} \quad (\text{A6.3d})$$

More generally, if $\mathbf{X}^T \mathbf{X}$ is singular, we can still solve this equation by using a generalized inverse $(\mathbf{X}^T \mathbf{X})^-$; see LW Appendix 3.

Example A6.5. Here we present one derivation of Henderson's mixed-model equations (Equation 19.4). Consider the mixed model $\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{u} + \mathbf{e}$, where $\mathbf{e} \sim \text{MVN}(0, \mathbf{R})$, $\mathbf{u} \sim \text{MVN}(0, \mathbf{G})$, and \mathbf{e} and \mathbf{u} are independent (Equation 19.1). If we recall the probability density function for a multivariate normal (Example A6.2), we have that

$$p(\mathbf{e}) \propto |\mathbf{R}|^{-1/2} \cdot \exp \left[-\frac{1}{2} \mathbf{e}^T \mathbf{R}^{-1} \mathbf{e} \right] \quad \text{and} \quad p(\mathbf{u}) \propto |\mathbf{G}|^{-1/2} \cdot \exp \left[-\frac{1}{2} \mathbf{u}^T \mathbf{G}^{-1} \mathbf{u} \right] \quad (\text{A6.4a})$$

We can further note that the conditional distribution of \mathbf{y} given \mathbf{u} is

$$(\mathbf{y} - \mathbf{X}\boldsymbol{\beta} - \mathbf{Z}\mathbf{u}) | \mathbf{u} = \mathbf{e} \sim \text{MVN}(0, \mathbf{R})$$

Hence,

$$p(\mathbf{y}, \mathbf{u}) = p(\mathbf{y} | \mathbf{u}) \cdot p(\mathbf{u}) = p(\mathbf{e}) \cdot p(\mathbf{u})$$

with the last step following because \mathbf{e} and \mathbf{u} are independent. From Equation A6.4a,

$$p(\mathbf{y}, \mathbf{u}) \propto$$

$$|\mathbf{R}|^{-1/2} |\mathbf{G}|^{-1/2} \cdot \exp \left[-\frac{1}{2} (\mathbf{y} - \mathbf{X}\boldsymbol{\beta} - \mathbf{Z}\mathbf{u})^T \mathbf{R}^{-1} (\mathbf{y} - \mathbf{X}\boldsymbol{\beta} - \mathbf{Z}\mathbf{u}) - \frac{1}{2} \mathbf{u}^T \mathbf{G}^{-1} \mathbf{u} \right] \quad (\text{A6.4b})$$

Now consider the log of the density,

$$\ell = \ln [p(\mathbf{y}, \mathbf{u})] \propto$$

$$\left(-\frac{1}{2} \right) \left[\ln(|\mathbf{R}|) + \ln(|\mathbf{G}|) + (\mathbf{y} - \mathbf{X}\boldsymbol{\beta} - \mathbf{Z}\mathbf{u})^T \mathbf{R}^{-1} (\mathbf{y} - \mathbf{X}\boldsymbol{\beta} - \mathbf{Z}\mathbf{u}) + \mathbf{u}^T \mathbf{G}^{-1} \mathbf{u} \right] \quad (\text{A6.4c})$$

We can expand the larger quadratic product to yield the last two terms of A6.4c as

$$-2\mathbf{y}^T \mathbf{R}^{-1} \mathbf{X}\boldsymbol{\beta} - 2\mathbf{y}^T \mathbf{R}^{-1} \mathbf{Z}\mathbf{u} + \boldsymbol{\beta}^T \mathbf{X}^T \mathbf{R}^{-1} \mathbf{X}\boldsymbol{\beta} + 2\boldsymbol{\beta}^T \mathbf{X}^T \mathbf{R}^{-1} \mathbf{Z}\mathbf{u} + \mathbf{u}^T \mathbf{Z}^T \mathbf{R}^{-1} \mathbf{Z}\mathbf{u} + \mathbf{u}^T \mathbf{G}^{-1} \mathbf{u} \quad (\text{A6.4d})$$

Using Equations A6.1c through A6.1e to take the derivatives of ℓ with respect to $\boldsymbol{\beta}$ and \mathbf{u} yields

$$\begin{pmatrix} \frac{\partial \ell}{\partial \boldsymbol{\beta}} \\ \frac{\partial \ell}{\partial \mathbf{u}} \end{pmatrix} = \begin{pmatrix} \mathbf{X}^T \mathbf{R}^{-1} \mathbf{y} - \mathbf{X}^T \mathbf{R}^{-1} \mathbf{X}\boldsymbol{\beta} - \mathbf{X}^T \mathbf{R}^{-1} \mathbf{Z}\mathbf{u} \\ \mathbf{Z}^T \mathbf{R}^{-1} \mathbf{y} - \mathbf{Z}^T \mathbf{R}^{-1} \mathbf{X}\boldsymbol{\beta} - \mathbf{Z}^T \mathbf{R}^{-1} \mathbf{Z}\mathbf{u} + \mathbf{G}^{-1} \mathbf{u} \end{pmatrix} \quad (\text{A6.4e})$$

