where the generation index value of $(t-1)$ in the maternal response occurs because its contribution to the change in z for the population in generation t depends on the values in their mothers (which are themselves from generation $t-1$). Additionally, there can be a component of response due to the effects of previous selection. Putting all these together,

the joint dynamics obtained by Kirkpatrick and Lande (1989, 1992) are

$$R_d(t) = \left(G_{dd} + \frac{m}{2} G_{md} \right) \beta_z(t) + G_{md} \beta_m(t) \quad (15.36a)$$

$$R_m(t) = \left(G_{md} + \frac{m}{2} G_{mm} \right) \beta_z(t) + G_{mm} \beta_m(t) \quad (15.36b)$$

$$R_z(t) = R_d(t) + mR_m(t-1) + m [P_{mm} \Delta \beta_m(t-1) + P_{mz} \Delta \beta_z(t-1)] \quad (15.36c)$$

Here, β_z and β_m are the selection gradients on the direct and maternal traits, respectively, and $G_{xy} = \sigma(A_x, A_y)$ and $P_{xy} = \sigma(z_x, z_y)$ are, respectively, the additive-genetic and phenotypic covariances between traits x and y . Note that the expression given for Equation 15.36c is based on the corrected version of Kirkpatrick and Lande (1992). As with the simple Falconer model, there are time lags in the response, R_z , on the focal trait due to dependency of the response on selection in the previous, as well as the current, generation (Equation 15.36c). By contrast, no such lags are seen for the maternal response, R_m .

A few other features of this model are worth noting. In the absence of additive-genetic variance for the direct trait ($G_{dd} = G_{md} = 0$), there may still be a permanent response in the direct trait due to response in the maternal trait, which is the $mR_m(t-1)$ term in Equation 15.36c. Likewise, in the absence of selection on the maternal effect ($\beta_m = 0$), Equation 15.36b shows that the maternal trait value, z_m , can still evolve when the direct and maternal trait are genetically correlated ($G_{md} \neq 0$). As reviewed by Wilson and Réale (2006), this covariance is often both significant and negative, so selection to increase the direct trait value can result in a declining maternal value (Cheverud 1984a). Chapter 22 greatly expands on this idea of an evolving environmental background (the overall social effects, and not just the maternal value) that influences the phenotype of a focal individual.

Example 15.4. Assume that there are constant selection differentials following the start of selection, so that (after the first generation) terms involving $\Delta\beta$ (changes in β) are zero. Equations 15.36b and 15.36c then simplify to

$$R_m(t) = \left(G_{md} + \frac{m}{2} G_{mm} \right) \beta_z + G_{mm} \beta_m \quad (15.37a)$$

$$\begin{aligned} R_z(t) &= \left(G_{dd} + \frac{m}{2} G_{md} \right) \beta_z + G_{md} \beta_m + mR_m(t-1) \\ &= \left(G_{dd} + \frac{m}{2} G_{md} \right) \beta_z + G_{md} \beta_m + m \left[\left(G_{md} + \frac{m}{2} G_{mm} \right) \beta_z + G_{mm} \beta_m \right] \\ &= \left(G_{dd} + \frac{3m}{2} G_{md} + \frac{m^2}{2} G_{mm} \right) \beta_z + (G_{md} + mG_{mm}) \beta_m \end{aligned} \quad (15.37b)$$

One central question in these (and more general) models concerns which trait (or traits) in the mother determine the value of the maternal effect in her offspring. Falconer made the simplification that the value, z_{mo} , of the direct trait in a mother is scaled (by m) to give the maternal effect in her offspring ($M = mz_{mo}$). The classical bivariate counterpart to this one-trait model is to assume a general measure z_m of maternal performance, where $M = z_{m,mo}$, namely its value in the mother (Dickerson 1947; Willham 1963, 1972; Cheverud 1984a; Riska et al. 1985; Kirkpatrick and Lande 1989). Under this model, the trait—or, more likely, some composite index of traits—comprising z_m is not specified (and hence not directly scored in mothers), although BLUP allows us to estimate its variance components (e.g., G_{mm} and G_{md}), given an appropriate pedigree design (Chapter 22). Under this model, $m = 1$ (as $M = z_{m,mo}$), which simplifies Equations 15.37a and 15.37b. If we assume that there is no direct selection on the maternal performance trait, $\beta_m = 0$, the response equations further simplify to

$$R_m = \left(G_{md} + \frac{1}{2} G_{mm} \right) \beta_z \quad (15.38a)$$

$$R_z = \left(G_{dd} + \frac{3}{2} G_{md} + \frac{1}{2} G_{mm} \right) \beta_z \quad (15.38b)$$

The assumption of selection only on the direct trait implies that $\beta_z = S_z/\sigma_z^2$, yielding

$$R_z = \left(h_d^2 + \frac{3}{2} \frac{G_{md}}{\sigma_z^2} + \frac{G_{mm}}{2\sigma_z^2} \right) S_z \quad (15.38c)$$

as $h_d^2 = G_{dd}/\sigma_z^2$. This is the **Dickerson-Willham model** of the selection response in the presence of heritable maternal effects (Chapter 22), which can also be expressed in terms of a **total heritability**

$$h_T^2 = \frac{G_{dd} + 1.5G_{md} + 0.5G_m}{\sigma_z^2} = \frac{\sigma^2(A_d) + 1.5\sigma(A_d, A_m) + 0.5\sigma^2(A_m)}{\sigma_z^2} \quad (15.38d)$$

yielding the response as

$$R_z = h_T^2 S_z \quad (15.38e)$$

If $G_{md} > 0$, then $h_T^2 > h_d^2$, and the direct heritability underestimates the total response (e.g., McAdam et al. 2002). Conversely, if G_{md} is sufficiently negative, then $h_d^2 > h_T^2$, and the direct heritability overestimates the response (e.g., Wilson et al. 2005a). Bijma (2011) more fully detailed the connections between the Dickerson-Willham and Falconer models (also see Chapter 22).

Maternal Selection vs. Maternal Inheritance

Finally, we note that, in addition to influencing offspring *phenotypes*, parents can potentially influence offspring *fitness*, which would then be a function of both the offspring's phenotype and that of its parents. Indeed, such a parental effect on fitness is simply a special case where the trait experiencing the maternal effect is fitness itself. Kirkpatrick and Lande (1989) called this process **maternal selection**, as opposed **maternal inheritance** (what we have been calling maternal effects, wherein the trait value is influenced by the mother). Hence, the latter is a maternal influence on the value of a specific trait (other than fitness itself), while the former is a maternal influence directly on fitness. One can have maternal selection (the mother's phenotype directly influences offspring fitness) without maternal inheritance (the mother's phenotype influences offspring trait value), and vice versa, or a trait could jointly experience both maternal selection and maternal inheritance (see Figure 15.5). A further complication is that the maternal trait that influences offspring fitness may itself be under selection in the mother. As detailed in Volume 3, accounting for all of these different interactions leads to more complex expressions for the inheritance of these traits than presented by Equations 15.36a–15.36c.

To see how the presence of maternal selection changes the selection-response equations, consider its simplest formulation (analogous to the Falconer dilution model of maternal inheritance), where the expected fitness of individual i is a function of its current phenotype, z_i , and the phenotype of the same trait, z_{mo_i} , in its mother. The linear regression predicting i 's relative fitness (e.g., Equation 13.25b) becomes

$$w_i = 1 + (\beta_z \cdot z_i) + (\beta_{ms} \cdot z_{mo_i}) + e_i \quad (15.39a)$$

Here, β_{ms} is expected change in relative offspring fitness from a one-unit change in the maternal phenotype while holding the offspring phenotype constant (the impact from maternal selection). Likewise, β_z is the impact on relative fitness of a unit change in offspring phenotype, while holding the maternal phenotype constant (the impact from direct selection on the offspring trait). Using the Robertson-Price identity (Equation 6.10), the selection differential, S , on this trait becomes

$$\begin{aligned} S &= \sigma(z_i, w_i) = \sigma(z_i, 1 + \beta_z z_i + \beta_{ms} z_{mo_i} + e_i) \\ &= \beta_z \sigma(z_i, z_i) + \beta_{ms} \sigma(z_i, z_{mo_i}) \end{aligned} \quad (15.39b)$$

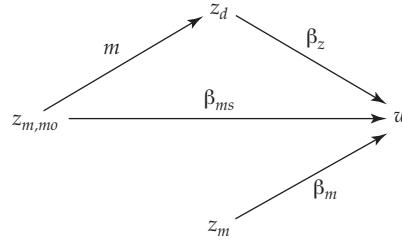

Figure 15.5 Some of the complications for predicting selection response that arise when maternal selection or maternal inheritance occur. The figure displays the simplest bivariate model, where the direct and maternal effects are separate traits. Here z_d and z_m denote the direct trait and maternal trait values, respectively, in the focal offspring, whose fitness is w . Similarly, $z_{m,mo}$ denotes the value of the maternal trait in the offspring's mother. For ease of presentation, paths involving potential genetic correlations (e.g., $z_m \leftrightarrow z_d$; $z_{m,mo} \rightarrow z_m$) are not shown. Maternal inheritance ($m \neq 0$) occurs when the value of $z_{m,mo}$ influences the value of z_d in her offspring. In the figure, this is indicated by the path whose coefficient is given by m , as we assume the maternal inheritance model given by Equation 15.35a. If β_z denotes the direct selection gradient on the focal trait, under maternal inheritance, the mother's maternal trait value indirectly influences the fitness of her offspring through the path $z_{m,mo} \rightarrow z_d \rightarrow w$, or an effect of $m\beta_z$. Maternal selection ($\beta_{ms} \neq 0$) occurs when there is a *direct* path from the mother's trait value to the fitness of her offspring (the single-step path $z_{m,mo} \rightarrow w$, whose coefficient is β_{ms}). The figure also allows for the possibility that there is direct selection on the value of the maternal trait itself (the gradient β_m , shown in the figure operating on the offspring), if, e.g., there is a direct fitness cost for high maternal performance, $\beta_m < 0$. Equations 15.35 through 15.37 give the dynamics for the case when $m \neq 0$ and $\beta_{ms} = 0$, while Equation 15.40 gives the relative fitness when $m = 0$ and $\beta_{ms} \neq 0$.

where $\sigma(z_i, z_{mo_i})$ is the phenotypic covariance between the trait in the offspring and its mother. If we assume that there are no maternal effects acting on the trait, then the covariance between an offspring's phenotypic value and that of its mother is simply half the additive genetic variance in the trait (LW Chapter 7), yielding $\sigma(z_i, z_{mo_i}) = \sigma_A^2/2$. Substituting this into Equation 15.39b yields the selection response in z as

$$R = h^2 S = h^2 (\beta_z \sigma_z^2 + \beta_{ms} \sigma_A^2 / 2) = \sigma_A^2 (\beta_z + \beta_{ms} h^2 / 2) \quad (15.39c)$$

The first term, $\sigma_A^2 \beta_z$, corresponds to the standard breeder's equation (Equation 13.8c), while the second term, $(h^2/2)\sigma_A^2 \beta_{ms}$, is the correlated change from selection on the mother's phenotype.

Because the value of the trait in the mother, z_{mo_i} , influences the fitness of her offspring, selection on this trait in the prereproductive females, which potentially alters the population distribution of trait values, impacts the fitness of the offspring (Kirkpatrick and Lande 1989). For example, suppose that larger mothers protect their young offspring better than smaller mothers ($\beta_{ms} > 0$), but that larger individuals are also selected against (for example, because they are more obvious to predators), so $\beta_z < 0$. In this case, there is selection for smaller individuals before reproduction, but the offspring of surviving larger mothers have increased fitness. Whether the response is positive or negative depends on the relative magnitudes of β_z and β_{ms} . From Equation 15.39c, $R > 0$ when $\beta_z + \beta_{ms} h^2 / 2 > 0$ or when $-\beta_z / \beta_{ms} < h^2 / 2$.

We can extend this simple model by assuming that the trait also experiences maternal inheritance. Under the dilution model, the maternal effect is a fraction, m , of the mother's trait value, $M = m \cdot z_{mo_i}$ (Equation 15.21), resulting in an equilibrium mother-offspring phenotypic covariance of $\sigma(z_i, z_{mo_i}) = m\sigma_A^2/[2-m]$ (LW Chapter 23). From Equation 15.39b, the resulting selection differential becomes

$$S(t) = \beta_z(t) \sigma_z^2 + \beta_{ms}(t) \sigma_A^2 \left(\frac{m}{2-m} \right) \quad (15.39d)$$

which is then used in the response dynamics under the dilution model (Kirkpatrick and Lande 1989). The multivariate extension of maternal selection (following a vector of traits influencing offspring fitness and, potentially, phenotype) was given by Kirkpatrick and Lande, and is examined in Volume 3.

Our treatment (Equations 15.39a through 15.39d) of maternal selection collapsed an inherently multivariate problem (separate traits in the mother influence offspring trait values and directly impact offspring fitness) into a univariate problem by assuming that a single trait does both (a dilution model for both maternal selection and maternal inheritance). Such a single-trait analysis obscures the important distinction between the gradient, β_{ms} , of offspring fitness on the maternal value in Equation 15.39a (maternal selection, the direct impact of a mother's phenotype on the fitness of her offspring), and the gradient, β_m , on maternal effects (selection on the maternal trait itself), see Figure 15.5.

Consider the simplest bivariate model, where z_d and z_m denote the values of the direct and maternal traits in a focal individual, and $z_{m,mo}$ denotes the value of the maternal trait in its mother. For example, suppose that fitness is a function of the height, z_d , and weight, z_m , of an individual and the weight, $z_{m,mo}$, of its mother. The regression for relative fitness now becomes

$$w_i = 1 + (\beta_z \cdot z_{d,i}) + (\beta_m \cdot z_{m,i}) + (\beta_{ms} \cdot z_{m,mo_i}) + e_i \quad (15.40)$$

Here, β_m represents the expected change in relative fitness given a one-unit increase in an individual's maternal trait value when holding its direct value ($z_{d,i}$) and the maternal value (z_{m,mo_i}) of the mother constant. This distinction between the fitness consequences of the value of the maternal trait to herself (β_m) and to her offspring (β_{ms}) is critical—a maternal-effect trait value may be harmful to an individual but helpful to its offspring, generating **antagonistic selection**. For example, having a large litter size is beneficial to a female but harmful to her offspring, as individuals from larger litters may have lower survivorship (Wilson et al. 2005b). Determining when a fitness component is assigned to an offspring versus a parent can be problematic (Wolf and Wade 2001), a point we consider further in Chapter 30.

16

Short-term Changes in the Variance: 1. Changes in the Additive Variance

In artificial selection experiments it seems likely that the effects of linkage disequilibrium will be more important than the slower and less dramatic effects due to changes in gene frequencies. Michael Bulmer (1976a)

Up to this point, we have been assuming that selection does not significantly change the variance of a trait, at least over the short term (a few generations). This arises from our focus on **directional selection** (direct selection on the mean) and the assumption that a large number of loci, each with a small effect, underlie a trait. Under such a genetic architecture, allele-frequency changes over the short term can be cumulatively large enough to have a significant effect on the mean while having little effect on the variance (Chapter 24). This constancy of variance assumption ignores the fact that selection also generates gametic-phase disequilibrium (LD), even among unlinked loci, which can swiftly and dramatically change the variance even in the absence of *any* allele-frequency change. Further, natural and artificial selection can act directly on the variance of a trait itself, as in the case of **stabilizing selection** for more uniformity or **disruptive selection** for more extreme phenotypes on either side of the mean. The breeder's equation only considers the change in mean and hence is uninformative in these latter two cases.

As we will show below, both directional and stabilizing selection generate negative disequilibrium (as alleles that increase trait values become negatively correlated within a gamete, even if unlinked), thus reducing σ_A^2 . Conversely, disruptive selection increases the phenotypic variance, and this generates positive disequilibrium, inflating the additive variance. This chapter develops the **Bulmer equation**, an analog of the breeder's equation for the change in the additive genetic variance from selection-induced LD. This equation predicts how changes in LD change h^2 , allowing updated values to be substituted into the breeder's equation for more accurate prediction of the selection response in the mean. It also predicts the short-term change in the variance under stabilizing and disruptive selection. Phenotypic assortative mating also generates disequilibrium, and we can use extensions of the Bulmer equation to simultaneously consider the effects of assortative mating and selection. Throughout this chapter, we assume (unless otherwise stated) the infinitesimal model holds and there is an infinite population size. Chapter 24 continues this discussion, relaxing many of the infinitesimal model assumptions (such as allowing for linkage and a finite number of loci) and more fully considering the impact from drift.

Changes in the genetic variance (though either LD or allele-frequency change) are not the only route by which selection can alter the phenotypic variance, σ_z^2 . If there is heritable variation in the environmental variance (i.e., σ_E^2 varies over genotypes), σ_E^2 itself can respond to selection, also resulting in a change in σ_z^2 , as discussed in Chapter 17.

CHANGES IN VARIANCE DUE TO GAMETIC-PHASE DISEQUILIBRIUM

In the absence of epistasis, gametic-phase disequilibrium does not change the population mean (Chapter 15). However, as first pointed out by Lush (1945), it affects the response to selection by introducing correlations between alleles at different loci (even if unlinked), thus altering the additive genetic variance, even in the absence of any allele-frequency change.