Denoting the value for $\boldsymbol{\beta}$ and \mathbf{u} that return a zero vector for Equation A6.4e as $\hat{\boldsymbol{\beta}}$ and $\hat{\mathbf{u}}$ yields the following set of matrix equations

$$\begin{pmatrix} \mathbf{X}^T \mathbf{R}^{-1} \mathbf{y} \\ \mathbf{Z}^T \mathbf{R}^{-1} \mathbf{y} \end{pmatrix} = \begin{pmatrix} \mathbf{X}^T \mathbf{R}^{-1} \mathbf{X}\hat{\boldsymbol{\beta}} + \mathbf{X}^T \mathbf{R}^{-1} \mathbf{Z}\hat{\mathbf{u}} \\ \mathbf{Z}^T \mathbf{R}^{-1} \mathbf{X}\hat{\boldsymbol{\beta}} + \mathbf{Z}^T \mathbf{R}^{-1} \mathbf{Z}\hat{\mathbf{u}} + \mathbf{G}^{-1} \hat{\mathbf{u}} \end{pmatrix} \quad (\text{A6.4f})$$

which immediately yields Henderson's mixed-model equations,

$$\begin{pmatrix} \mathbf{X}^T \mathbf{R}^{-1} \mathbf{y} \\ \mathbf{Z}^T \mathbf{R}^{-1} \mathbf{y} \end{pmatrix} = \begin{pmatrix} \mathbf{X}^T \mathbf{R}^{-1} \mathbf{X} & \mathbf{X}^T \mathbf{R}^{-1} \mathbf{Z} \\ \mathbf{Z}^T \mathbf{R}^{-1} \mathbf{X} & \mathbf{Z}^T \mathbf{R}^{-1} \mathbf{Z} + \mathbf{G}^{-1} \end{pmatrix} \begin{pmatrix} \hat{\boldsymbol{\beta}} \\ \hat{\mathbf{u}} \end{pmatrix} \quad (\text{A6.4g})$$

Using the second equation (row two) of Equation A6.4g returns

$$\mathbf{Z}^T \mathbf{R}^{-1} \mathbf{X} \hat{\boldsymbol{\beta}} + (\mathbf{Z}^T \mathbf{R}^{-1} \mathbf{Z} + \mathbf{G}^{-1}) \hat{\mathbf{u}} = \mathbf{Z}^T \mathbf{R}^{-1} \mathbf{y} \quad (\text{A6.4h})$$

which can be rearranged to yields

$$\hat{\mathbf{u}} = (\mathbf{Z}^T \mathbf{R}^{-1} \mathbf{Z} + \mathbf{G}^{-1})^{-1} \mathbf{Z}^T \mathbf{R}^{-1} (\mathbf{y} - \mathbf{X} \hat{\boldsymbol{\beta}}) \quad (\text{A6.4i})$$

as an alternative expression to Equation 19.3b for the BLUP of \mathbf{u} .

THE HESSIAN MATRIX, LOCAL MAXIMA/MINIMA, AND MULTIDIMENSIONAL TAYLOR SERIES

In univariate calculus, the local extrema of a function occur when its slope (first derivative) is zero. The multivariate extension is that the gradient vector is zero, so the slope of the function with respect to all variables is zero. A point \mathbf{x}_e where this occurs is called a **stationary** or **equilibrium** point, and corresponds to either a local maximum, minimum, saddle point, or inflection point. As with the calculus of single variables, determining which of these cases is correct depends on the second derivative. With n variables, the appropriate generalization is the **Hessian** matrix

$$\mathbf{H}_{\mathbf{x}}[f] = \nabla_{\mathbf{x}} \left[\left(\nabla_{\mathbf{x}}[f] \right)^T \right] = \frac{\partial^2 f}{\partial \mathbf{x} \partial \mathbf{x}^T} = \begin{pmatrix} \frac{\partial^2 f}{\partial x_1^2} & \cdots & \frac{\partial^2 f}{\partial x_1 \partial x_n} \\ \vdots & \ddots & \vdots \\ \frac{\partial^2 f}{\partial x_1 \partial x_n} & \cdots & \frac{\partial^2 f}{\partial x_n^2} \end{pmatrix} \quad (\text{A6.5})$$

Note that this is the **outer product** of $\nabla_{\mathbf{x}}[f]$ with itself. Recall for an n -dimensional column vector $\mathbf{a}_{n \times 1}$ that while the inner product, $\mathbf{a}_{1 \times n}^T \mathbf{a}_{n \times 1} = \sum a_i$, returns a 1×1 matrix (a scalar), the outer product, $\mathbf{a}_{n \times 1} \mathbf{a}_{1 \times n}^T$, returns an $n \times n$ matrix whose ij th element is $a_i a_j$, or (in our case)

$$\mathbf{H}_{ij} = \frac{\partial(f(\mathbf{x})/\partial x_i)}{\partial x_j} = \frac{\partial^2 f(\mathbf{x})}{\partial x_i \partial x_j}$$

This matrix is symmetric, as mixed partials are equal under suitable continuity conditions, and it measures the local multidimensional curvature of the function.

Example A6.6. Compute the Hessian matrix for the multivariate normal distribution with respect to the data vector \mathbf{x} . If we recall from Equation A6.2a that $\nabla_{\mathbf{x}} [\varphi(\mathbf{x}, \boldsymbol{\mu})] = -\varphi(\mathbf{x}, \boldsymbol{\mu}) \cdot \mathbf{V}^{-1} (\mathbf{x} - \boldsymbol{\mu})$, we have

$$\begin{aligned}\mathbf{H}_{\mathbf{x}} [\varphi(\mathbf{x}, \boldsymbol{\mu})] &= \nabla_{\mathbf{x}} \left[\left(\nabla_{\mathbf{x}} [\varphi(\mathbf{x}, \boldsymbol{\mu})] \right)^T \right] = -\nabla_{\mathbf{x}} [\varphi(\mathbf{x}, \boldsymbol{\mu}) \cdot (\mathbf{x} - \boldsymbol{\mu})^T \mathbf{V}^{-1}] \\ &= -\nabla_{\mathbf{x}} [\varphi(\mathbf{x}, \boldsymbol{\mu})] \cdot (\mathbf{x} - \boldsymbol{\mu})^T \mathbf{V}^{-1} - \varphi(\mathbf{x}, \boldsymbol{\mu}) \cdot \nabla_{\mathbf{x}} [(\mathbf{x} - \boldsymbol{\mu})^T \mathbf{V}^{-1}] \\ &= -[-\varphi(\mathbf{x}, \boldsymbol{\mu}) \cdot \mathbf{V}^{-1} (\mathbf{x} - \boldsymbol{\mu})] \cdot (\mathbf{x} - \boldsymbol{\mu})^T \mathbf{V}^{-1} - \varphi(\mathbf{x}, \boldsymbol{\mu}) \cdot [\mathbf{V}^{-1}] \\ &= \varphi(\mathbf{x}, \boldsymbol{\mu}) \cdot \left(\mathbf{V}^{-1} (\mathbf{x} - \boldsymbol{\mu})(\mathbf{x} - \boldsymbol{\mu})^T \mathbf{V}^{-1} - \mathbf{V}^{-1} \right)\end{aligned}\quad (\text{A6.6a})$$

Here we have used the product rule (Equation A6.1i) and Equation A6.1b, respectively (recall that \mathbf{V} is a symmetric matrix of constants). In a similar manner, the Hessian with respect to the vector of means, $\boldsymbol{\mu}$, is

$$\mathbf{H}_{\boldsymbol{\mu}} [\varphi(\mathbf{x}, \boldsymbol{\mu})] = \varphi(\mathbf{x}, \boldsymbol{\mu}) \cdot \left(\mathbf{V}^{-1} (\mathbf{x} - \boldsymbol{\mu})(\mathbf{x} - \boldsymbol{\mu})^T \mathbf{V}^{-1} - \mathbf{V}^{-1} \right)\quad (\text{A6.6b})$$

To see how the Hessian matrix determines the nature of equilibrium points, a slight digression on the **multidimensional Taylor series** is needed. Consider the (second-order) Taylor series of a scalar function of n variables, $f(x_1, \dots, x_n)$, expanded about the point \mathbf{x}_o ,

$$f(\mathbf{x}) \simeq f(\mathbf{x}_o) + \sum_{i=1}^n (x_i - x_{o,i}) \frac{\partial f}{\partial x_i} + \frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n (x_i - x_{o,i})(x_j - x_{o,j}) \frac{\partial^2 f}{\partial x_i \partial x_j} + \dots\quad (\text{A6.7a})$$

where all partials are evaluated at \mathbf{x}_o . If we note that the first sum is the inner product of the gradient and $(\mathbf{x} - \mathbf{x}_o)$, and the double sum is a quadratic product involving the Hessian, we can express Equation A6.7a in matrix form as

$$f(\mathbf{x}) \simeq f(\mathbf{x}_o) + \nabla^T (\mathbf{x} - \mathbf{x}_o) + \frac{1}{2} (\mathbf{x} - \mathbf{x}_o)^T \mathbf{H} (\mathbf{x} - \mathbf{x}_o)\quad (\text{A6.7b})$$

where ∇ and \mathbf{H} are the gradient and Hessian of f with respect to \mathbf{x} when evaluated at \mathbf{x}_o ,

$$\nabla \equiv \nabla_{\mathbf{x}} [f] |_{\mathbf{x}=\mathbf{x}_o} \quad \text{and} \quad \mathbf{H} \equiv \mathbf{H}_{\mathbf{x}} [f] |_{\mathbf{x}=\mathbf{x}_o}$$