To see this, let $a_1^{(k)}$ and $a_2^{(k)}$ be the average effects of the two alleles at locus k from a random individual, where the subscripts 1 and 2 denote the maternally and paternally derived alleles, respectively. Assuming (for now) random mating, there is no covariance between alleles of maternal and paternal origin, so that $\sigma(a_1^{(k)}, a_2^{(j)}) = 0$ for all k and j . However, when gametic-phase disequilibrium is present, there can be covariances between alleles at different loci from the same parent, so that $\sigma(a_1^{(k)}, a_1^{(j)})$ and $\sigma(a_2^{(k)}, a_2^{(j)})$ can be nonzero. That is, there can be correlations between alleles in any particular gamete. Because σ_A^2 is the variance of the sum of average effects over all loci

$$\sigma^2 \left(\sum_{k=1}^n [a_1^{(k)} + a_2^{(k)}] \right) = 2 \sum_{k=1}^n \sigma^2(a^{(k)}) + 4 \sum_{k=1}^n \sum_{k < j} \sigma(a^{(j)}, a^{(k)}) \quad (16.1a)$$

$$= 2 \sum_{k=1}^n C_{kk} + 4 \sum_{k=1}^n \sum_{k < j} C_{jk} \quad (16.1b)$$

where n is the number of loci and C_{jk} is the covariance between allelic effects at loci j and k (when contributed by the same parent, and hence on the same gamete). This decomposes the additive variance as

$$\sigma_A^2 = \sigma_a^2 + d \quad (16.2)$$

where $\sigma_a^2 = 2 \sum C_{kk}$ is the additive variance in the absence of gametic-phase disequilibrium, while the disequilibrium contribution $d = 4 \sum_{j < k} C_{kj}$ is the covariance between allelic effects at different loci (in terms of the notation used in LW Equation 7.14, $d = \sigma_{A,A}$).

The component of the additive genetic variance that is unaltered by changes in gametic-phase disequilibrium, σ_a^2 , is often referred to as the **additive genic variance** (or simply the **genic variance**) to distinguish it from the additive *genetic* variance, σ_A^2 . In the absence of disequilibrium, the genic and genetic variances are equivalent. Negative disequilibrium ($d < 0$) implies the presence of hidden additive variance ($\sigma_A^2 < \sigma_a^2$), with σ_A^2 increasing toward σ_a^2 as the disequilibrium decays. If $d > 0$, the additive variance is inflated relative to a random-mating population ($\sigma_A^2 > \sigma_a^2$), with σ_A^2 decreasing toward σ_a^2 as disequilibrium decays. Because $n(n - 1)$ terms contribute to d , whereas n terms contribute to σ_a^2 , gametic-phase disequilibrium can generate large changes in the additive genetic variance even when changes in the individual covariances, C_{jk} , are all very small (Chapter 24).

The allelic effects, $a^{(k)}$ (and hence the genic variance, σ_a^2), are altered as allele frequencies change, resulting in a permanent change in σ_A^2 . Changes in σ_a^2 due to selection strongly depend on the initial distribution of allelic effects and frequencies (Chapters 5 and 24–26), both of which are extremely difficult to estimate. Changes in d , however, are generally less sensitive to the initial distribution of allelic effects (Sorensen and Hill 1982). Any changes in σ_A^2 due to changes in d are *transient*—in the absence of selection, recombination removes disequilibrium and the additive genetic variance, σ_A^2 , returns to the additive genic variance, σ_a^2 , as d decays to zero.

Thus, under our (short-term response) assumption that allele frequencies remain effectively constant, changes in σ_A^2 are due entirely to changes in d , as the C_{kk} terms in Equation 16.1b (corresponding to σ_a^2) are only altered by allele-frequency change. Hence, the additive genetic variance in generation t is calculated by $\sigma_A^2(t) = \sigma_a^2 + d(t)$, yielding a change in variance of $\Delta\sigma_A^2(t) = \Delta d(t)$. Under random mating in the absence of selection, the disequilibrium between pairs of unlinked loci is halved in each generation (LW Equation 5.12), thus halving the covariance between allelic effects

$$d(t+1) = \frac{d(t)}{2} \quad (16.3)$$

Countering this process, selection tends to generate gametic-phase disequilibrium. For example, directional selection to change the mean usually reduces the variance of a character, thus generating negative values of d anew in each generation (Felsenstein 1965).

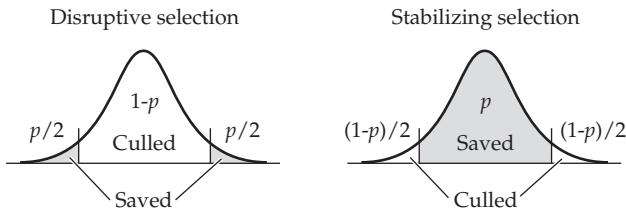

Figure 16.1 Artificial stabilizing and disruptive selection using **double truncation**. In both cases, a fraction, p , of the population is allowed to reproduce. Under stabilizing selection, the central p of the distribution is saved, while under disruptive selection, the uppermost and lowermost $p/2$ are saved.

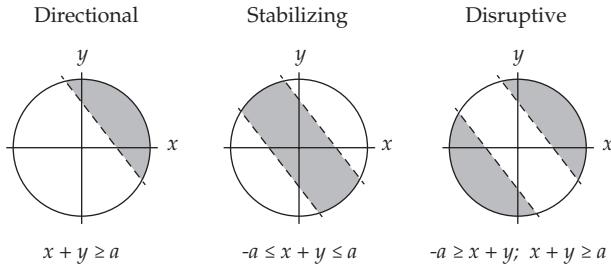

Figure 16.2 The generation of covariances (gametic-phase disequilibrium, LD) by the various type of truncation selection. The variables x and y (e.g., allelic effects at two different loci) are uncorrelated before selection, with their distribution indicated by the open circle. **Left:** Under directional selection, only those values of $x + y$ above some threshold (say, a) are retained. The resulting distribution (the shaded area above the line for $x + y = a$) now displays a negative covariance between the remaining x and y values. **Middle:** Under stabilizing selection, only those values in the range of $-a \leq x + y \leq a$ are retained, also generating a negative covariance. **Right:** Under disruptive selection, only values of $x + y \geq a$ or $x + y \leq -a$ are retained, now resulting in a positive covariance between the remaining x and y values.

As shown in Figure 16.1, stabilizing selection reduces the phenotypic variance and, in the process, creates negative values of d (as we will shortly demonstrate), while disruptive selection increases the phenotypic variance, generating positive d . Stabilizing and disruptive selection are occasionally referred to as **centripetal selection** and **centrifugal selection**, respectively (Simpson 1944). Figure 16.2 shows how directional and stabilizing selection generate negative covariances (and hence negative values of d) between loci under selection, while disruptive selection generates positive covariances (and hence positive values of d).

More generally, for values of z that are normally distributed, selection reduces the phenotypic variance when $\partial^2 \ln w(z) / \partial z^2 < 0$ for all z (Shnol and Kondrashov 1993), generating negative values of d . If this partial differential is > 0 for all values of z , selection increases the variance, generating positive values of d . One function that does not change the variance (when $z \sim$ normal) is the exponential fitness function, $w(z) = \exp(-az)$, as

$$\frac{\partial^2 \ln w(z)}{\partial z^2} = -\frac{\partial^2 az}{\partial z^2} = 0$$

for all z , and hence the variance following selection neither increases or decreases (Charlesworth 1990).

Assuming the validity of the infinitesimal model, Bulmer (1971b, 1974a, 1976a, 1980) solved the question of how these within-generation changes in the variance translate into between-generation changes (response in the variance). Chapter 24 moves beyond the infinitesimal model by considering the impact of linkage with a finite number of loci and finite population size. Estimation of the nature and amount of selection acting on the mean and the variance of a character is examined in Chapters 29 and 30.

CHANGES IN VARIANCE UNDER THE INFINITESIMAL MODEL

Because allele frequencies remain essentially constant under the assumptions of the infinitesimal model, the additive genic variance, σ_a^2 , remains constant and all changes in the additive genetic variance, σ_A^2 , are due to changes in d . Assuming the population is initially in gametic-phase equilibrium, so that $d(0) = 0$, then $\sigma_A^2(0) = \sigma_a^2$, yielding

$$\sigma_A^2(t) = \sigma_a^2 + d(t) = \sigma_A^2(0) + d(t)$$

Let $h^2(t)$ and $\sigma_z^2(t)$ denote the heritability and phenotypic variance before selection in generation t , and h^2 and σ_z^2 be the values of these quantities in the absence of gametic-phase disequilibrium.

While LD can alter the additive variance, what is its impact on the dominance genetic variance? Under the infinitesimal model, Bulmer (1971b) suggested that gametic-phase disequilibrium does not change σ_D^2 . To see Bulmer's argument, first note from LW Equation 5.16b, that with a finite number of loci (n), the disequilibrium contribution to dominance genetic variance is of the order of $n^2 \bar{D}^2$, where \bar{D} is the average pairwise disequilibrium. Under the infinitesimal model, the total disequilibrium (summing over all pairs of loci) remains bounded as the number of loci increases, implying that \bar{D} is of the order of n^{-2} as there are $n(n - 1)/2 \approx n^2/2$ pairs of loci contributing to \bar{D} . The contribution to dominance variance from disequilibrium is thus of the order of $n^2(n^{-2})^2 = n^{-2}$, which converges to zero in the infinitesimal-model limit (as the number of loci $n \rightarrow \infty$). There is, however, some delicacy involved in this argument. In Chapter 24, we show that with strong directional dominance, the amount of inbreeding depression becomes unbounded as one increases the number of loci to the infinitesimal limit. These arguments on the lack of impact from LD on σ_D^2 assume the presence of a large number of small-effect loci. By contrast, Jorjani et al. (1998) used simulations to show that with a modest number of loci and small population size, changes in disequilibrium (in their case, from assortative mating) can significantly change the dominance variance. While we make the Bulmer assumption that there is no effect of dominance throughout this chapter, further exploration of the impact of disequilibrium on σ_D^2 is warranted.

With this assumption in mind, in the absence of any epistatic variance, genotype \times environment interactions or correlations, the phenotypic variance and heritability at generation t become

$$\sigma_z^2(t) = \sigma_E^2 + \sigma_D^2 + \sigma_A^2(t) = \sigma_z^2 + d(t) \quad (16.4a)$$

$$h^2(t) = \frac{\sigma_A^2(t)}{\sigma_z^2(t)} = \frac{\sigma_a^2 + d(t)}{\sigma_z^2 + d(t)} \quad (16.4b)$$

where $\sigma_z^2 = \sigma_z^2(0)$ is the phenotypic variance before selection in the initial (unselected) population ($d(0) = 0$). Thus, knowledge of the value of $d(t)$ is sufficient to predict the variances in generation t , and hence the heritability and the response in the mean, using

$$R(t) = h^2(t) S(t) = h^2(t) \bar{i}(t) \sigma_z(t) \quad (16.4c)$$

Under the infinitesimal model, genotypic values are normally distributed before selection (Bulmer 1971b, 1976b). Recalling that $z = G + E$, we then see that if the environmental values, E , are also normally distributed, the joint distribution of phenotypic and genotypic values is multivariate normal. Hence, from standard statistical theory (e.g., LW Chapter 8), the regression of offspring phenotypic value, z_o , on parental phenotypes, z_m and z_f , is linear and homoscedastic, with

$$z_o = \mu + \frac{h^2}{2}(z_m - \mu) + \frac{h^2}{2}(z_f - \mu) + e \quad (16.5a)$$

where

$$\sigma_e^2 = \left(1 - \frac{h^4}{2}\right) \sigma_z^2 \quad (16.5b)$$

The derivation of Equation 16.5 follows from standard multiple-regression theory and the correlations between relatives (see Example 6 in LW Chapter 8 for details).

We denote the within-generation change in variance by $\delta(\sigma_z^2) = \sigma_{z^*}^2 - \sigma_z^2$, where z^* refers to a phenotypic value from the selected population. (More generally, $\sigma_{z^*}^2$ is the fitness-weighted trait variance; see Chapter 29). Throughout this chapter we use the notation δ to distinguish the *within-generation* change of a variable from its *between-generation* change, Δ , as the latter incorporates the effects of genetic transmission across a generation. If we take variances of both sides of Equation 16.5a and assume random mating (so that $\sigma(z_f, z_m) = 0$) and identical selection on both sexes, the phenotypic variance among the offspring from selected parents becomes

$$\begin{aligned}\sigma^2(z_o) &= \frac{h^4}{4} [\sigma^2(z_m^*) + \sigma^2(z_f^*)] + \sigma_e^2 \\ &= \frac{h^4}{2} [\sigma_z^2 + \delta(\sigma_z^2)] + \left(1 - \frac{h^4}{2}\right) \sigma_z^2 \\ &= \sigma_z^2 + \frac{h^4}{2} \delta(\sigma_z^2)\end{aligned}\quad (16.6)$$

The change in phenotypic variance in the offspring due to selection on their parents generating disequilibrium is thus $(h^4/2) \delta(\sigma_z^2)$. Because there is no change in the environmental, dominance, or genic variances, this change is all in the disequilibrium component, d , of the additive genetic variance, σ_A^2 . Combining Equations 16.6 and 16.3 yields a general recursion for changes in the variance under the infinitesimal model with unlinked loci of

$$d(t+1) = \frac{d(t)}{2} + \frac{h^4(t)}{2} \delta(\sigma_{z(t)}^2) \quad (16.7a)$$

implying that the between-generation change in the disequilibrium contribution is

$$\begin{aligned}\Delta d(t) &= \Delta \sigma_{z(t)}^2 = \Delta \sigma_A^2(t) \\ &= -\frac{d(t)}{2} + \frac{h^4(t)}{2} \delta(\sigma_{z(t)}^2)\end{aligned}\quad (16.7b)$$

This **Bulmer equation** (1971a) is the variance analog of the breeder's equation, which predicts short-term changes in the variance as opposed to the mean. The first term is the decay due to recombination in the disequilibrium contribution from the previous generation (assuming loci are unlinked), while the second term is the amount of new disequilibrium generated by selection that is passed onto the offspring generation. As with the breeder's equation, this second term is a function of the within-generation change (δ) in the phenotypic variance and the fraction ($h^4/2$) transmitted to the next generation. When loci are linked with a recombination fraction of c , a larger fraction $(1 - c)$ of any previous d remains, yielding the change (from recombination alone) of $\Delta d(t) = (1 - c)d(t) - d(t) = -cd(t)$. Chapter 24 examines the effect of linked loci in more detail.

Note from Equation 16.7b that if we start from a base population in linkage equilibrium, $d(0) = 0$, the sign of the within-generation change in the variance, $\delta(\sigma_{z(t)}^2)$, equals the sign of d . Selection that *decreases* the phenotypic variance generates negative values of d , while selection that *inflates* the variance generates positive values of d . This change in the variance (typically a reduction) due to selection generating disequilibrium is called the **Bulmer effect**. Provided the joint distribution of phenotypic and genotypic values remains multivariate normal, under the infinitesimal model, the complete dynamics of the phenotypic distribution are jointly described by the change in the variance (Equations 16.7a and 16.7b), while the change in the mean is given by updating the breeder's equation, $R(t) = h^2(t) S(t)$, using Equation 16.4b.

Equation 16.7a makes the further point that if we wish to use variance components to predict the response to selection, we need to start from an *unselected base population*. If

a population has experienced recent prior selection, then $d(0) \neq 0$, and hence the change in σ_A^2 (and, in turn, the response to selection) cannot be predicted without knowing the value of d in the starting population. Finally, setting $\Delta d = 0$ in Equation 16.7b shows that, at equilibrium,

$$\tilde{d} = \tilde{h}^4 \tilde{\delta}(\sigma_z^2) \quad (16.7c)$$

where the tilde denotes an equilibrium value.

One very important implication for evolution follows from Equation 16.7a, which shows that loci underlying traits whose variance is reduced following selection tend to be in negative disequilibrium. Specifically, the frequency of gametes containing two positive (or two negative) alleles are underrepresented compared to the situation in random mating. Fitness itself is also a quantitative trait, which is influenced by numerous loci and environmental effects. Following selection, the variance in fitness is decreased, and hence Equation 16.7a implies that favorable alleles will be in negative disequilibrium. This reduces any additive variance in fitness, which in turn reduces the efficiency of selection.

Example 16.1. Data from Rendel (1943) suggest that stabilizing selection occurs on egg weight in ducks. Of 960 eggs followed, 64.5% hatched. The change in mean egg weight (in grams) after selection was negligible, but the variance showed a significant decrease. The variance before selection was 52.7 (using all 960 eggs), and declined to 43.9 after selection (in those eggs that hatched), yielding $\delta(\sigma_z^2) = -8.8$. Assuming that the reduction in variance due to gametic-phase disequilibrium is at equilibrium and setting \tilde{h}_z^2 at 0.60 (the heritability for egg weight in poultry) gives from Equation 16.7c,

$$\tilde{d} = \tilde{h}^4 \tilde{\delta}(\sigma_z^2) = (0.6)^2(-8.8) = -3.2 \quad \text{and} \quad \tilde{\sigma}_A^2 = \tilde{h}^2 \tilde{\sigma}_z^2 = 0.6 \cdot 52.7 = 31.6$$

Assuming the infinitesimal model holds, if selection stops, the additive variance is expected to eventually increase to

$$\sigma_A^2 = \sigma_a^2 = \tilde{\sigma}_A^2 - \tilde{d} = 31.6 + 3.2 = 34.8$$

with half of this change occurring in one generation (assuming all underlying loci are unlinked). Similarly, $\sigma_z^2 = 52.7 + 3.2 = 55.9$ and $h^2 = 34.8/55.9 = 0.62$. (Example from Bulmer 1971b.)

Within- and Among-Family Variance Under the Infinitesimal Model

An alternative, instructive approach to the phenotypic regression argument leading to Equation 16.7a is to consider the regression of offspring breeding value (A_o) on the breeding values of its parents (A_f , A_m). Under the infinitesimal model, the joint distribution of parental and offspring breeding values before selection is multivariate normal (Bulmer 1971b), and Example 7 in Chapter 8 of LW shows that the distribution of breeding values in the offspring of parents with breeding values of A_f and A_m is given by the regression

$$A_o = \frac{1}{2}A_m + \frac{1}{2}A_f + e \quad (16.8a)$$

The residual e is the contribution due to segregation, which is normally distributed with a mean of zero and variance of $\sigma_a^2/2$, half the current genic variance (Bulmer 1971b; Felsenstein 1981; Tallis 1987), see Example 16.2.

Because e is the residual of a regression, it is uncorrelated with both A_f and A_m (LW Chapters 3 and 8). Computing variances and assuming random mating (so that A_f and A_m

are uncorrelated),

$$\begin{aligned}
 \sigma_A^2(t+1) &= \sigma_{A_o}^2(t+1) = \sigma^2 \left(\frac{A_m(t)}{2} + \frac{A_f(t)}{2} \right) + \sigma_e^2 \\
 &= \frac{1}{4} \left(\sigma_{A_m}^2(t) + \sigma_{A_f}^2(t) \right) + \frac{1}{2} \sigma_A^2(0) \\
 &= \frac{1}{2} \sigma_{A^*}^2(t) + \frac{1}{2} \sigma_a^2
 \end{aligned} \tag{16.8b}$$

where $\sigma_{A^*}^2(t)$ is the variance of the breeding values of the selected parents (with assortative mating, Equation 16.8b has an additional term, $\sigma(A_m^*, A_f^*)/2$; see Equation 16.21b). Equation 16.8b shows that additive variance can be decomposed into an *among-family* component (half the additive *genetic* variance, $\sigma_{A^*}^2(t)/2$), that measures the differences between the mean breeding values of families, and a *within-family* component (half the additive *genic* variance, $\sigma_a^2/2$) due to segregation that measures the variation within families. Equations 16.8a and 16.8b imply that under the infinitesimal model (and in an infinite population), *the within-family additive variance remains constant*. The change in the additive-genetic variance is thus entirely due to changes in the variance of the mean values of different families. Positive disequilibrium ($d > 0$) increases the among-family component while negative disequilibrium ($d < 0$) decreases it (Reeve 1953). For example, under directional selection, selected parents (being chosen for exceptional trait values) are more similar to each other than are two random individuals from the unselected base population.

The within-family variance, $\sigma_a^2/2$, deserves additional comment. This is often called the **Mendelian sampling variance** or the **segregation variance**. Notice that this variance (under the infinitesimal model) is *not* affected by selection, as we assume there is only negligible change in allele frequencies. As we will see shortly, however, it can be decreased by drift or inbreeding. Likewise, with a finite (but large) number of loci, σ_a^2 can indeed be affected by selection, but the change per generation is typically very small (Chapter 24). An especially important implication of this constant within-family segregation variance is that it tends to largely restore a normal distribution of breeding values following selection. As Equation 16.8a demonstrates, the distribution of breeding values in the offspring is the sum of two components: the breeding values of the selected parents plus the contribution due to segregation. Even if the distribution of breeding values in the selected parents departs significantly from normality, segregation tends to reduce this departure for a Gaussian. Interestingly, Smith and Hammond (1987) found that the short-term deviation from normality is largest when selection is moderate, with deviations becoming smaller as selection increases. This can be seen from Equation 16.8a by writing $A_o = A_{mp} + e$, where A_{mp} is the midparental breeding value and e is the contribution due to segregation (offspring receiving alternative alleles from heterozygous loci). As selection intensity increases, the variation due to A_{mp} decreases (as the selected individuals fall into an ever-decreasing range of phenotypes), and the majority the variation of A_o is accounted for by the normally distributed random variable, e , thus decreasing any departure from normality induced by the distribution of A_{mp} .

The derivation of Equations 16.7a, 16.7b, and 16.8a assumes that breeding values remain normally distributed. If selection changes the distribution of breeding values sufficiently away from normality, the parent-offspring regression may cease to be linear and homoscedastic. Consequences of departures from linearity were briefly discussed in Chapter 13 and are explored more fully in Chapter 24. The heteroscedasticity of the residuals implies that σ_e^2 in Equation 16.8a may depend on the actual parental values chosen, which greatly complicates matters. In all discussions that follow, we assume that these departures from normality can be ignored. Chapter 24 works at relaxing these assumptions.

Example 16.2. To show why the residual variance in Equation 16.8a depends on the genic variance, σ_a^2 , we assume the presence of random mating and unlinked loci, and that allele-

frequency changes from selection can be ignored. Focusing on a single locus, suppose a parent has a genotype of $A_i A_j$, with allelic effects of a_i and a_j , where i and j index random alleles. The expected contribution from this locus to the breeding value of its offspring is $(a_i + a_j)/2$, as each allele is transmitted with a probability of 0.5. The resulting deviation between the actual contribution and expected contribution when A_i is transmitted is $a_i - (a_i + a_j)/2 = (a_i - a_j)/2$. Likewise, this deviation is $(a_j - a_i)/2$ when A_j is transmitted. Hence, the offspring variance in the contribution to its breeding value for this particular locus is simply the average of the squares of these two deviations, or

$$\frac{1}{2} \left[\frac{(a_j - a_i)^2}{4} + \frac{(a_i - a_j)^2}{4} \right] = \frac{(a_j - a_i)^2}{4}$$

Expanding the quadratic product and taking the expected value yields

$$E \left[\frac{(a_j - a_i)^2}{4} \right] = \frac{E[a_j^2]}{4} + \frac{E[a_i^2]}{4} - \frac{E[a_i \cdot a_j]}{2}$$

Under random mating, the alleles at a locus are independent, and the last term is simply $E[a] \cdot E[a] = 0$, which yields a contribution to the segregation variance from a single locus in a single parent of $E[a^2]/2$. Summing over both parents gives the variance in the breeding value from this locus in their offspring as $E[a^2]$, which is half the random-mating, linkage-equilibrium additive variance at this locus, $\sigma_a^2 = 2E[a^2]$ (Equation 16.1b). Further, because of independent assortment, the contributions from each unlinked loci from a parent are uncorrelated, and summing over all loci yields a residual variance of $\sigma_a^2/2$.

Conversely, if a parent is inbred (with f being the probability that both alleles at a randomly chosen locus are identical by descent, IBD), then the alleles A_i and A_j are no longer independent. With a probability of f they are IBD, and hence the same allele; otherwise they are independent alleles, yielding

$$E[a_i \cdot a_j] = fE[a^2] + (1-f)E[a] \cdot E[a] = fE[a^2]$$

and now

$$E \left[\frac{(a_j - a_i)^2}{4} \right] = \frac{E[a^2]}{4} + \frac{E[a^2]}{4} - f \frac{E[a^2]}{2} = (1-f) \frac{E[a^2]}{2}$$

Summing over all loci results in a segregation variance of $\sigma_a^2(1 - \bar{f})/2$, where \bar{f} is the average of the inbreeding levels of the two parents.

Accounting for Inbreeding and Drift

As shown in Example 16.2, the effects of drift and regular inbreeding are easily accommodated under the infinitesimal model (Verrier et al. 1989). Recall that the segregation variation is simply half the additive genic variance of the parental population. When genetic drift is present, Equation 11.2 yields a genic variance in generation t of

$$\sigma_a^2(t) = \sigma_a^2(0) \left(1 - \frac{1}{2N_e} \right)^t \quad (16.9a)$$

resulting in a segregation variance in generation t of $\sigma_a^2(t)/2$. As shown by Keightley and Hill (1987), drift has only a small effect on the disequilibrium

$$\Delta d(t) = -\frac{d(t)}{2} \left(1 + \frac{1}{N_e} \right) - \frac{1}{2} \left(1 - \frac{1}{N_e} \right) \kappa h^2(t) \sigma_A^2(t) \quad (16.9b)$$

where $\kappa = 1 - \sigma_{z^*}^2/\sigma_z^2$ is the fractional reduction in phenotypic variance following selection (Equation 16.10a). When population size is finite, the additive variance in any particular

generation, $\sigma_A^2(t) = \sigma_a^2(t) + d(t)$, can be computed by jointly iterating Equations 16.9a and 16.9b.

Similarly, when the parents are inbred, the segregation variance is also correspondingly reduced. This variance arises from the segregation of alleles in heterozygotes in the parents (and hence the term Mendelian sampling variance). As parents become more inbred, the heterozygosity, and hence the segregation variance, decreases. Assuming there is no correlation between the parents, the within-family segregation variance under inbreeding is

$$\frac{\sigma_a^2(t)}{2} = \frac{\sigma_a^2(0)}{2} \left[1 - \frac{f_m(t) + f_f(t)}{2} \right] \quad (16.9c)$$

where f_m and f_f denote the average amount of inbreeding in the selected male and female parents (measured by their respective inbreeding coefficients, f ; Chapter 2; LW Chapter 10). The additive variance recursion (Equation 16.8b), under the assumptions of the infinitesimal model, becomes

$$\sigma_A^2(t+1) = \frac{1}{4} \left[\sigma_{A_m^*}^2(t) + \sigma_{A_f^*}^2(t) \right] + \frac{\sigma_a^2(0)}{2} \left[1 - \frac{f_m(t) + f_f(t)}{2} \right] \quad (16.9d)$$

These results for the reduction in σ_a^2 under inbreeding apply to the case of only additive variance. When nonadditive variance is present, the changes in additive variance under inbreeding are potentially much more complex (Chapter 11).

CHANGES IN VARIANCE UNDER TRUNCATION SELECTION

Provided the normality assumptions of the infinitesimal model hold, the changes in variance under any selection model can be computed by obtaining the within-generation change in the phenotype variance, $\delta(\sigma_{z(t)}^2)$, and applying Equation 16.7a or 16.7b. In the general case, this requires numerical iteration to obtain the equilibrium heritability and genetic variance. However, in many cases, the phenotypic variance after selection can be written as

$$\sigma_{z^*}^2 = (1 - \kappa) \sigma_z^2 \quad (16.10a)$$

where κ is a constant independent of the current value of the variance. In such settings,

$$\delta(\sigma_z^2) = \sigma_{z^*}^2 - \sigma_z^2 = -\kappa \sigma_z^2 \quad (16.10b)$$

When Equation 16.10a holds (implying that selection generates a constant proportional reduction in variance), simple analytic solutions for the equilibrium variances and heritability can be obtained (again, assuming the validity of the infinitesimal model). Truncation selection—both as we have defined it for directional selection (Chapter 14) and **double truncation** giving disruptive or stabilizing selection (Figure 16.1)—satisfies Equation 16.10. As shown in Table 16.1, for truncation selection on a normally distributed phenotype, κ is strictly a function of the fraction, p , of the population saved and the type of truncation selection used. Figure 16.3 plots values of κ as a function of p for these three different truncation selection schemes.

Suppose selection is such that Equation 16.10a is satisfied. We allow for differential selection on the sexes by letting the variance after selection in males and females be $\sigma^2(z_m^*) = (1 - \kappa_m) \sigma_z^2$ and $\sigma^2(z_f^*) = (1 - \kappa_f) \sigma_z^2$, respectively. If parental phenotypes are uncorrelated (i.e., there is random mating),

Table 16.1 Changes in the phenotypic variance under the various schemes of single and double truncation given in Figure 16.1. Assuming the character is normally distributed before selection, the phenotypic variance after selection is calculated as $\sigma_{z^*}^2 = (1 - \kappa) \sigma_z^2$, where κ (as shown in the table) is a function of the fraction, p , of individuals saved. Here φ denotes the unit normal density function and $x_{[p]}$ satisfies $\Pr(U \leq x_{[p]}) = p$ (equivalently, $\Pr[U > x_{[1-p]}] = p$), where U is a unit normal random variable. Finally, \bar{t} is the selection intensity and is also a function of p (Equation 14.3a). While first presented in the quantitative genetics literature by Bulmer (1976a), these expressions can be found in Johnson and Kotz (1970a).

Directional Truncation Selection: Uppermost p saved

$$\kappa = \frac{\varphi(x_{[1-p]})}{p} \left(\frac{\varphi(x_{[1-p]})}{p} - x_{[1-p]} \right) = \bar{t} (\bar{t} - x_{[1-p]}) \quad (16.11a)$$

Stabilizing Truncation Selection: Middle fraction p of the distribution saved

$$\kappa = \frac{2\varphi(x_{[1/2+p/2]}) x_{[1/2+p/2]}}{p} \quad (16.11b)$$

Disruptive Truncation Selection: Uppermost and lowermost $p/2$ saved

$$\kappa = -\frac{2\varphi(x_{[1-p/2]}) x_{[1-p/2]}}{p} \quad (16.11c)$$

$$\sigma_{z^*(t)}^2 = \frac{\sigma^2[z_f^*(t)]}{2} + \frac{\sigma^2[z_m^*(t)]}{2} = (1 - \kappa) \sigma_z^2(t) \quad (16.12a)$$

where

$$\kappa = \frac{\kappa_f + \kappa_m}{2} \quad (16.12b)$$

The within-generation change in the variance due to selection becomes

$$\delta(\sigma_{z(t)}^2) = -\kappa \sigma_z^2(t) = -\kappa \frac{\sigma_A^2(t)}{h^2(t)} \quad (16.12c)$$

where we have used the identity $\sigma_z^2 = \sigma_A^2/h^2$. Substituting Equation 16.12c into Equation 16.7a recovers the result of Bulmer (1974a),

$$d(t+1) = \frac{d(t)}{2} - \frac{\kappa}{2} h^2(t) \sigma_A^2(t) = \frac{d(t)}{2} - \frac{\kappa}{2} \frac{[\sigma_a^2 + d(t)]^2}{\sigma_z^2 + d(t)} \quad (16.12d)$$

with last step following from $h^2 \sigma_A^2 = (\sigma_A^2/\sigma_z^2) \sigma_A^2 = \sigma_A^4/\sigma_z^2$.

At equilibrium, $\tilde{d} = -\kappa \tilde{h}^2 \tilde{\sigma}_A^2$, and because $\tilde{\sigma}_A^2 = \sigma_a^2 + \tilde{d}$ and $\tilde{h}^2 = (\sigma_a^2 + \tilde{d})/(\sigma_z^2 + \tilde{d})$, we have

$$\tilde{d} = -\kappa \frac{(\sigma_a^2 + \tilde{d})^2}{\sigma_z^2 + \tilde{d}} \quad (16.12e)$$

This quadratic equation in \tilde{d} has one admissible solution (the constraint being that $\tilde{\sigma}_A^2 = \tilde{d} + \sigma_a^2 \geq 0$). Solving yields

$$\tilde{\sigma}_A^2 = \sigma_z^2 \gamma, \quad \text{where} \quad \gamma = \frac{2h^2 - 1 + \sqrt{1 + 4h^2(1 - h^2)\kappa}}{2(1 + \kappa)} \quad (16.13a)$$

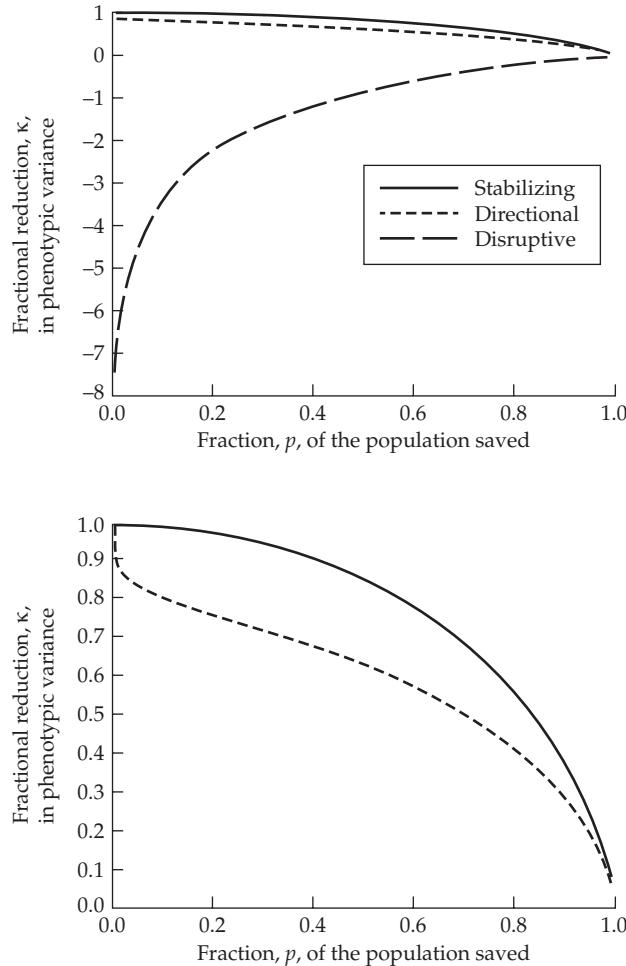

Figure 16.3 The fractional reduction, κ , of phenotypic variance removed by truncation selection (Figure 16.1) as a function of the fraction, p , of individuals saved. Following selection, the new variance is $(1 - \kappa)\sigma_z^2$. **Top:** The lower-most curve (values of $\kappa < 0$) corresponds to disruptive selection (and hence an *increase* in the variance, $\sigma_{z^*}^2 > \sigma_z^2$), while the upper two curves ($\kappa > 0$) correspond to directional (middle curve) and stabilizing selection (upper curve), and hence a decrease in the variance, $\sigma_{z^*}^2 < \sigma_z^2$. **Bottom:** Close-up for directional (lower curve) and stabilizing selection (upper curve).