At an equilibrium point, $\hat{\mathbf{x}}$, all first partials are zero, so $(\nabla_{\mathbf{x}} [f])^T$ is evaluated at $\hat{\mathbf{x}}$ is a vector of length zero. Whether this point is a maximum or minimum is then determined by the quadratic product involving the Hessian when evaluated at $\hat{\mathbf{x}}$. Consider a vector, \mathbf{d} , of a small change from the equilibrium point

$$f(\hat{\mathbf{x}} + \mathbf{d}) - f(\hat{\mathbf{x}}) \simeq \frac{1}{2} \cdot \mathbf{d}^T \mathbf{H} \mathbf{d}\quad (\text{A6.8a})$$

Because \mathbf{H} is a symmetric matrix, we can diagonalize it and apply a canonical transformation (Equation A5.17a) to simplify the quadratic product in Equation A6.8a, which returns

$$f(\hat{\mathbf{x}} + \mathbf{d}) - f(\hat{\mathbf{x}}) \simeq \frac{1}{2} \sum_{i=1}^n \lambda_i y_i^2\quad (\text{A6.8b})$$

where $y_i = \mathbf{e}_i^T \mathbf{d}$, with \mathbf{e}_i and λ_i representing the eigenvectors and eigenvalues of the Hessian when evaluated at $\hat{\mathbf{x}}$. Thus, if \mathbf{H} is **positive-definite** (all eigenvalues of \mathbf{H} are positive), f increases in all directions around $\hat{\mathbf{x}}$, and hence $\hat{\mathbf{x}}$ is a local minimum of f . If \mathbf{H} is **negative-definite** (all eigenvalues of \mathbf{H} are negative), f decreases in all directions around $\hat{\mathbf{x}}$, and $\hat{\mathbf{x}}$ is a local maximum of f . If the eigenvalues differ in sign (\mathbf{H} is **indefinite**), $\hat{\mathbf{x}}$ corresponds to a saddle point (to see this, suppose $\lambda_1 > 0$ and $\lambda_2 < 0$; any change along the vector \mathbf{e}_1 results in an increase in f , while any change along \mathbf{e}_2 results in a decrease in f).

Example A6.7. Consider the following demonstration (due to Lande 1979a) that the mean population fitness increases. A round of selection changes the current vector of means from $\boldsymbol{\mu}$ to $\boldsymbol{\mu} + \Delta\boldsymbol{\mu}$. Expanding the log of mean fitness in a Taylor series around the current population mean gives the change in mean population fitness as

$$\begin{aligned}\Delta \ln \bar{W}(\boldsymbol{\mu}) &= \ln \bar{W}(\boldsymbol{\mu} + \Delta\boldsymbol{\mu}) - \ln \bar{W}(\boldsymbol{\mu}) \\ &\simeq \left(\nabla_{\boldsymbol{\mu}} [\ln \bar{W}(\boldsymbol{\mu})] \right)^T \Delta\boldsymbol{\mu} + \frac{1}{2} \Delta\boldsymbol{\mu}^T \mathbf{H}_{\boldsymbol{\mu}} [\ln \bar{W}(\boldsymbol{\mu})] \Delta\boldsymbol{\mu}\end{aligned}\quad (\text{A6.9a})$$

If we assume that second- and higher-order terms can be neglected (as would occur with weak selection and the population mean away from an equilibrium point), then Equation A6.9a simplifies to

$$\Delta \ln \bar{W}(\boldsymbol{\mu}) \simeq \left(\nabla_{\boldsymbol{\mu}} [\ln \bar{W}(\boldsymbol{\mu})] \right)^T \Delta\boldsymbol{\mu} \quad (\text{A6.9b})$$

Further assuming that the joint distribution of phenotypes and additive genetic values is MVN, then substituting Equation A6.2e into Equation A6.9b yields

$$\Delta \ln \bar{W}(\boldsymbol{\mu}) \simeq \boldsymbol{\beta}^T \Delta\boldsymbol{\mu} \quad (\text{A6.9c})$$