Because $\tilde{\sigma}_A^2 - \sigma_A^2 = \tilde{d}$, we can write

$$\tilde{\sigma}_z^2 = \sigma_z^2 + (\tilde{\sigma}_A^2 - \sigma_A^2) = \sigma_z^2(1 + \gamma - h^2) \quad (16.13b)$$

yielding an equilibrium heritability of

$$\tilde{h}^2 = \frac{\tilde{\sigma}_A^2}{\tilde{\sigma}_z^2} = \frac{\gamma}{1 + \gamma - h^2} \quad (16.13c)$$

Following Gomez-Raya and Burnside (1990), we can also express the equilibrium heritability as

$$\tilde{h}^2 = \frac{-1 + \sqrt{1 + 4h^2(1 - h^2)\kappa}}{2\kappa(1 - h^2)} \quad (16.13d)$$

Figure 16.4 plots the equilibrium heritability as a function of κ and the initial heritability in the absence of any disequilibrium.

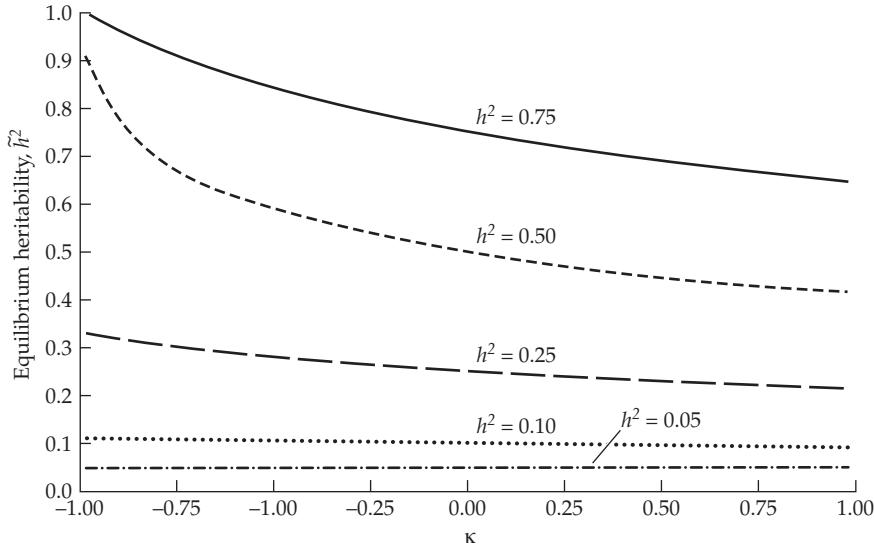

Figure 16.4 Equilibrium h^2 values as a function of κ and the initial heritability, h^2 . Note that for $\kappa < 0$, the variance is *increased* by selection ($\sigma_{z^*}^2 > \sigma_z^2$, as occurs with disruptive selection) and the equilibrium h^2 is greater than its initial value.

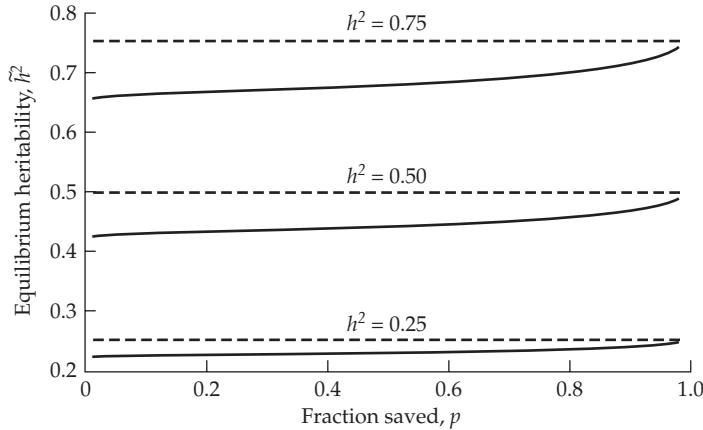

Figure 16.5 Equilibrium heritability values under directional (truncation) selection as a function of the fraction, p , saved and the initial heritability, h^2 . The three curves correspond to initial heritability values of 0.75, 0.5, and 0.25, with the dashed lines displaying the constant heritability values and the solid line displaying the value at equilibrium.

Changes in Correlated Characters

Suppose the joint distribution of phenotypic values for our trait under selection, z , and two other phenotypically correlated traits, x and y , is multivariate normal. If the within-generation change in the phenotypic values of z is given by Equation 16.10a, then classical results (Pearson 1903) for the multivariate distribution imply that the variance in x following selection on (only) z is calculated by

$$\sigma^2(x^*) = (1 - \kappa \rho_{x,z}^2) \sigma^2(x) \quad (16.14a)$$

implying that

$$\delta [\sigma^2(x)] = -\kappa \rho_{x,z}^2 \sigma^2(x) \quad (16.14b)$$

where $\rho_{x,z}$ is the phenotypic correlation between traits x and z . If selection reduces the variance in z ($0 < \kappa < 1$), then the variance in any correlated character is also reduced,

independent of the sign of the correlation (as change is a function of ρ^2). Likewise, the covariance between x and y following selection on z is calculated by

$$\sigma(x^*, y^*) = \sigma(x, y) - \kappa \frac{\sigma(x, z)\sigma(y, z)}{\sigma_z^2} \quad (16.14c)$$

yielding a within-generation change in this covariance of

$$\delta[\sigma(x, y)] = -\kappa \frac{\sigma(x, z)\sigma(y, z)}{\sigma_z^2} \quad (16.14d)$$

These results will prove useful in Volume 3 when we consider the Bulmer effect for multivariate traits, such as selection on an index or using BLUP.

Directional Truncation Selection: Theory

A fractional change, $\sigma_{z^*}^2 = (1 - \kappa)\sigma_z^2$, in the phenotypic variance occurs under various forms of truncation selection. Directional truncation selection results in a reduction in the phenotypic variance following selection ($\kappa > 0$), generating negative values of d and a corresponding reduction in both the additive variance and heritability. When the trait is normally distributed, recalling LW Equation 2.15 yields

$$\sigma_{z^*}^2 = [1 - \bar{t}(\bar{t} - x_{[1-p]})]\sigma_z^2 \quad (16.15a)$$

and hence, as given in Table 16.1,

$$\kappa = \bar{t}(\bar{t} - x_{[1-p]}) \quad (16.15b)$$

where \bar{t} is the selection intensity (Equation 14.3).

The stronger the selection (i.e., the smaller the value of p and hence the larger the value of \bar{t}), the larger is the disequilibrium generated and the greater is the reduction in additive variance (Figure 16.5). Because the response to selection depends on the additive genetic variance in the selected parents, the response to selection in the first generation is unaffected (assuming the parents from the base population are in gametic-phase equilibrium). However, over the next two or three generations, essentially all of the reduction in h^2 due to buildup of negative d occurs, after which heritability remains essentially constant (see Example 16.3). Equations 16.13a through 16.13d provide the equilibrium (or **asymptotic**) variances and heritabilities. The ratio of the asymptotic to initial (assuming $d = 0$) rates of response is given by

$$\frac{\tilde{R}}{R(0)} = \frac{\bar{t}\tilde{h}\tilde{\sigma}_A}{\bar{t}h(0)\sigma_A(0)} = \sqrt{\frac{\tilde{h}^2}{h^2(0)[1 + \kappa\tilde{h}^2]}} \quad (16.16)$$

as obtained by Gomez-Raya and Burnside (1990). As shown in Figure 16.5, the reduction in heritability is greatest when selection is strong (i.e., when the fraction saved, p , is small) and heritability is high.

Example 16.3. Suppose directional truncation selection is performed (equally on both sexes) on a normally distributed character with $\sigma_z^2 = 100$, $h^2 = 0.5$, and $p = 0.20$ (the upper 20% of the population is saved). To examine the impact of LD on the selection response, we first need to compute the fraction, κ , of phenotypic variance removed by selection. To apply Equation 16.15b, we need to compute both $x_{[0.8]}$ and \bar{t} . To do so, note that for a unit normal random variable, U , that $\Pr(U \leq 0.842) = 0.8$, yielding $x_{[0.8]} = 0.842$, and from Equation 14.3a

$$\bar{t} = \varphi(x_{[0.8]})/0.2 = \varphi(0.842)/p = 0.280/0.20 = 1.400$$

From Equation 16.15b, the fraction of variance removed by selection is

$$\kappa = \bar{\iota} (\bar{\iota} - x_{[0.8]}) = 1.400 (1.400 - 0.842) = 0.781$$

With κ in hand, Equation 16.12d becomes

$$d(t+1) = \frac{d(t)}{2} - 0.391 \frac{[50 + d(t)]^2}{100 + d(t)}$$

Starting selection in generation 0 on a base population in gametic-phase equilibrium (and hence $d(0) = 0$), iteration of this expression yields

Generation	0	1	2	3	4	5	∞
$d(t)$	0.00	-9.78	-11.90	-12.39	-12.51	-12.54	-12.54
$\sigma_A^2(t)$	50.00	40.22	38.10	37.61	37.49	37.46	37.46
$h^2(t)$	0.50	0.45	0.43	0.43	0.43	0.43	0.43

For example, in generation 2

$$h^2(2) = \frac{\sigma_A^2(2)}{\sigma_z^2(2)} = \frac{\sigma_A^2(0) + d(2)}{\sigma_z^2(0) + d(2)} = \frac{50 - 11.90}{100 - 11.90} = 0.43$$

Note that essentially all of the decline in additive variance occurs in the first three generations.

An important point to note is that the within-generation reduction in the variance is close to 80% ($\kappa = 0.781$), but the resulting decrease in the phenotypic variance (at equilibrium) is $100 - 12.54 = 87.46$, only a 13% decrease. As was found for the response in the mean using the breeder's equation, only a fraction of the within-generation change in the variance is transmitted between generations. As with the change in mean (Chapter 13), this arises because only a fraction of the variation is due to additive-genetic variance. Another contributing factor is the additional variation generated by Mendelian sampling in each generation, which partly mitigates the decrease in variance from selection.

We can also obtain the equilibrium additive variance directly from Equation 16.13a. Here $\tilde{\sigma}_A^2 = \sigma_z^2 \gamma = 100 \gamma$, with

$$\gamma = \frac{2 \cdot 0.5 - 1 + \sqrt{1 + 4 \cdot 0.5 \cdot (1 - 0.5) \cdot 0.781}}{2(1 + 0.781)} = 0.3746$$

and hence $\tilde{\sigma}_A^2 = 37.46$, as found by iteration. Likewise, Equation 16.13c returns the equilibrium heritability as

$$\tilde{h}^2 = \frac{\gamma}{1 + \gamma - h^2} = \frac{0.3746}{1 + 0.3746 - 0.5} = 0.43$$

Again, this matches the value found by iteration.

How does this reduction in σ_A^2 influence the per-generation change in mean, $R(t)$? Because $\bar{\iota}$ is unchanged (being entirely a function of the fraction, p , of adults saved), but h^2 and σ_z^2 change over time, substituting $\sigma_A(t) = h(t)\sigma_z(t)$ into Equation 13.6b yields the single-generation response in generation t as

$$R(t) = h^2(t) \bar{\iota} \sigma_z(t) = 1.40 h^2(t) \sqrt{\sigma_z^2 + d(t)} = 1.40 h^2(t) \sqrt{100 + d(t)}$$

Thus, the selection response declines from an initial value of $R = 1.4 \cdot 0.5 \cdot 10 = 7$ to an asymptotic per-generation value of $\tilde{R} = 1.4 \cdot 0.43 \cdot \sqrt{87.46} = 5.6$. Using the unadjusted breeder's equation to predict change in mean over several generations without accounting for the Bulmer effect would have overestimated the expected response by 25%.

Table 16.2 Heritability and additive genetic variance in an experimental population undergoing directional selection on abdominal bristle number in *Drosophila melanogaster*. The base population is denoted by B. At the third generation of selection (H3), and following four generations of selection plus three generations of no selection (C7, in generation 7), h^2 was estimated from the response to divergent selection (Chapter 18) and σ_A^2 was subsequently estimated by $\hat{h}^2 \sigma_z^2$. The standard error for \hat{h}^2 in all cases was 0.04. (After Sorensen and Hill 1982.)

	$\hat{h}^2(t)$			$\hat{\sigma}_A^2(t)$		
	B	H3	C7	B	H3	C7
Replicate 1	0.42	0.45	0.59	3.63	5.83	7.66
Replicate 2	0.38	0.26	0.26	2.96	2.28	2.08

Directional Truncation Selection: Experimental Results

How well do these predictions, which make a number of assumptions (additivity, infinitesimal model, normality), hold up for directional selection? Somewhat surprisingly, not many experiments have directly examined these issues. One reason is that the predicted change in h^2 under directional selection is usually expected to be small (Figure 16.5) and hence laborious to detect (requiring very large sample sizes, even when h^2 is large and p is small). One indirect study is that of Atkins and Thompson (1986), who subjected Blackface sheep to selection for increased bone length. Following 18 years of selection, the realized heritability (the ratio of observed response to selection differential; see Equation 18.10) was estimated to be 0.52 ± 0.02 . Using the infinitesimal model, they predicted the expected base population heritability to be 0.57, in agreement with the estimated base population heritability of 0.56 ± 0.04 . Further, the infinitesimal model predicts a 10% decrease in phenotypic variance, and the authors observed a 9% decrease in the upwardly selected line and an 11% decrease in the downwardly selected line.

A more direct study is that of Sorensen and Hill (1982), who subjected two replicate lines of *Drosophila melanogaster* to directional truncation selection on abdominal bristle number for four generations and then relaxed selection (Table 16.2). They interpreted their data as being consistent with the presence of a major allele (or alleles) at low frequency in the base population. These alleles are lost by sampling accidents in some lines (e.g., replicate 2, which shows no net increase in additive variance). If not lost, they are expected to increase rapidly in frequency due to selection, thus increasing additive variance (replicate 1), with this increase being partly masked by the generation of negative disequilibrium with other loci. Once selection stops, disequilibrium breaks down, resulting in a further increase in additive variance (compare the additive variance in lines H3 and C7 in replicate 1). Hence, even when major alleles are present, generation of gametic-phase disequilibrium reduces the rate of selection response.

Effects of Epistasis: Does the Griffing Effect Overpower the Bulmer Effect?

As discussed in Chapter 15, Griffing (1960a, 1960b) showed that when additive epistasis is present, gametic-phase disequilibrium increases the response to directional selection, with the change in mean augmented by $S\sigma_{AA}^2/2\sigma_z^2$. This (transient) increase in the rate of response has been termed the Griffing effect. Thus, in the presence of additive epistasis, disequilibrium is, on one hand, expected to increase the rate of response, while on the other hand it is also expected to decrease the rate of response by decreasing the expressed additive genetic variance (the Bulmer effect). Which change is more important?

Based on a small simulation study, Mueller and James (1983) concluded that if epistatic variance is small relative to additive variance and the proportion of pairs of loci showing epistasis is also small, the Bulmer effect dominates the Griffing effect, and disequilibrium reduces the response to selection. More generally, as Chapter 15 stresses, the Griffing effect only transiently inflates the response. It has no effect on the permanent component of response, while the Bulmer effect does. Specifically, while the change in variance under the

Bulmer effect and change in the mean from additive-by-additive genetic variance under the Griffing effect both decay to zero under random mating once selection stops, the change in the mean from $h^2 S$ is permanent. By lowering the additive variance during selection, the Bulmer effect results in a reduced permanent response. Hence, under the infinitesimal model, final response is lowered by the Bulmer effect and not influenced by the Griffing effect.

Double-Truncation Selection: Theory

Table 16.1 and Figure 16.3 show that $\kappa > 0$ under stabilizing double-truncation selection, so that selection reduces the within-generation phenotypic variance and generates negative disequilibrium. Conversely, $\kappa < 0$ for disruptive selection, with selection increasing the within-generation variance and generating positive disequilibrium. Hence, when the assumptions of the infinitesimal model hold, heritability is expected to decrease under stabilizing selection and increase under disruptive selection (Figure 16.4), although all of this response in the variance is transient. Upon the cessation of selection, the additive genetic variance decays back to its base-population value.

Consideration of Equation 16.13a shows that under stabilizing selection ($\kappa > 0$), the value $\gamma = \tilde{\sigma}_A^2 / \sigma_z^2$ (which measures the fraction of the initial phenotypic variance that is additive genetic variance at equilibrium) satisfies $0 < \gamma < h^2$. Similarly, under disruptive selection, $\gamma > h^2$, with one twist. If disruptive selection is sufficiently strong, $\kappa < -[4h^2(1-h^2)]^{-1}$, there is no positive real root for γ , and the variance increases without limit in the infinitesimal model (Bulmer 1976a). This is a consequence of the infinite number of loci in the infinitesimal limit. What happens with a finite number of loci is suggested from simulation studies of Bulmer (1976a), who examined the behavior when disruptive selection generated sufficiently negative κ values to ensure that there is no positive real root of Equation 16.13a. Bulmer assumed 12 identical additive diallelic loci (alternative alleles contributing 1 and 0, respectively, to the genotypic value). After a few generations, this population showed essentially complete disequilibrium, with most individuals having values of 0, 12, and 24 (with frequencies of 1/4, 1/2, 1/4). At equilibrium, the population behaved as though there were a single locus segregating two alleles (contributing 0 and 12), each with a frequency of 1/2. Thus, the expectation when there is no positive real solution for $\tilde{\sigma}_A^2$ is that the population approaches a state of essentially complete disequilibrium while under selection.

The approach to the equilibrium value, \tilde{d} , also behaves differently under disruptive selection. Under directional and stabilizing selection, the majority of reduction in the additive variance occurs in the first few generations. However, the increase in the variance toward its equilibrium value under disruptive selection requires many more generations, as Example 16.4 illustrates.

Example 16.4. Consider a normally distributed character with $\sigma_z^2 = 100$ and $h^2 = 0.5$ in a random-mating population. To compare the effects of stabilizing and disruptive selection, suppose that in one replicate, disruptive selection is practiced via double truncation with $p = 0.5$ (the upper and lower 25% of the population are saved), while stabilizing selection with $p = 0.5$ (the upper and lower 25% are culled) is practiced in the other. To obtain κ (from Table 16.1), first note that for stabilizing selection, $x_{[1/2+p/2]} = x_{[0.75]} = 0.674$, while for disruptive selection, $x_{[1-p/2]} = x_{[0.75]}$, with $\varphi(0.674) = 0.318$. Using these values, Equations 16.11b and 16.11c yield

$$\kappa = \pm(2 \cdot 0.318 \cdot 0.674) / 0.5 = \pm 0.857$$

where the plus sign is used for stabilizing selection, and the minus sign is used for disruptive selection. Equation 16.12d becomes

$$d(t+1) = \frac{d(t)}{2} \mp 0.429 \frac{[50 + d(t)]^2}{100 + d(t)}$$

where, because the equation is in terms of $-\kappa$, the minus sign in this expression corresponds to stabilizing selection and the plus sign to disruptive selection. Starting selection on a base population with $d = 0$ and iterating the above equation yields

Disruptive selection								
Generation	0	1	2	3	4	5	20	∞
$d(t)$	0.00	10.73	19.65	27.22	33.72	39.34	74.83	82.69
$\sigma_A^2(t)$	50.00	60.37	69.65	77.22	83.72	89.34	124.83	132.69
$h^2(t)$	0.50	0.55	0.58	0.61	0.63	0.64	0.71	0.73

Stabilizing selection							
Generation	0	1	2	3	4	5	∞
$d(t)$	0.00	-10.73	-12.77	-13.20	-13.29	-13.31	-13.32
$\sigma_A^2(t)$	50.00	39.27	37.23	36.80	36.71	36.69	36.68
$h^2(t)$	0.50	0.44	0.43	0.42	0.42	0.42	0.42

Note that with disruptive selection, the absolute change in d is much greater and the time to approach equilibrium considerably longer than with stabilizing selection.

Now suppose that after the equilibrium value of d has been reached, both of these two populations are then subjected to directional selection. In particular, assume directional truncation selection, with the upper 20 percent of the population being saved. The recursion equation for the disequilibrium contribution is given in Example 16.3, but now the initial disequilibrium values are $d(0) = -13.32$ for the population with a previous history of stabilizing selection and $d(0) = 82.69$ for the population with a previous history of disruptive selection. From Example 16.3, the per-generation response is $R(t) = h^2(t) 1.4 \sigma_z(t)$, which is plotted in Figure 16.6 for both populations. The resulting changes in d and the heritability under these two treatments are also plotted in Figure 16.6. If stabilizing or disruptive selection are stopped for k generations before truncation selection, $d(0)$ is replaced by $d(0)/2^k$.

Initially there is a large difference in d (and hence in h^2 and in the response) between the replicates, but after three generations, both have essentially the same value, converging to $\tilde{d} = -12.54$ and hence a per-generation response of $\tilde{R} = 5.6$, the equilibrium value under directional truncation selection (see Example 16.3). As plotted in Figure 16.6, the replicate that was originally subjected to disruptive selection shows a higher cumulative response, due to larger responses resulting from higher heritabilities in the first few generations. This difference in cumulative response is permanent—it does not decay away once selection stops.

Hence, we expect that if an unselected base population is divided into three replicates, one first subjected to disruptive selection, another subjected to stabilizing selection, and the third to no selection, and if directional selection is then applied, the largest response should occur in the disruptively selected replicate and the smallest in the replicate that underwent stabilizing selection. This pattern is indeed seen in artificial selection experiments on *Drosophila* sternopleural bristles (Thoday 1959) and wing length (Tantawy and Tayel 1970).

Double Truncation Selection: Experimental Results

Experiments examining the effects of selection on the variance were reviewed by Prout (1962a), Thoday (1972), Soliman (1982), and Hohenboken (1985). One complication with many of these results is that only phenotypic variances are examined, making it problematic to distinguish between changes in genetic and environmental contributions (Chapter 17).

Nonetheless, as expected under the infinitesimal model, several experiments using stabilizing artificial selection (typically by double truncation) have revealed a reduction in the phenotypic variance that is largely due to reduction in the additive variance. Examples include sternopleural bristle number (Gibson and Bradley 1974), developmental time (Prout 1962a), wing venation (Scharloo 1964; Scharloo et al. 1967), and wing length (Tantawy

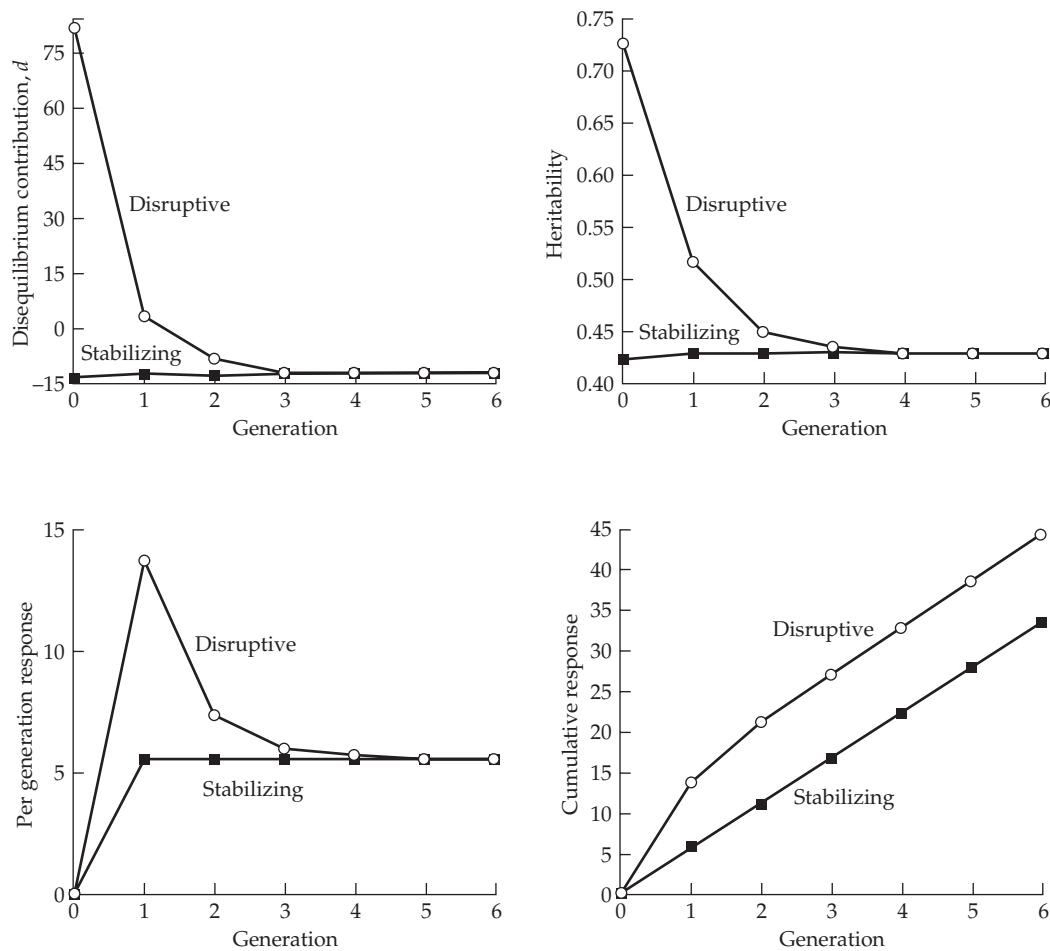

Figure 16.6 The response to the same amount of direction selection for two different starting populations, one initially subjected to stabilizing selection and the other to disruptive selection. See Example 16.4 for details.

and Tayel 1970) in *Drosophila melanogaster*, and developmental time in *Tribolium castaneum* (Soliman 1982). Gibson and Bradley (1974) found that some decrease in the phenotypic variance of bristle number was also due to a decrease in the environmental variance.

Other experiments obtained different results. For example, selection on sternopleural bristle number done by Gibson and Thoday (1963) resulted in no change in the phenotypic variance because the decrease in additive variance was apparently countered by an increase in the environmental variance (strictly speaking, the increase was in the residual variance, which could include nonadditive genetic variance as well as environmental effects). Likewise, 95 generations of stabilizing selection on pupal weight in *T. castaneum* done by Kaufman et al. (1977) resulted in a decrease in the additive variance, but only a slight decrease in the heritability, reflecting a corresponding decrease in the residual variance as well. Bos and Scharloo (1973a, 1973b) observed no decrease in the phenotypic variance following stabilizing selection on *Drosophila* body size. Grant and Mettler (1969) observed a significant increase in variance in one replicate and a significant decrease in the other for two lines subjected to stabilizing selection for a *Drosophila* behavioral trait (escape behavior). Falconer (1957) reported finding no decrease in additive variance when abdominal bristle number in *Drosophila melanogaster* was subjected to stabilizing selection. However, a reanalysis by Bulmer (1976a) suggested that a reduction in variance had indeed occurred, close to the value predicted from the infinitesimal model.

The conclusion from this collection of studies is that while reductions in the environmental variance itself sometimes occur, the reduction in the additive variance is often the main source for the observed decrease in phenotypic variance. We will return to the expected response in the environmental variation in Chapter 17.

In contrast, disruptive selection experiments generally show rather large increases in the phenotypic variance. Increases in the heritability and / or additive variance in response to disruptive selection were observed in *Drosophila* for sternopleural bristle number (Thoday 1959; Millicent and Thoday 1961; Barker and Cummins 1969) and wing venation traits (Scharloo 1964; Scharloo et al. 1967), and for pupal weight in *Tribolium* (Halliburton and Gall 1981). Increases in the residual variance were also seen in many of these studies, reflecting changes in either the environmental or nonadditive genetic variances, or both. On the other hand, for *Drosophila* development time, Prout (1962a) observed that the heritability actually decreased relative to the base population, indicating that the large increase observed in phenotypic variance was due to changes in the residual variance. Robertson (1970c) observed an increase in the phenotypic variance following disruptive selection on *Drosophila melanogaster* sternopleural bristles, but no significant corresponding increase in heritability.

While a change in variance is one prediction from the infinitesimal model, a more striking prediction is the behavior of the variance upon relaxation of selection, as any gametic-phase disequilibrium generated by selection quickly decays (for unlinked loci). Thus, more solid support for the predictions of the infinitesimal can come from experiments that also follow the variance upon relaxation of selection. This was done by Sorensen (1980) and Sorensen and Hill (1982), who disruptively selected on abdominal bristle number in *Drosophila melanogaster*. They observed large changes in the phenotypic variance, with realized heritability increasing from 0.37 to 0.69 in two generations of selection. Following four generations of no selection, heritability decreased to 0.44 (the standard error for all heritability estimates was 0.04). This pattern is consistent with the expected decay in response due to the decay of gametic-phase disequilibrium (which here is expected to be positive, thus inflating σ_A^2).

RESPONSE UNDER NORMALIZING SELECTION

While double truncation is the common mode of artificial stabilizing selection, one standard model for approximating stabilizing selection in natural populations is **normalizing** (or **non-optimal**) selection (Weldon 1895; Haldane 1954),

$$W(z) = \exp\left(-\frac{(z - \theta)^2}{2\omega^2}\right) \quad (16.17)$$

Here, the optimal value is $z = \theta$, and the strength of selection is given by the width, ω^2 , of the fitness function, which corresponds to the variance term in a normal distribution. When ω^2 is large (corresponding to a large variance in the fitness function), selection is weak, as the fitness function falls off slowly around the optimal value, θ . Conversely, a small value of ω^2 corresponds to a small variance in the fitness function and strong selection, with fitness quickly declining away from θ . Formally, it is useful to compare ω^2 to the phenotypic variance, with $\omega^2 \gg \sigma_z^2$ corresponding to weak selection and $\omega^2 \ll \sigma_z^2$ corresponding to strong selection.

If phenotypes are normally distributed before selection, with a mean of μ and variance of σ_z^2 , then after selection, phenotypes remain normally distributed, with a new mean and variance

$$\mu^* = \mu + \frac{\sigma_z^2}{\sigma_z^2 + \omega^2}(\theta - \mu) \quad \text{and} \quad \sigma_{z^*}^2 = \sigma_z^2 \left(1 - \frac{\sigma_z^2}{\sigma_z^2 + \omega^2}\right) \quad (16.18a)$$

Writing the change in variance as $\sigma_{z^*}^2 = (1 - \kappa) \sigma_z^2$, Equation 16.18a shows that $\kappa = \sigma_z^2 / (\sigma_z^2 + \omega^2)$ is no longer a constant, but rather a function of the changing variance, σ_z^2 . Thus, previous

results assuming a constant, κ , no longer apply. However, under normalizing selection, the distribution of genotypes remains normal after selection, and hence parent-offspring regressions remain linear throughout. Thus, we can apply the breeder's equation to predict changes in the mean and Equation 16.7a to predict changes in the variance (under the infinitesimal model). Here,

$$S = \frac{\sigma_z^2}{\sigma_z^2 + \omega^2} (\theta - \mu) \quad \text{and} \quad \delta(\sigma_{z^*}^2) = -\frac{\sigma_z^4}{\sigma_z^2 + \omega^2} \quad (16.18b)$$

Note that both directional and stabilizing selection can occur simultaneously with normalizing selection, as when $\mu \neq \theta$, the mean changes under selection. Substituting Equation 16.18b into the breeder's equation yields

$$R(t) = h^2(t) S(t) = h^2(t) \frac{\sigma_z^2(t) [\theta - \mu(t)]}{\sigma_z^2(t) + \omega^2} \quad (16.19)$$

This shows that the mean converges to θ , as the sign of R is given by the sign of $\theta - \mu(t)$, which is positive when $\mu(t)$ is below θ and negative when above it. However, Equation 16.18a shows that the change in variance is independent of the current mean value, μ . From Equation 16.7a, the change in the disequilibrium contribution is given by

$$d(t+1) = \frac{d(t)}{2} - \frac{h^4(t)}{2} \frac{\sigma_z^4(t)}{\sigma_z^2(t) + \omega^2} = \frac{d(t)}{2} - \frac{1}{2} \frac{[\sigma_a^2 + d(t)]^2}{\sigma_z^2 + d(t) + \omega^2} \quad (16.20a)$$

implying that the equilibrium value, \tilde{d} , satisfies

$$\tilde{d} = \frac{\tilde{d}}{2} - \frac{1}{2} \frac{[\sigma_a^2 + \tilde{d}]^2}{\sigma_z^2 + \tilde{d} + \omega^2} \quad (16.20b)$$

This rearranges to the quadratic equation

$$2\tilde{d}^2 + (\sigma_z^2 + \omega^2 + 2\sigma_a^2)\tilde{d} + \sigma_a^4 = 0 \quad (16.20c)$$

which has one admissible solution (again, the constraint being that additive genetic variance must be nonnegative, hence $\tilde{d} + \sigma_a^2 \geq 0$),

$$\tilde{d} = \frac{-b + \sqrt{b^2 - 8\sigma_a^4}}{4} \quad \text{with} \quad b = \sigma_z^2 + \omega^2 + 2\sigma_a^2 \quad (16.20d)$$

Example 16.5. Suppose that normalizing selection occurs on a normally distributed character with $\sigma_z^2 = 100$, $h^2 = 0.5$, and $\omega^2 = 200$. From Equation 16.20a, with $\sigma_a^2 = 0.5 \cdot 100 = 50$, the dynamics of the disequilibrium contribution are given by

$$d(t+1) = \frac{d(t)}{2} - \frac{1}{2} \frac{[50 + d(t)]^2}{300 + d(t)}$$

Equation 16.20d gives $\tilde{d} = -6.46$, and hence $\tilde{h}^2 = (50 - 6.46)/(100 - 6.46) = 0.47$. Most of the reduction in heritability occurs in the first few generations, as iteration of Equation 16.20a yields

Generation	0	1	2	3	4	5	∞
d_t	0	-4.17	-5.64	-6.16	-6.35	-6.42	-6.46
$\sigma_A^2(t)$	50.00	45.83	44.37	43.84	43.65	43.58	43.54
$h^2(t)$	0.50	0.48	0.47	0.47	0.47	0.47	0.47

Thus, under the infinitesimal model, the distribution reaches an equilibrium, with the phenotypes (before selection) normally distributed with a mean of θ and variance of $\tilde{\sigma}_z^2 = 100 - 6.46 = 93.54$.

SELECTION WITH ASSORTATIVE MATING

Assortative mating changes the additive genetic variance relative to expectations in a randomly mating population, mainly by generating gametic-phase disequilibrium (LW Chapter 7). Assortative mating also results in some inbreeding (measured by a slight increase in homozygosity), but if the number of loci is large, the deviation of genotypes from Hardy-Weinberg frequencies is expected to be small. In the limiting infinitesimal model, no changes in genotypic frequencies occur at single loci, although large changes in variance can occur due to gametic-phase disequilibrium. Positive assortative mating (in which the phenotypic correlation, ρ , between mates is positive) generates positive d , thus increasing σ_A^2 , while negative assortative mating ($\rho < 0$, also called **disassortative mating**) generates negative d , decreasing σ_A^2 . As with selection, these changes in the variance are temporary and dissipate after a few generations of random mating (for unlinked loci).