Because $\Delta\boldsymbol{\mu}$ is the response vector, \mathbf{R} , rearranging Equation 13.26a yields $\boldsymbol{\beta} = \mathbf{G}^{-1}\mathbf{R} = \mathbf{G}^{-1}\Delta\boldsymbol{\mu}$. Substituting this expression into Equation A6.9c yields

$$\Delta \ln \bar{W}(\boldsymbol{\mu}) \simeq (\mathbf{G}^{-1} \Delta\boldsymbol{\mu})^T \Delta\boldsymbol{\mu} = (\Delta\boldsymbol{\mu})^T \mathbf{G}^{-1} \Delta\boldsymbol{\mu} \geq 0 \quad (\text{A6.9d})$$

The inequality follows because \mathbf{G} is a variance-covariance matrix and hence is nonnegative-definite (all its eigenvalues are nonnegative). Under these conditions, mean population fitness never decreases, although because $\Delta\boldsymbol{\mu} \neq \nabla_{\boldsymbol{\mu}} [\ln \bar{W}(\boldsymbol{\mu})]$, the local increase in fitness does not necessarily improve in the fastest possible manner. Note that

$$\Delta \ln \bar{W}(\boldsymbol{\mu}) = \ln \bar{W}(\boldsymbol{\mu}[t+1]) - \ln \bar{W}(\boldsymbol{\mu}[t]) = \ln \left(\frac{\bar{W}(\boldsymbol{\mu}[t+1])}{\bar{W}(\boldsymbol{\mu}[t])} \right) \quad (\text{A6.9e})$$

so $\Delta \ln \bar{W}(\boldsymbol{\mu}) > 0$ implies $\bar{W}(\boldsymbol{\mu}[t+1]) > \bar{W}(\boldsymbol{\mu}[t])$. Notice from Equation A6.2f that when fitnesses are frequency-dependent, $\nabla_{\boldsymbol{\mu}} [\ln \bar{W}(\boldsymbol{\mu})]$ has an extra term beyond $\boldsymbol{\beta}$, and the above proof does not hold (namely, mean fitness can decrease).

OPTIMIZATION UNDER CONSTRAINTS

Occasionally, we wish to find the maximum or minimum of a function subject to a constraint. The solution is to use **Lagrange multipliers**. Suppose we wish to find the extrema of a function, $f(\mathbf{x})$, subject to the constraint that $h(\mathbf{x}) = c$. We first construct a new function by considering

$$g(\mathbf{x}, \lambda) = f(\mathbf{x}) - \lambda[h(\mathbf{x}) - c] \quad (\text{A6.10a})$$

Because $h(\mathbf{x}) - c = 0$, the extrema of $g(\mathbf{x}, \lambda)$ correspond to the extrema of $f(\mathbf{x})$ under the constraint. Local maxima and minima are obtained by solving the following set of equations:

$$\nabla_{\mathbf{x}}[g(\mathbf{x}, \lambda)] = \nabla_{\mathbf{x}}[f(\mathbf{x})] - \lambda \cdot \nabla_{\mathbf{x}}[h(\mathbf{x})] = \mathbf{0} \quad (\text{A6.10b})$$

$$\frac{d g(\mathbf{x}, \lambda)}{d \lambda} = h(\mathbf{x}) - c = 0 \quad (\text{A6.10c})$$

Observe that the second equation is satisfied by the constraint.

Example A6.8. A standard approach for selection on multiple traits is to use a **selection index**, I , which is a new (univariate) trait that is a linear combination of n characters $\mathbf{z} = (z_1, z_2, \dots, z_n)^T$, with

$$I = \mathbf{b}^T \mathbf{z} = \sum_{k=1}^n b_k z_k \quad (\text{A6.11a})$$

Notice that what matters for the weights are their *relative proportions*, as, if we were to multiply all of the weights by the same constant (e.g., $a b_k$), this new index would still choose the same individuals. Hence, to obtain a standardized index, we impose the constraint $\mathbf{b}^T \mathbf{b} = 1$. We denote the directional selection differential on the index by S_I , and observe that if \mathbf{S} is the vector of directional selection differentials generated by selecting on I , then $S_I = \mathbf{b}^T \mathbf{S}$.

Smith (1936) and Hazel (1943) showed that a larger response in a target index is obtained by selecting on a *different* index. Suppose our aim is to maximize the response in the index,

$$J = \mathbf{a}^T \boldsymbol{\mu} = \sum a_k \mu_k \quad (\text{A6.11b})$$

What are the standardized weights, \mathbf{b} , for the optimal **Smith-Hazel** index (for a fixed amount of selection, $S_I = s$)? If we assume that the conditions leading to the multivariate breeder's equation hold, the function to maximize is

$$f(\mathbf{b}) = \mathbf{a}^T \Delta \boldsymbol{\mu} = \mathbf{a}^T \mathbf{R} = \mathbf{a}^T \mathbf{G} \mathbf{P}^{-1} \mathbf{S} \quad (\text{A6.11c})$$