Results Using the Infinitesimal Model

Assortative mating is easily incorporated into the infinitesimal model (Fisher 1918; Bulmer 1980). Previously, we assumed that selected parents are randomly mated to form the next generation, independent of their phenotype. However, under assortative mating, the selected parents no longer randomly mate, as mating is based on the phenotypes. We assume that assortative mating follows selection, and so the selected parental phenotypic values, z_f^* and z_m^* , are correlated. Returning to Equation 16.5a, the offspring variance is given by

$$\sigma^2(z_o) = \frac{h^4}{4} \sigma^2(z_m^* + z_f^*) + \sigma_e^2 \quad (16.21a)$$

If we write the variance of a sum as $\sigma^2(x + y) = \sigma_x^2 + \sigma_y^2 + 2\rho_{xy}\sigma_x\sigma_y$, this becomes

$$\sigma^2(z_o) = \frac{h^4}{4} \left(\sigma^2(z_m^*) + \sigma^2(z_f^*) + 2\rho \sigma(z_f^*) \sigma(z_m^*) \right) + \sigma_e^2 \quad (16.21b)$$

Assuming selection is such that $\sigma^2(z_x^*) = (1 - \kappa_x)\sigma_z^2$ for $x = f$ or m , Equation 16.21b becomes

$$\sigma^2(z_o) = \frac{h^4}{2} \sigma_z^2 \left(1 - \frac{\kappa_f + \kappa_m}{2} + \rho \sqrt{(1 - \kappa_f)(1 - \kappa_m)} \right) + \sigma_e^2 \quad (16.21c)$$

If we compare this expression with Equation 16.12a, we see that under assortative mating, Equation 16.12d holds, with

$$\kappa = \frac{\kappa_f + \kappa_m}{2} - \rho \sqrt{(1 - \kappa_f)(1 - \kappa_m)} \quad (16.21d)$$

Likewise, Equations 16.13a through 16.13d hold with κ now given by Equation 16.21d. This generalization is from Tallis (1987; Tallis and Leppard 1988a), and was extended to multiple traits by Tallis and Leppard (1988b).

If there is no selection ($\kappa_f = \kappa_m = 0$), $\kappa = -\rho$ and previous results for assortative mating (LW Equations 7.18 through 7.20) follow immediately from Equations 16.12, 16.7c, and 16.13, respectively. More generally, when the amount of selection and assortative mating change in each generation,

$$d(t+1) = \frac{d(t)}{2} - \frac{\kappa(t)}{2} h^2(t) \sigma_A^2(t) \quad (16.22)$$

where $\kappa(t)$ is given by Equation 16.21d, with κ_f , κ_m , and ρ taking on values for generation t .

Under the infinitesimal model, analyzing the joint effects of assortative mating and selection is straightforward. When selection is the same in both sexes, the effect of assortative mating is to change a value of κ in the absence of assortative mating to a new value of $\kappa - \rho(1 - \kappa)$. Negative gametic-phase disequilibrium is generated when this quantity is positive (indicating a reduction in variance), while positive disequilibrium is generated when it is negative. Note that if $\kappa > 0.5$, then $\kappa - \rho(1 - \kappa) > 0$ and no amount of positive assortative mating can generate positive disequilibrium. However, for all values of κ , there is some amount of negative assortative mating such that $\kappa - \rho(1 - \kappa) > 0$. Even if selection generates positive disequilibrium ($\kappa < 0$, such as with disruptive selection), sufficiently strong negative assortative mating ($\rho < \kappa/[1 - \kappa]$) generates negative disequilibrium, thus reducing the additive genetic variance.

Assortative Mating and Enhanced Response

Given that positive assortative mating increases the additive genetic variance, Breese (1956) and James and McBride (1958) suggested that the response to selection could be increased by employing assortative mating among the selected parents. However, experimental support for such an increase is mixed. Studies in both *Drosophila melanogaster* (McBride and Robertson 1963) and *Tribolium castaneum* (Wilson et al. 1965; Campo and Garcia Gil 1993, 1994) exhibited slight (but not statistically significant) increases in response when parents were assortatively mated. Conversely, Sutherland et al. (1968) and Garcia and Sanchez (1992) found no effect of assortative mating when selecting on body weight in mice and pupal weight in *Drosophila*.

One reason for an apparent absence of an impact from assortative mating is simply a lack of power due to a small expected effect (Example 16.6). Biological reasons may further obscure any such difference. Wright (1921c) first noticed that apparently random mating in small populations can still stochastically generate correlations between mates, creating what he termed **unconscious assortative mating**. Simulation studies showed that rather large population sizes ($N_e > 400$) are required to avoid unconscious assortative mating (Jorjani et al. 1997a, 1997b, 1997c), and most selection experiments employ much smaller effective population sizes (Chapter 26). Jorjani (1995) suggested that unconscious assortative mating in the presumed random-mating controls (diluting any expected differences), when coupled with low power, may account for this lack of experimental consistency with the theory.

The effect of coupling assortative mating with truncation selection was examined in detail by Baker (1973), DeLange (1974), Fernando and Gianola (1986), Smith and Hammond (1987), and Tallis and Leppard (1988a). Shepherd and Kinghorn (1994) found a much larger effective gain with assortative mating when selection (and mating) is based on estimated breeding values (BLUP selection) as opposed to simple individual selection (i.e., individual phenotypes). The general conclusion is that the relative increase in selection response is greatest when h^2 is large and selection is weak. However, unless the population is subjected to multiple generations of assortative mating before selection, the increase (for individual selection under the infinitesimal model) is at most 6%, consistent with the very small increases seen in experiments. When the number of loci is small, assortative mating can have a larger effect, due to faster allele-frequency change, as opposed to generation of positive disequilibrium (Fernando and Gianola 1986).

Example 16.6. Starting with a base population that is initially in gametic-phase equilibrium with $h^2 = 0.5$ and $\sigma_z^2 = 100$, individuals are positively assortatively mated (with $\rho = 0.5$) for k generations before being subjected to directional truncation selection, with $p = 0.20$. What is the difference in response to one generation of selection in the assortatively mated population relative to a random-mating base population?

To answer this question, we first need to compute the expected disequilibrium contribution following k generations of assortative mating in the population before selection. Here, $\kappa_f = \kappa_m = 0$ and Equation 16.21d yields $\kappa = -\rho = -0.5$, which is used to iterate Equation 16.22,

$$d(t+1) = \frac{d(t)}{2} + 0.25 h^2(t) \sigma_A^2(t) \quad (16.23a)$$

where $d(0) = 0$, $h^2(0) = 0.5$, and $\sigma_A^2(0) = 50$. As shown in the table below, assortative mating, by itself, generates $d > 0$, reaching an upper limit (for these genetic and mating parameters) of $\tilde{d} = 20.71$. From Example 16.3, the single-generation response using a population with $d(k)$ is given by

$$\begin{aligned} R(k) &= 1.4 h^2(k) \sigma_z(k) = 1.4 \left(\frac{\sigma_A^2(0) + d(k)}{\sigma_z^2(0) + d(k)} \right) \sqrt{\sigma_z^2(0) + d(k)} \\ &= 1.4 \left(\frac{50 + d(k)}{100 + d(k)} \right) \sqrt{100 + d(k)} \end{aligned} \quad (16.23b)$$

Iterating Equation 16.23a for k generations and substituting the resulting $d(k)$ value into Equation 16.23b gives the following values for a single generation of response following k generations of assortative mating:

k	0	1	2	3	5	10	∞
$d(t)$	0.00	6.25	10.57	13.58	17.17	20.09	20.71
$h^2(t)$	0.50	0.53	0.55	0.56	0.57	0.58	0.59
$R(t)$	7.00	7.64	8.06	8.35	8.69	8.95	9.01
$R(t)/R_{rm}$	1.00	1.09	1.15	1.19	1.24	1.28	1.29

$R_{rm} = 7.00$ is the first-generation response under random mating and $d(0) = 0$. With $k = 3$ generations of assortative mating in the base population, at the start of selection $d(0) = 13.58$ and $h^2 = 0.56$, giving a response of 8.35.

While there can be up to a 29% increase in the rate of response to a single generation of selection when starting from an assortatively mated base population, it is extremely inefficient to assortatively mate a population for several generations before applying selection. For example, with a single generation of assortative mating followed by a single generation of selection, the total response is 7.64. If instead one just selected both generations (from a randomly mated base population), the responses are 7.00 in the first generation and (from Example 16.3) 5.93 in the second, for a total response almost twice as large (12.93/7.64). Further, once selection starts, the initially positive d from assortative mating (which inflates σ_A^2 , and hence h^2 and the selection responses) decays very rapidly (Figure 16.6). Only half the previous value of d is passed onto the next generation, where it is supplemented by negative d values generated by selection (Equation 16.7b), which quickly drives d to negative values and greatly reduces R/R_{rm} . Assuming $d(0) = 20.71$, after a single generation of selection, $d(1) = -3.55$ and $h^2 = 0.48$, and the selection response in the next generation drops to 6.62 (compared to a response of 5.93 under random mating of the selected parents). In the second generation of selection, $d(2) = -9.25$, with a response of 5.98.

Example 16.7. Consider the same population and selection parameters as in the previous example, but with selection and assortative mating now occurring simultaneously, starting at generation 0. What is the difference in response if random mating occurs in one replicate and assortative mating with $\rho = 0.5$ occurs in the other? From Example 16.3, directional truncation selection with $p = 0.2$ on both sexes yields $\kappa_f = \kappa_m = 0.781$, with the variance reduction from Equation 16.21d becoming

$$\kappa = \kappa_f - \rho(1 - \kappa_f) = 0.781 - 0.5(1 - 0.781) = 0.672$$

and (from Equation 16.22), the change in d in the assortatively mated population becomes

$$d(t+1) = \frac{d(t)}{2} - \frac{0.672}{2} h^2(t) \sigma_A^2(t)$$

Assuming the initial population is in gametic-phase equilibrium $d(0) = 0$, iteration yields

Generation	0	1	2	3	4	5	∞
$d(t)$	0.00	-8.40	-10.55	-11.12	-11.27	-11.31	-11.33
$h^2(t)$	0.50	0.45	0.44	0.44	0.44	0.44	0.44
$R(t)$	7.00	6.09	5.84	5.77	5.76	5.75	5.75
$R_{rm}(t)$	7.00	5.93	5.68	5.63	5.61	5.61	5.61
$R(t)/R_{rm}(t)$	1.00	1.03	1.03	1.02	1.02	1.02	1.02

where $R_{rm}(t) = \bar{h} h_{rm}^2(t) \sqrt{\sigma_z^2 + d_{rm}(t)}$ is the selection response in generation t of random mating, and the values of $h_{rm}^2(t)$ and $d_{rm}(t)$ come from Example 16.3.

Note that the response in the first generation (generation 0) is the same in both populations: the response to selection depends on the additive variance of the parents, and in the first generation, both populations have the same variance (as $d(0) = 0$ in both). Thereafter, there is at most a 3% increase in the rate of response under assortative mating. Even with perfect positive assortative mating ($\rho = 1$), $\kappa - \rho(1 - \kappa) = 2\kappa - 1 = 0.564$ gives a maximum value of $R(t)/R_{rm}(t) \simeq 1.05$.

Disruptive Selection, Assortative Mating, and Reproductive Isolation

We would be remiss if we did not mention the historical interest in the connection between disruptive selection and assortative mating as a mechanism for reproductive isolation. In the early 1960s, the general view was that speciation (reproductive isolation between populations) required geographic (or other) isolation, a view strongly championed by Mayr (1963). However, the idea that **sympatric speciation** (Maynard-Smith 1962a, 1966) could develop without the need for such isolation was bolstered by an experimental observation by Gibson and Thoday (1962). They observed that disruptive selection on sternopleural bristle number in *D. melanogaster* seemed to generate two distinct groups (high vs. low flies), which appeared to assortatively mate (individuals with an intermediate phenotype were absent from the population, whereas they would be expected under random mating). Their explanation was that crosses between high and low parents generate less fit offspring (having intermediate values), and that selection generated preferential mating over the short time course of this experiment; i.e., it appeared that only 12 generations of disruptive selection had generated partial reproductive isolation.

However, this striking observation was not reproducible (Scharloo et al. 1967; Barker and Cumming 1969; Charbora 1968; Thoday and Gibson 1970). Indeed, Scharloo (1971) suggested that the base population for selection used by Thoday and Gibson might have been composed of flies from different geographic origins, and hence already possessing partial isolation that was uncovered, rather than evolved, by their experiment. While Thoday and Gibson's interpretation of their experiments is now largely discounted, the notion of **reinforcement** (the evolution of mating preferences to reduce the production of less fit hybrids when diverged populations come back into contact) remains a concept of interest (Noor 1999; Servedio and Noor 2003; Ortiz-Barrientos et al. 2009).

Short-term Changes in the Variance:

2. Changes in the Environmental Variance

It is the purpose of this short communication to suggest that recent views on the nature of the developmental process make it easier to understand how the genotypes of evolving organisms can respond to the environment in a more co-ordinated fashion. Waddington (1942)

In our discussion of the response to selection, one assumption thus far has been that the environmental variation is **homoscedastic**—constant across genotypes—and hence not subject to modification by selection. However, a fairly universal, and very striking, observation is that most traits show at least some genetic variation in an outbred population. One can imagine that sensitivity to the environment, as measured by the environmental variance, is such a trait (Waddington 1957; Hill 2007), and thus can potentially respond to selection. If true, selection for (or against) extreme individuals, such as directional and disruptive selection for the former, and stabilizing selection for the latter, may also result in selection for increased (or decreased) values of the environmental variance, σ_E^2 . There are also settings that favor *direct* selection on σ_E^2 , such as breeding for more uniformity in an agricultural or laboratory trait (Hohenboken 1985). There can also be fitness consequences for uniformity in domesticated populations. For example, preweaning survival increases as the within-litter variance (a function of σ_E^2) in weight decreases in both pigs (Milligan et al. 2002) and rabbits (Garreau et al. 2008). Selection on σ_E^2 likely occurs in natural populations as well, such as selection on the within-plant variation in flowering time (Devaux and Lande 2009). Finally, Gibson (2009) and Feinberg and Irizarry (2010) argued that selection on the inherent stochasticity of developmental systems may play an important role in our understanding of human diseases. All of these considerations have spurred an interest in selection response in σ_E^2 (reviewed by Hill and Mulder 2010).

One technical comment before proceeding is that simple scale effects can also result in a change in the variance—if the coefficient of variation of a trait remains constant as its mean changes, then its variance must also change as well. As discussed in LW Chapter 11, a suitable transformation (such as the log of the trait value) often removes these scale effects, and we assume this has been done previous to any analysis.

BACKGROUND: HERITABLE VARIATION IN σ_E^2

Scales of Environmental Sensitivity

The environment an organism experiences can be partitioned into many different scales of resolution, but operationally we are usually concerned with just two: those features shared by all individuals in some common setting (**macroenvironments**), and those features unique to each individual (**microenvironments**). Differential sensitivity (i.e., performance) of genotypes over any of these scales indicates genotype \times environmental ($G \times E$) interactions (LW Chapter 22). Volume 3 examines the selection response in the presence of $G \times E$ over macro-scale differences (such as different growing regions for a crop or different host plants for an insect), by treating the trait value in each macroenvironment as a correlated character (Falconer 1952). A related topic concerns **norms of reactions**, which are performance curves over a gradient for a particular environmental feature (such as temperature). The analysis of response for such **function-valued traits** is also deferred until our final volume.

Our focus here is on sensitivity to microenvironmental variation, which itself can oc-

cur over several different scales. The most fundamental consideration is **developmental noise**, which can sometimes be measured by differences in the trait values of homologous structures within an individual, such as the amount of **fluctuating asymmetry** (differences in trait values on the left and right side of bilaterally symmetric organisms; LW Chapter 11; see also Leamy and Klingenberg 2005; Dongen 2006; Hansen et al. 2006; Graham et al. 2010). Presumably such within-individual variation reflects “noise” in the developmental process—variation in the end product of the same genotype in the same macroenvironment. A related measure of microenvironmental variation is the variance in the repeated performance (records) of an individual over time, such as offspring size in different litters from a single mother. While any source of environmental variation contributes to σ_E^2 , different pathways may be involved in environmental sensitivity at these different scales (Pélabon et al. 2010).

Environmental vs. Genetic Canalization

The idea that genotypes may vary in their microenvironmental sensitivity has a rich history, dating back to Waddington’s (1942) notion of **canalization** and Schmalhausen’s (1949) **autoregulation**—developmental buffering against small perturbations (be they environmental or genetic). Under these views, a wide range of genotypes and environments yield essentially the same developmental end product. Waddington (1957, 1959) also stressed that canalization is an *evolved system*, and hence to some extent a selectable trait. Part of Waddington’s concern was sensitivity to the environment, with genotypes showing **environmental canalization** (or **environmental robustness**) having lower environmental variances. However, he was also concerned with the fact that a particular genotype may find itself in a variety of different *genetic* environments, and that genotypes may also differ in their sensitivities to these different backgrounds. **Genetic canalization** (or **genetic robustness**) is the stability of a particular genotype when placed in a variety of different genetic backgrounds, and it is a function of the epistasis between a genotype of interest and the universe of genetic backgrounds in which it may find itself. These two measures of sensitivity can be easily confounded, yet they are fundamentally different. Environmental robustness (which requires G x E if genotypes vary in environmental sensitivity) does not necessarily imply genetic robustness (which requires epistasis), and vice versa. As reviewed in Flatt (2005) and Hansen (2006), the conditions for the evolution of genetic canalization (an overall reduction in the sensitivity of a genotype to its genetic background) are more restrictive than for environmental canalization, in part because the target background under the former is itself continually evolving.