under the associated constraint function

$$g(\mathbf{b}) - c = \mathbf{b}^T \mathbf{b} - 1 = 0 \quad (\text{A6.11d})$$

Because $S_I = \mathbf{b}^T \mathbf{S}$, and we have the constraint that $\mathbf{b}^T \mathbf{b} = 1$, set $\mathbf{S} = s \cdot \mathbf{b}$, so that $S_I = \mathbf{b}^T \mathbf{S} = s \cdot \mathbf{b}^T \mathbf{b} = s$. If we use these functions, Equation A6.10a yields

$$\begin{aligned} \nabla_{\mathbf{b}}[g(\mathbf{b}, \lambda)] &= s \cdot \nabla_{\mathbf{b}}[\mathbf{a}^T \mathbf{G} \mathbf{P}^{-1} \mathbf{b}] - \lambda \cdot \nabla_{\mathbf{b}}[\mathbf{b}^T \mathbf{b}] \\ &= s \cdot (\mathbf{a}^T \mathbf{G} \mathbf{P}^{-1})^T - (2\lambda) \cdot \mathbf{b} \end{aligned} \quad (\text{A6.11e})$$

which is equal to zero when

$$\mathbf{b} = (2\lambda/s) \cdot \mathbf{P}^{-1} \mathbf{G}^T \mathbf{a} \quad (\text{A6.11f})$$

Note that the constant $2\lambda/s$ simply standardizes the weights (so that $\mathbf{b}^T \mathbf{b} = 1$), and hence the Smith-Hazel weights are usually written as

$$\mathbf{b}_{SH} = \mathbf{P}^{-1} \mathbf{G}^T \mathbf{a} \quad (\text{A6.11g})$$

which can be standardized by noting that

$$\mathbf{b} = \frac{\mathbf{b}_{SH}}{\|\mathbf{b}_{SH}\|} = \frac{\mathbf{b}_{SH}}{\sqrt{\mathbf{b}_{SH}^T \mathbf{b}_{SH}}}$$

Index selection is examined in detail in Volume 3.