Using an appropriate design, the genetic and environmental sensitivities for a particular genotype can be separated. Under a repeated-measures design, the genetic background remains constant and the residual variance is due entirely to environmental sensitivity (plus measurement error). A second (but obviously more restrictive) design is the use of a series of inbred lines or clones (Fraser and Schadt 2010; Geiler-Samerotte et al. 2013). For a particular genotype of interest (such as a marker locus tagging a quantitative trait location [QTL]), the *among-line* trait variance of a genotype across a series of lines (and hence different genetic backgrounds) is a measure of its genetic sensitivity, while the *within-line* variance of the target genotype is a measure of its environmental sensitivity.

Example 17.1. Fraser and Schadt (2010) considered mRNA expression levels for thousands of genes over a series of 19 mouse inbred lines. Within each line, roughly 20 individuals were scored at $\sim 160,000$ markers. For a given trait (the expression level of a specified gene), the within-line variation was contrasted between the two alternative homozygous genotypes at each marker. Because there is essentially no genetic variation within an inbred line, significant differences in the within-line variance over marker genotypes indicate linkage to a QTL influencing environmental robustness (differences in σ_E^2). Conversely, a significant difference in the dispersion of the mean values of the marker genotypes *across* inbred lines (increased

among-line variance) indicates that the marker is linked to a QTL influencing genetic robustness. Using this approach, these authors found QTLs for both types of robustness. QTLs for environmental robustness were largely *trans*-acting and sex-specific (different QTLs in the two sexes). In contrast, QTLs for genetic robustness were often *cis*-acting and were not sex-specific. There was no detected overlap between the two classes of QTLs. In reporting their results, the authors used the convention that an eQTL mapping close to its target site was regarded as *cis*, while an eQTL mapping further away, or on a different chromosome, was regarded as *trans* (Chapter 12).

One caveat about this study concerns the among-line variance. Given the small number (19) of genotypic backgrounds (inbred lines), we expect that by chance some markers will be nonrandomly distributed with respect to QTLs that influence the line means. This could result in alternative genotypes at these markers showing different patterns of among-line variance, not because of any epistatic interactions, but rather because they were not sufficiently randomized with respect to background QTLs influencing the mean of the target trait.

Evidence for Heritable Variation in the Environmental Variance

The suggestion that different genotypes may have different environmental variances is not new. For example, Robertson and Reeve (1952) and Lerner (1954) noted that inbred lines often have larger environmental variances than their outbred counterparts (see Whitlock and Fowler [1999] for a more recent example). This led Lerner to propose that **genetic homeostasis** (developmental buffering across environments) is facilitated by heterozygosity, while environment sensitivity (σ_E^2) increases with homozygosity. Consistent with this suggestion is the observation that developmental noise (measured by the amount of fluctuating asymmetry) often decreases with increasing levels of protein (i.e., isozyme) heterozygosity (reviewed in Mitton and Grant 1984; Livshits and Kobylansky 1985; Chakraborty 1987; Zouros and Foltz 1987; Britten 1996; Vøllestad et al. 1999).

Direct evidence for genetic variation in σ_E^2 is provided by comparing inbred lines. Mackay and Lyman (2005) observed different amounts of environmental variation for bristle number across chromosomal substitution lines of *Drosophila* from a common source population. Similar findings using inbred lines were seen by Ordas et al. (2008) in maize, by Hall et al. (2007) in *Arabidopsis*, by Ansel et al. (2008) in yeast, and by a number of workers using the *Drosophila melanogaster* Genetic Reference Panel (DGRP) lines (Harbison et al. 2013; Ayrøles et al. 2015; Huang et al. 2015; Morgante et al. 2015; Sørensen et al. 2015). Characters showing among-line variation in σ_E^2 included morphological, physiological, and behavioral traits, as well as expression-level traits (i.e., mRNA levels). The DGRP lines show an exception to the inverse relationship between σ_E^2 and levels of heterozygosity. These lines contain varying amounts of residual heterozygosity (which is substantial in several cases due to segregating chromosomal inversions), with the amount of residual heterozygosity being uncorrelated with σ_E^2 .

While these studies provide direct evidence for *genetic* variation in σ_E^2 , our concern is with *heritable* variation—additive genetic variation in the trait that can respond to selection. Direct evidence for heritable variation for the level of developmental noise derives from traits that usually respond to selection for either increased or decreased fluctuating asymmetry (LW Chapter 11). However, this is only one potential component of the microenvironmental variance, so what evidence is there for a heritable component of σ_E^2 in general?

Indirect support comes from observations of heritable variation in the within-family variance in livestock traits. Van Vleck (1968) and Clay et al. (1979) observed significant sire differences in the variation in milk yield in dairy cattle across half-sib families, while Rowe et al. (2006) found significant sire variation in the within-family residual variance for 35-day body weight in broiler chickens. While variation among sires is consistent with a heritable component for within-family variances, it can also arise simply from genetic segregation. In particular, heteroscedasticity of family variances is a classic (but weak) test for the presence

of a major gene, with parents heterozygous for the major allele having a larger within-family variance than homozygous parents (LW Chapter 13).

A more recent line of evidence for heritable variation in σ_E^2 comes from a significantly improved fit of statistical models assuming a heritable component of the residual variance (and hence a correlation in σ_E^2 among relatives) over those that assume no such heritable variation. Such an improved fit was seen for fecundity in sheep (SanCristobal-Gaudy et al. 2001), body weight in the snail *Helix aspersa* (Ros et al. 2004), and litter size in pigs (Sorensen and Waagepetersen 2003), with additional examples listed in Table 17.2. The caveat about these results is the concern that violations of the underlying statistical models may lead to an incorrect suggestion that such genetic variation exists when in fact it is absent. Indeed, E. Yang et al. (2011) showed that these analyses are strongly biased by the presence of intrinsic skew in the data, as the presence of heritable variation in σ_E^2 is also manifested as skew (Ros et al. 2004). Yang et al. simultaneously fitted a model along with a general Box-Cox transformation (LW Chapter 11) of their data to remove any intrinsic skewness. After accounting for skew, evidence for genetic variance in σ_E^2 was reduced in some cases, while it was strengthened in others (Table 17.2). The bottom line from the analysis of these models is that there does appear to be real evidence for heritable variation in σ_E^2 , but estimating some of the genetic parameters associated with this variance (in particular, the correlation between breeding values for trait means and residual variances) can be very delicate.

Another line of evidence derives from the mapping of major genes involved in trait variances. The classic example involves the heat shock protein HSP90, which has been shown to buffer both genetic and environmental effects (reviewed in Sangster et al. 2008). In a second potential example, J. Yang et al. (2012) showed that different genotypes at the *FTO* (fat mass and obesity-associated protein) locus display different residual variances for body mass in humans. However, because *FTO* effects were scored in segregating populations, it is unclear whether its variance effect is due to genetic or environmental canalization.

Finally, QTLs can be associated with trait variances. Denoted as **vQTLs** (variance QTLs) by Rönnegård and Valdar (2011) and **veQTLs** (variance in expression-level traits) by Huang et al. (2015), such QTLs denote sites where the trait variance differs over marker genotypes. While early QTL mapping projects noted that some marker genotypes differ in trait variances (e.g., Edwards et al. 1987), the formal development of specific methods to map such QTLs is more recent (Ordas et al. 2008; Paré et al. 2010; Struchlain et al. 2010; Visscher and Posthuma 2010; Jimenez-Gomes et al. 2011; Rönnegård and Valdar 2011, 2012; Hothorn et al. 2012; Shen et al. 2012). While these studies have found a number of candidate regions, as with among-sire differences in family variances, they reflect differences in the *residual* (as opposed to strictly the *environmental*) variance for marker genotypes, which can arise from differences in sensitivity to genetic background when alternative vQTL genotypes are assessed in segregating populations. Indeed, Paré et al. (2010) and Deng and Paré (2011) suggested using variance heterogeneity across markers as a preliminary scan for potentially epistatic loci. Nonetheless, a number of recent studies have mapped vQTLs using variation in σ_E^2 over inbred lines, directly showing at least some genetic control on σ_E^2 (Hall et al. 2007; Ansel et al. 2008; Harbison et al. 2013; Huang et al. 2015; Sørensen et al. 2015).

Collectively, these observations suggest that heritable variation in the environmental variation likely exists for many traits, and that selection for changes in phenotypic variance can result in a response that in part derives from changes in the overall environmental variance of the population. Consistent with this view, recall that changes in σ_E^2 were seen in several of the stabilizing- and disruptive-selection experiments reviewed in Chapter 16.

MODELING GENETIC VARIATION IN σ_E^2

A variety of statistical models have been proposed to account for the heritable transmission of at least part of the environmental variance. The starting point for each model is that the

phenotypic value of an individual of genotype i can be written as

$$z_i = \mu + G_i + E \quad \text{where} \quad E \sim (0, \sigma_i^2) \quad (17.1a)$$

The notation $x \sim (\mu, \sigma^2)$ denotes that x comes from a distribution with a mean of μ and variance of σ^2 . For ease of development, we generally assume that the trait has an entirely additive-genetic basis, meaning that $G = A$, namely the standard breeding value for the trait. Normally, this breeding value is either unsubscripted or is denoted as A_z to connect it with z . However, for models with a heritable (i.e., a breeding-value) component to σ_E^2 , we need to keep track of two *separate* breeding values, *both* of which influence z . One, A_m , influences the mean of z (so that $G = A_m$ in Equation 17.1a), while another breeding value, A_v , influences the environmental variance of z . As we will detail shortly, several different models have been proposed to connect A_v and σ_E^2 (reviewed in Table 17.1). These two breeding values, A_m and A_v , can be correlated, which further complicates the dynamics of selection response. Changes in the mean of A_m change the mean of z (the standard response to selection as measured by a change in the mean), while changes in the mean of A_v change the average value of σ_E^2 (yielding a response in the environmental variance).

Because we allow σ_E^2 to vary over genotypes, its population value is not the usual constant that was assumed in previous chapters, but rather an average value that may change over time. Taking the expectation (to avoid confusion, in this chapter we will use roman E for expectation and italic E for environmental values), the population environmental variance is the average of the σ_i^2 ,

$$\sigma_E^2 = E[\sigma_i^2] \quad (17.1b)$$

When working with a series of pure lines, one can estimate σ_i^2 directly. The more interesting (and difficult) problem arises when considering an outbred population. In this case, we have to deal with both estimation and the vexing issue of modeling transmission. Models allowing for heterogeneity of environmental variance were introduced by breeders in the 1990s (e.g., Foulley et al. 1992; Foulley and Quaas 1995; Cullis et al. 1996), but these models ignored the question of selection (and evolution) of the environmental variance itself. As outlined below, the first formal analyses of the evolution of the environmental variance were population-genetic models presented by Gavrilets and Hastings (1994c) and Wagner et al. (1997), and breeding-value-based models presented by SanCristobal-Gaudy et al. (1998).

The Multiplicative Model

Gavrilets and Hastings (1994c) assumed some underlying environmental factor, e (such as temperature), with different genotypes having different sensitivity, γ_i , to this factor, hence

$$E = \gamma_i e \quad \text{where} \quad e \sim (0, \sigma_e^2) \quad (17.2a)$$

This **multiplicative model** is simply the joint-regression model for genotype \times environment interactions (LW Equation 22.13b; Volume 3), and was also used by Wagner et al. (1997). Under Equation 17.2a, the conditional environmental variance (given the genotypic value and its environmental sensitivity) is

$$\sigma^2[E | G, \gamma_i] = \gamma_i^2 \sigma_e^2 \quad (17.2b)$$

As shown in Example 17.2 (below), taking the expected value over the population distribution of sensitivity values, $\gamma \sim (\mu_\gamma, \sigma_\gamma^2)$, yields the unconditional environmental variance in the population

$$\sigma_E^2 = (\mu_\gamma^2 + \sigma_\gamma^2) \sigma_e^2 \quad (17.2c)$$

Note that while γ_i can be negative, Equation 17.2b shows that it influences the environmental variance through its square, γ_i^2 . Thus, the magnitude, rather than the sign, of γ_i determines its impact on σ_E^2 . Under the multiplicative model, the environmental variance for the population decreases by selecting μ_γ to zero and/or by decreasing the variance, σ_γ^2 ,

of environmental sensitivities. The problematic issue here is modeling the change in the distribution of the genotypic-specific sensitivities, γ . The simplest approach is to assume that the environmental sensitivity, γ , is an entirely additive quantitative trait, so that $\gamma = A_v$, namely, the breeding value for the environmental variance.

Analysis of Equation 17.2c led Gavrilets and Hastings to comment on the relationship between developmental noise and heterozygosity mentioned previously. Lerner (1954) assumed this relationship to be causative, with higher levels of heterozygosity directly causing decreased environmental variance. However, Gavrilets and Hastings noted that when $\mu_\gamma^2 = 0$, as might occur with selection to decrease σ_E^2 , then under the simple additive model ($\gamma = A_v$), the environmental variance for a given trait is proportional to the additive genetic variance in environmental sensitivity, $\sigma_\gamma^2 = \sigma^2(A_v)$.

Gavrilets and Hastings noted that a correlation between heterozygosity and σ_E^2 simply falls out as a consequence of their model, rather than from any functional relationship between the two. They reach this conclusion by using the result that, for an additive trait (in our case, $\gamma = A_v$), the genetic variance is a *decreasing* function of the number of heterozygous loci (Chakraborty 1987), so that when the average heterozygosity in a population increases, $\sigma^2(A_v)$ decreases, and hence (from Equation 17.2c), so does σ_E^2 . While their theoretical point is valid, it is actually addressing a slightly different issue than Lerner's argument. The Gavrilets and Hastings model suggests that *populations* with less heterozygosity are expected to show increased levels of σ_E^2 , while Lerner was suggesting that *individuals* with reduced heterozygosity show increased σ_E^2 .

If we allow for dominance in the quantitative-trait formulation of γ , the result is $\gamma = A_v + D_v$, where the dominance value, D_v , is *not* transmitted from parent to offspring. Further, by construction, D_v has a mean value of zero and under the infinitesimal model, the dominance variance is not changed by selection (Chapter 16). Under this extension, the mean environmental variance becomes

$$\sigma_E^2 = (\mu_{A_v}^2 + \sigma_{A_v}^2) \sigma_e^2 + \sigma_{D_v}^2 \sigma_e^2 \quad (17.2d)$$

This same argument applies if we replace $\sigma_{D_v}^2$ by the total nonadditive genetic variance. While selection can reduce the first component in Equation 17.2d (either by driving the mean breeding value to zero and/or reducing $\sigma_{A_v}^2$), the component involving nonadditive variance remains unchanged. Hence, implicit in assuming a breeding value for this model (or any of the others discussed below) is that any nontransmissible genetic variation in σ_E^2 remains unchanged by selection. Genetic variation in σ_E^2 , by itself, is *not sufficient* for a selection response, as the latter requires that *at least part of this variation must be transmissible* under the breeding scheme being used.

The Exponential Model

While we have presented the multiplicative model within a breeding-value framework, this was not explicitly done by Gavrilets and Hastings (1994c), who (coming from a population-genetics background) were more concerned with the evolution of the environmental variance than with estimating A_v . Conversely, SanCristobal-Gaudy et al. (1998), coming from an animal breeding background, were more concerned with the estimation of A_v . They did so by modeling E using an **exponential model**

$$E = \exp\left(\frac{A_v}{2}\right) \cdot e \quad \text{where } e \sim N(0, \sigma_e^2) \quad \text{and} \quad A_v \sim N(\mu_{A_v}, \sigma_{A_v}^2) \quad (17.3a)$$

Why the breeding value appears as $A_v/2$ (rather than simply A_v) will become apparent shortly.

The connection with the multiplicative model follows if we note that for small $|x|$, $e^x \simeq 1 + x$, so that $E \simeq [1 + (A_v/2)] \cdot e$ for $|A_v| \ll 2$, implying $\gamma_i \simeq 1 + (A_v/2)$. By assuming normality and independence (of e , A_v , and A_m), SanCristobal-Gaudy et al. (1998) obtained likelihood estimators for the breeding values for the environmental variance (A_v) and trait

Table 17.1 Models for heritable variation in the environmental value, E , involve two separate breeding values, A_m and A_v , underlying the phenotype, z , of a focal trait. The former breeding value is associated with the mean of the focal trait and the latter influences the environmental variance. The table reviews three different models for translating A_v into a value of σ_E^2 , assuming some intrinsic environmental value, $e \sim N(0, \sigma_e^2)$. All three models start with the usual decomposition of $z = \mu + A_m + E$, where $A_m \sim N(\mu_{A_m}, \sigma_{A_m}^2)$ is the breeding value for z (the subscript m is a mnemonic for mean). The departure from this standard model is that rather than assuming σ_E^2 to be constant over all genotypes, we assume it has a heritable component (a breeding value, A_v) that influences the emergent value of σ_E^2 . We assume $A_v \sim N(\mu_{A_v}, \sigma_{A_v}^2)$, and let U denote a unit normal random variable. See the text for full details on each model.