Organism and Trait Index

- 12-cadherin-domain protein
Helicoverpa, 928
- ABCC2 membrane transporter gene, 928
- Abdominal bristle number (*Drosophila*), 410, 485, 563, 566, 567, 593, 598, 609, 610, 613, 614, 933, 936, 938, 940, 941, 942, 946, 966, 967, 976, 977, 983, 1062, 1076, 1077
- Abnormal spindle-like microcephaly associated *ASPM* gene human, 386–387
- ABO gene (human), 333–334
- Accessory gland proteins *Drosophila*, 256
- ACE gene (*Drosophila*), 239
- Acetylcholinesterase *Drosophila*, 239
- Achaete scute gene complex *Drosophila*, 1076
- Achondroplasia (dog), 299
- Acps protein (*Drosophila*), 256
- Adaptive evolution rate *Drosophila melanogaster*, 249, 368
Drosophila miranda, 249
Drosophila simulans, 249, 368
human, 249, 368
Populus tremula, 249
- Adaptive mutations *Drosophila melanogaster*, 372
human, 372–373
- Adaptive mutations in human transcription binding sites, 376
- Adaptive radiation *Cyprinodon*, 1162
- Adaptive sites, fraction of *Arabidopsis lyrata*, 365–367, 375
Arabidopsis thaliana, 365–367, 375
Capsella grandiflora, 367
chicken, 367
Drosophila melanogaster, 365–367, 373, 375, 376
Drosophila miranda, 365, 367
Drosophila pseudoobscura, 367
Drosophila simulans, 367, 375, 376
Escherichia coli, 367
European rabbit, 367
Helianthus annuus, 365–367
Helianthus petiolaris, 365–367
human, 367, 377
mouse, 361, 367
Populus tremula, 367
Schiedea, 366
- Adaptive sites, X chromosome *Drosophila melanogaster*, 361
- Adaptive walk *Aspergillus nidulans*, 1008
G4, 1008
ID11, 1008
 $\phi 174$, 1008
- Adjusted food intake (*AFI*) mouse, 642–643, 654
- ADNA. *See* Ancient DNA
- Afrobolivina* (Foraminifer) size, 443, 445
- Age at first reproduction human, 708–709
- Age of maturity *Orchesella cincta*, 538
- Albinism human, 178
- Alcohol dehydrogenase (*Adh*) gene *Drosophila melanogaster*, 209, 344–345, 349
Drosophila sechellia, 349
Drosophila simulans, 344–345
- Altitude adaptation human, 281, 298–299
- Ambystoma opacum* (marbled salamander) mate choice, 1102
- Ammonite. *See* *Kosmoceras*
- Amphibian. *See* *Ambystoma* (marbled salamander), *Chrysemys* (painted turtle), *Rana* (bullfrog), *Taricha* (rough-skinned newt)
- Anas platyrhynchos*. *See* duck
- Ancient DNA human, 242
maize, 340
- Anolis sagrei* (Brown anole) competition, 1137
- Anser caerulescens* (Snow goose) clutch size, 709, 712
- Antipredator behavior *Thamnophis*, 1147–1148
- Antler mass *Cervus elaphus*, 709
- Antler size *Cervus elaphus*, 713
- APC human gene (*adenomatous polyposis coli*), 102
- Apis mellifera*. *See* European honey bee
- Arabidopsis lyrata* fraction of adaptive sites, 365–367, 375
FRIGIDA (FRI) gene, 352, 355
- Arabidopsis thaliana* adaptive sites, fraction of, 365–367, 375
environmental variance, 575
FRIGIDA (FRI) gene, 352, 355
growth, 438
mutation rate, 106
photoperiod genes, 461
recombination rate, 93
reproduction, 438
size, 1188
sweeps, 296
- Arabis* (Tower mustard plant) Chitinase genes, 384
- Arthropod. *See* *Carcinus* (european green crab), *Daphnia* (waterflea), insects
- Arachis hypogaea*. *See* Peanut
- Armor *Gasterosteus aculeatus*, 231
- Aspergillus nidulans* (fungus) adaptive walk, 1008
- Asteraceae. *See* *Echinacea*, *Heianthus*
- Asturiana de los Valles cattle, 231
- Avena barbata* (wild oat) fitness, 1182
germination date, 1182
reproductive tillers, 1182
weight, 1182
- Avena sativa*. *See* oats
- Avocado (*Persea americana*) recombination rate, 93
- Bacillus thuringiensis* (Bacteria) *bt* toxin, 928
Cry1Ac toxin, 928
- Background selection *Drosophila melanogaster*, 252
tomato, 255
- Bacteria. *See* *Bacillus*, *Escherichia*, *Pseudomonas*
- Balancing selection human, 333–334
- Barley (*Hordeum vulgare*) ear size, 406
multiple origins, 335
recombination rate, 93
- Balsaminaceae. *See* *Impatiens*
- Barren stalk 1 gene (maize), 337, 339
- Bean (*Phaseolus*) multiple origins, 335
- Belgian blue cattle, 231
- Beneficial mutation distribution *Escherichia coli*, 1009, 1010
ID11, 1009
Influenza A Virus, 1009
 $\phi 6$, 1009
Pseudomonas aeruginosa, 1009
Pseudomonas fluorescens, 1009
Saccharomyces cerevisiae, 1010
- β -lactamase gene (*E. coli*), 1008
- Bicyclus anynana* (butterfly) wing patterns, 409
- Bill morphology *Geospiza fortis*, 673–674
- Bimacula phenotype, *Panaxia dominula*, 271
- Birds. *See* *Anser* (snow goose), *Branta* (barnacle goose), chicken (*Gallus*), *Chrysococcyx* (didric cuckoo), *Coturnix* (Japanese quail), *Cyanistes* (blue tit), *Cygnus* (mute swan), duck (*Anas*), *Ficedula* (collared flycatcher), Galliformes,

- Birds. (*cont.*)
Geospiza (Darwin's finch), *Larus* (red-billed gull), *Molothrus* (shiny cowbird), *Parus* (great tit), *Passer* (house sparrow), *Picoides* (downy wood-pecker), *Ploceus* (village weaver bird), *Strix* (Ural owl), *Sturnus* (starling), *Tanypygia* (zebra finch)
- Birth weight
Cervus elaphus, 709
 human, 1125, 1127
 mouse, 582
 rabbit, 582, 589
 sheep, 714
- Biston betularia* (peppered moth)
 cortex gene, 238
 industrial melanism, 238
- Bivalves. *See* *Mytilus*
- Black mustard (*Brassica nigra*)
 recombination rate, 94
- Bobbed mutation
Drosophila, 940
- BoCal* gene (cabbage), 337
- Body mass index (BMI) (human), 242, 468, 469
- Body size
Afrobolivina, 443, 445
Caenorhabditis elegans, 438
 Cope's law, 1173
 chicken, 4
Drosophila melanogaster, 566, 787
Geospiza fortis, 673–674
 mouse, 407, 609, 946, 1074
Pristomyrmex pungens, 1188
Rana catesbeiana, 1085
Salmo trutta, 457
- Body stripes
Thamnophis ordinoides, 1147–1148
- Body weight. *See* Weight, body
- Bombyx mandarina* (wild silk-moth), 341
- Bombyx mori*. *See* silkworm
- Bone length
 sheep, 563
- Boraginaceae. *See* *Cynoglossum*, *Nemophila*
- Bovine (*Bos taurus*)
 Angus, 276
Asturiana de los Valles, 231
 Belgian blue, 231
 dairy trends, 646–647
 double-muscle, 231
 effective population size, 97, 98
 Holstein, 276
 Holstein-Angus divergence, 27–279
 milk yield, 418, 575, 941
MSTN gene, 231
myostatin gene, 231
 pedigree error rate, 691, 696
 Piedmontese, 231
 selected sites, 276
- Brachyptery
Sogatella furcifera, 515–516
- Branta leucopsis* (barnacle goose)
 body mass, 712
 tarsus length, 709
- Brassica nigra*. *See* black mustard
- Brassica oleracea acephala*. *See* kale
- Brassica oleracea botrytis*. *See* cauliflower
- Brassica oleracea italicica*. *See* broccoli
- Brassica oleracea*. *See* cabbage
- Brassica rapa*. *See* mustard
- Brassicaceae, *See* *Arabidopsis*, *Arabis*, *Brassica*, *Cakile*, *Capsella*
- BRCA1* gene (human), 379, 1278
- BRCA2* gene (human), 1278
- Break depth
Geospiza fortis, 1127
- Breast cancer, 1278
- Breeding date
Ficedula albicollis, 709
 Fisher's model, 676–677
Parus major, 709, 714
- Brewer's yeast, *see* *Saccharomyces cerevisiae*
- Broccoli (*Brassica oleracea italicica*), 337
- Brood parasitism
Chrysococcyx caprius, 946
Molothrus bonariensis, 946
- Brown gene (*Drosophila*), 36–40
- Bt resistance, 928
Helicoverpa armigera, 928
- Bt toxin. *See* *Bacillus thuringiensis*
- Budding yeast, *see* *Saccharomyces cerevisiae*
- Cabbage (*Brassica oleracea*)
BoCal gene, 337
 floral structure, 337
- Caenorhabditis elegans* (nematode)
 body size, 438
 chromosomal distribution of gene density, 245
 gene expression, 1038, 1039
 global hard sweeps, 241
 life history traits, 438
 mutation rate, 106
 mutational pleiotropy, 1000
 pathogen resistance, 956
- Cakile edentula* (sea rocket flower)
 density, 1188
 height, 1188
 stem mass, 1188
- Callosobruchus maculatus* (seed beetle)
 trait fitness-evolvability correlation, 162
- Canis lupus familiaris*. *See* dog
- Capsella grandiflora* (shepherd's-purse plant)
 fraction of adaptive sites, 367
- Carapace length (*Carcinus*), 1134
- Carapace traits (*Chrysemys*), 1306
- Carcinus maenas* (European green crab)
 carapace length, 1134
 natural selection, 10
- Caryophyllaceae. *See* *Silene*, *Schiedea*
- Caspase-12 gene (human), 237
- Cattle *See* bovine.
- Cauliflower (*Brassica oleracea botrytis*), 337
- CCR5 receptor (human), 33–35
- CCR5- δ 32 mutation (human), 33–35, 321–322
- CD40 gene (human), 326
- Cephalopods. *See* *Kosmoceras*
- Cervus elaphus* (red deer)
 additive variance in fitness, 164
 antler mass, 709
 antler size, 713
 birth mass, 709
 effective population size, 66, 67
 trait fitness-evolvability correlation, 162
- Characteristic dispersal length
 human, 241
- Chicken (*Gallus gallus*)
 body weight, 582, 613, 929
 broiler weight, 575
 egg production, 937
 feed-to-protein conversion efficiency, 4
 fraction of adaptive sites, 367
 growth, 4, 943
 growth genes, 943
 shank length, 936
 size, 4
- Chimpanzee (*Pan troglodytes*)
melanocortin 1 receptor (MC1R) gene, 358
 neutrality index, 355
 per-site mutation rate, 99, 106
- Chionomys nivalis* (snow vole)
 body mass, 710, 711, 712
- Chitinase genes (*Arabis*), 384
- Chlamydomonas reinhardtii* (protist)
 mutation rate, 106
- Chloroquine resistance
Plasmodium, 291
- Cholesterol measure (HDL), 418
- Chromosome inversions
Drosophila, 285
- Chrysemys picta marginata* (painted turtle)
 carapace traits, 1306
- Chrysococcyx caprius* (didric cuckoo bird)
 brood parasitism, 946
- Cichlid fishes
 jaw and teeth features, 466
- Cit* gene (*E. coli*), 1013
- Citrate utilization (*E. coli*), 1013
- Clethrionomys glareolus* (bank vole)
 mating success, 1011
- Cluck size
Anser caerulescens, 709, 712
 birds, 522
Cygnus olor, 709
Ficedula albicollis, 160, 538
 Price-Liou model, 675