Model	E	$\sigma^2(E A_v)$	$\sigma^2(E) = E[\sigma^2(E A_v)]$
Multiplicative	$A_v \cdot e$	$A_v^2 \sigma_e^2$	$(\mu_{A_v}^2 + \sigma_{A_v}^2) \sigma_e^2$
Exponential (or log-additive)	$\exp(A_v/2) \cdot e$	$\exp(A_v) \sigma_e^2$	$\exp(\mu_{A_v} + \sigma_{A_v}^2/2) \sigma_e^2$
Additive	$\sqrt{A_v + \sigma_e^2} \cdot U$	$A_v + \sigma_e^2$	$\mu_{A_v} + \sigma_e^2$

mean (A_m). They explicitly considered estimation under either a sire design (using half-sib values to estimate the values of A_v and A_m in the common parent) or under a model where repeated measurements on a single individual and its relatives are used to estimate breeding values for σ_E^2 (Chapters 13 and 19). SanCristobal-Gaudy et al. (2001) extended this approach to threshold traits (in particular, litter size). Bayesian estimators under this model were developed by Sorensen and Waagepetersen (2003) and Ros et al. (2004).

Given A_v , the conditional distribution of the environmental variance becomes

$$\sigma^2(E | A_v) = \sigma^2[\exp(A_v/2) \cdot e | A_v] = [\exp(A_v/2)]^2 \sigma_e^2 = \sigma_e^2 \exp(A_v) \quad (17.3b)$$

where the last step follows by recalling that $[\exp(a)]^2 = \exp(2a)$. Hence, the environmental variance is a constant (σ_e^2) multiplied by a scaling factor that is an exponential function of the breeding value A_v for the environmental variance (which motivates our use of $A_v/2$ in Equation 17.3a). Decreasing A_v results in an individual with reduced environmental sensitivity (reduced σ_E^2). The constant, σ_e^2 , can be interpreted as the environmental variance for an individual with an environmental breeding value of zero, $A_v = 0$.

The exponential model is also called the **log-additive model**, as the breeding value is additive on a log scale

$$\ln[\sigma^2(E | A_v)] = \ln(\sigma_e^2) + A_v \quad (17.3c)$$

As detailed in Example 17.2, the expectation of Equation 17.3b (over the population distribution of A_v values) yields a mean environmental variance of

$$\sigma_E^2 = \sigma_e^2 \exp(\mu_{A_v} + \sigma_{A_v}^2/2) \quad (17.3d)$$

Equation 17.3d shows that either decreasing the mean breeding value, μ_{A_v} , or its additive variance, $\sigma_{A_v}^2$, decreases the environmental variance. Comparison of Equations 17.2c and 17.3d shows one subtle difference between the multiplicative and exponential models. Under the former, the contribution to the environmental variance is a function of $\mu_{A_v}^2$, meaning that the minimal population environmental variance occurs when $\mu_{A_v} = 0$, and any deviation away from zero increases the average environmental variance. By contrast, under the exponential model, decreasing μ_{A_v} always decreases the average value of σ_E^2 in the population. Thus, under the exponential model, σ_E^2 can be selected to be arbitrarily small, while under the multiplicative model, it has a lower bound set by $\sigma_{A_v}^2$ (and more generally, by the dominance variance as well; see Equation 17.2d).

The Additive Model

Our last formulation for modeling genetic variation in E was suggested by Hill and Zhang (2004) and Mulder et al. (2007), where

$$E = U \cdot \sqrt{\sigma_e^2 + A_v} \quad \text{where} \quad U \sim N(0, 1) \quad \text{and} \quad A_v \sim N(\mu_{A_v}, \sigma_{A_v}^2) \quad (17.4a)$$

This is the **additive model**, as the environmental variance for an individual with breeding value A_v is simply

$$\sigma^2(E | A_v) = \sigma_e^2 + A_v \quad (17.4b)$$

with the constraint on the breeding value being that $\sigma_e^2 + A_v > 0$. The additive model is a *local* analysis around the current mean, as selection to decrease A_v can eventually result in this constraint being violated, which generates a negative variance. Under the additive model, the mean population value for the environmental variance is simply

$$\sigma_E^2 = E(\sigma_e^2 + A_v) = \sigma_e^2 + \mu_{A_v} \quad (17.4c)$$

Unlike in the multiplicative and exponential models, changes in σ_E^2 under the additive model depend only on changes in the mean breeding value, and not on its variance (Table 17.1).

The additive model has the advantage of being much more tractable, but it has the disadvantage that it breaks down when the breeding value becomes sufficiently negative ($A_v < -\sigma_e^2$). In contrast, the exponential model has additivity on the log of the variance scale, which is a nice statistical feature, as log variances are approximately normally distributed (Box 1953; Layard 1973). Mulder et al. (2007) discussed additional connections between the additive and exponential models, while Hill and Mulder (2010) reviewed different estimation methods under these models.

Example 17.2. Here we derive the unconditional variances for the models summarized in Table 17.1. Consider the multiplicative model first, where

$$\sigma_E^2 = E[\gamma^2 \sigma_e^2] = \sigma_e^2 E[\gamma^2]$$

Recalling that $E[x^2] = \mu_x^2 + \sigma_x^2$ yields

$$\sigma_E^2 = \sigma_e^2 E[\gamma^2] = \sigma_e^2 (\sigma_\gamma^2 + \mu_\gamma^2)$$

Now consider the exponential model (Equation 17.3a). By construction, both E and e have expected values equal to zero, and the variances of E and e are simply the expected values of E^2 and e^2 . Taking expectations

$$\sigma_E^2 = E[(e \cdot \exp\{A_v/2\})^2] = \sigma_e^2 E[(\exp\{A_v/2\})^2] = \sigma_e^2 E[\exp(A_v)]$$

This follows by again recalling that $[\exp(x/2)]^2 = \exp(2x/2) = \exp(x)$. The rightmost expectation in this expression is calculated with respect to the distribution of breeding values, A_v , by recalling (Equation 14.19a) that for a normally distributed random variable, x , with a mean of μ and variance of σ^2 , $E[e^x] = \exp(\mu + \sigma^2/2)$. Because we assumed that $A_v \sim N(\mu_{A_v}, \sigma_{A_v}^2)$, the average environmental variance for the population becomes

$$\sigma_E^2 = \sigma_e^2 \exp\left(\mu_{A_v} + \frac{\sigma_{A_v}^2}{2}\right)$$

The Heritability of the Environmental Variance, h_v^2

Estimates of $\sigma^2(A_v)$ under any of the models for σ_E^2 reviewed in Table 17.1 are obtained using fairly complicated likelihood functions on data from sets of relatives; see SanCristobal-Gaudy et al. (1998, 2001), Sorensen and Waagepetersen (2003), Ros et al. (2004), or any of the other references in Table 17.2 for details. Table 17.2 presents these estimates scaled as heritabilities and evolvabilities (Equation 13.22b) to facilitate comparison over traits, which raises the issue how the heritability of the environmental variance is defined.

Mulder et al. (2007) suggested that one definition is as the slope of the regression of the breeding value, A_v , of an individual on some appropriate function of the phenotype value, z . Under the additive-model framework (Equation 17.4a), they show that the appropriate transformation is the square, z^2 , of phenotypic value. To see this, recall from Equation 17.4a that under this model

$$z = \mu + A_m + E = \mu + A_m + U\sqrt{A_v + \sigma_e^2}$$

If we assume that A_m and A_v are uncorrelated and recall for a unit normal random variable, U , that $E(U^2) = 1$ (as U^2 is a χ_1^2 random variable, which has a mean of 1; LW Equation A5.15b), then

$$\begin{aligned} \sigma(A_v, z^2) &= \sigma(A_v, [\mu + A_m + E]^2) = \sigma(A_v, E^2) \\ &= \sigma(A_v, U^2[A_v + \sigma_e^2]) = \sigma(A_v, A_v) = \sigma^2(A_v) \end{aligned} \quad (17.5a)$$

From regression theory (LW Chapter 3), the slope of the regression of A_v on z^2 is simply this covariance divided by the variance of the predictor variable

$$h_v^2 = \frac{\sigma(A_v, z^2)}{\sigma^2(z^2)} \quad (17.5b)$$

If z is normally distributed, then $\sigma^2(z^2) = 2\sigma_z^4 + 3\sigma^2(A_v)$ (see Mulder et al. 2007 for details), yielding a heritability of

$$h_v^2 = \frac{\sigma^2(A_v)}{2\sigma_z^4 + 3\sigma^2(A_v)} \quad (17.5c)$$

Hence, estimates of h_v^2 are obtained by substituting an estimate of $\sigma^2(A_v)$ —which can be estimated within a likelihood framework (see the previously mentioned references)—along with the value of σ_z^4 , into Equation 17.5c.

Table 17.2 reviews estimated h_v^2 values from a number of studies. Note from this table that values of h_v^2 are low (typically less than 0.05), while the evolvabilities, i.e., $\sigma(A_v)/\sigma_E^2$, the coefficient of variation of the environmental variance (Equation 13.22b), are large. Although the selection response may be slow (given the low heritability), there is much variation to exploit, as a high evolvability implies that significant proportional change in the trait value can be achieved (Chapter 13). Recall from Equation 13.22b that the expected response, scaled in terms of the mean value, can be expressed as

$$R(\sigma_E^2)/\sigma_E^2 = \bar{h}_v CV_{A_v} = \bar{h}_v \sqrt{0.038} \cdot 0.41 = 0.08 \bar{h}_v$$

where we have used the average values for h_v^2 and CV_{A_v} from Table 17.2. Recalling that $\bar{h}_v \simeq 2$ when we save the upper 5% of the population (Example 14.1), the expected scaled response per generation is 0.16 in this setting, implying that slightly more than six generations are required to double the mean value of the variance under this strength of selection.

The table also shows that some caution is in order when using these likelihood-based estimates, which can be very model-specific. In particular, the fragility of these estimates can be seen by comparing the estimated additive-genetic correlation, $\rho(A_m, A_v)$, in the litter-size studies (Yang et al. 2011). Data are often transformed before an analysis for any number of reasons (LW Chapter 11), and one of the more flexible approaches is the Box-Cox

Table 17.2 Estimates of the heritability, h_v^2 , and evolvability, $CV_{A_v} = \sigma(A_v)/\sigma_E^2$, of the environmental variance (Equation 13.22b), as well as bivariate-model estimates of the additive-genetic correlation, ρ , between A_m and A_v . For the Yang et al. (2011) results, BC denotes that a Box-Cox transformation was fitted simultaneously with the model, while results without this notation indicate that this transformation was not used. (Based, in part, on Mulder et al. 2007 and Hill and Mulder 2010.)

transformation (LW Equation 11.4), which includes the standard log transform as a special case. For pigs, using untransformed data resulted in $\rho(A_m, A_v) = -0.64$, which changed to 0.70 when a Box-Cox transformation was first applied to the data. For rabbits, $\rho(A_m, A_v)$ changes from -0.73 to 0.28. Likewise, estimates of the heritabilities and evolvabilities were also lower when the likelihood model included a Box-Cox transformation.

Finally, our discussion thus far has focused on narrow-sense heritabilities. Broad-sense heritability estimates, H_v^2 , for the genetic variance of σ_E^2 , based on among-line variation in σ_E^2 , are often an order of magnitude higher than the narrow-sense values shown in Table 17.2. For example, Morgante et al (2015) observed H_v^2 values for σ_E^2 of 0.75, 0.54, and 0.36 for three behavioral and physiological traits in *Drosophila*, which were of comparable magnitude with the broad-sense estimates for the traits themselves (values of 0.37, 0.56, and 0.58, respectively). This apparent difference between the broad- and narrow-sense estimates for the genetic variance of σ_E^2 may reflect something deep, such as a significant amount (indeed, the majority) of genetic variance for σ_E^2 being nonadditive (and hence the numerator of H_v^2 , the total genetic variance, being much larger than the numerator of h_v^2 , the additive genetic variance). Or it may simply reflect the fact that direct estimates for H_v^2 by comparing variances over inbred lines may be much more powerful than the more complex likelihood-based methods used in the estimation of variance components of σ_E^2 in outbred populations.

SELECTION ON σ_E^2

As with the breeder's equation for the response of the mean to selection, the response of σ_E^2 is a function of two features: the nature of transmission and the nature of selection. Our following discussion is thus partitioned into these two features. We begin with a discussion of transmission, examining how a change in the mean value of A_v (the response R_{A_v}) translates into a change in σ_E^2 in the next generation. As might be expected, the results are highly dependent on which of the models given in Table 17.1 is assumed.

We then examine the nature of selection on σ_E^2 . This can occur via three different pathways. The first route is through direct selection on A_v generated by selection on the phenotypic value, z , of a trait. A second route is that selection can be based on direct expression of σ_E^2 in an individual through repeated measurements, selecting for individuals with a larger (or smaller) range in these records. The final route is as a correlated response (Equation 13.26c), with selection on z resulting in selection on the breeding value, A_m , for the trait, which in turn may be correlated with A_v . The machinery of multivariate selection is needed to consider the totality of response in this latter case, so we focus solely here on the direct response (i.e., assuming $\rho[A_m, A_v] = 0$), and defer a full discussion of this general case until Volume 3.

However, a few brief comments on the nature of this potential genetic correlation, $\rho(A_m, A_v)$, are still in order. If the coefficient of variation, σ_z/μ_z , remains roughly constant under selection, this implies that as the mean increases, so does the variance (and, thus, presumably, so does σ_E^2). When A_m and A_v are positively correlated, simple selection to increase the mean (to increase μ_{A_m}) results in a correlated response that also increases μ_{A_v} , and therefore σ_E^2 . While most estimated $\rho(A_m, A_v)$ values are negative (Table 17.2), there are reasons these should be viewed with caution. Current statistical models for estimating A_v assume no intrinsic skew in the data other than that generated by any correlation between A_m and A_v . If skew is present for other reasons, this can significantly bias estimates of this correlation (Ros et al. 2004), as shown in the previous discussion on the results of Yang et al. (2011).

Translating the Response in A_v Into Response in σ_E^2

A number of authors have modeled the selection response of the phenotypic variance (from either direct or indirect selection on the variance) when there are heritable differences in environmental sensitivity (Gavrillets and Hastings 1994c; Wagner et al. 1997; SanCristobal-Gaudy et al. 1998, 2001; Sorensen and Waagepetersen 2003; Hill and Zhang 2004; Ros et al. 2004; Mulder et al. 2007, 2008). A critical step in modeling this selection response is treating the phenotypic value and residual variance as two separate (and potentially correlated) traits, both with heritable (i.e., additive-genetic) variation. While some models (Gavrillets and Hastings 1994c; Wagner et al. 1997; Hill and Zhang 2004) are based on strict population-genetic analysis (following the change in individual allele frequencies), most are based on schemes that assign breeding values to the heritable component of σ_E^2 (Table 17.1). Under the infinitesimal model, the expected breeding value in the offspring (for either A_m or A_v) is simply the mean breeding values of its parents (Chapter 13). Using the expressions given in Table 17.1 allows us to map changes in μ_{A_v} , the mean breeding value for environmental sensitivity, onto changes in σ_E^2 .

The simplest case is the additive model (Equation 17.4b). Suppose we let the selection response, R_{A_v} , denote the change in the mean breeding value (for the environmental variance) of the selected parents from the mean breeding value of the entire population. The resulting change in σ_E^2 becomes

$$\begin{aligned}\Delta\sigma_E^2(t) &= \sigma_E^2(t+1) - \sigma_E^2(t) \\ &= [\mu_{A_v}(t+1) + \sigma_e^2] - [\mu_{A_v}(t) + \sigma_e^2] \\ &= [\mu_{A_v}(t) + R_{A_v}(t)] - \mu_{A_v}(t) = R_{A_v}(t)\end{aligned}\quad (17.6a)$$

The response is a bit more complex under the multiplicative and exponential models,

as the mean population value, σ_E^2 , for the environmental variance is a nonlinear function of both the mean and the variance of A_v (Table 17.1). For the multiplicative model

$$\sigma_E^2 = [\mu_{A_v}^2 + \sigma^2(A_v)] \sigma_e^2$$

Because the mean breeding value in generation $t+1$ can be expressed as the previous mean plus the response, $\mu_{A_v}(t+1) = \mu_{A_v}(t) + R_{A_v}(t)$, if we assume that there is no change in the additive variance of environmental sensitivities following selection ($\Delta\sigma^2(A_v) = 0$), we have

$$\begin{aligned}\Delta\sigma_E^2(t) &= \sigma_E^2(t+1) - \sigma_E^2(t) \\ &= ([\mu_{A_v}(t) + R_{A_v}(t)]^2 + \sigma_{A_v}^2) \sigma_e^2 - [\mu_{A_v}^2(t) + \sigma_{A_v}^2] \sigma_e^2 \\ &= [2\mu_{A_v}(t)R_{A_v}(t) + R_{A_v}^2(t)] \sigma_e^2\end{aligned}\quad (17.6b)$$

Change in $\sigma^2(A_v)$ due to selection-generated linkage disequilibrium can be similarly accounted for by using Equation 16.8b.

Under the exponential model and again assuming that there is no change in $\sigma_{A_v}^2$, Equation 17.3d implies that

$$\begin{aligned}\Delta\sigma_E^2(t) &= \sigma_E^2(t+1) - \sigma_E^2(t) \\ &= \sigma_e^2 \exp[\mu_{A_v}(t) + R_{A_v}(t) + \sigma_{A_v}^2/2] - \sigma_e^2 \exp[\mu_{A_v}(t) + \sigma_{A_v}^2/2] \\ &= \sigma_e^2 \exp[\mu_{A_v}(t) + \sigma_{A_v}^2/2] [\exp(R_{A_v}\{t\}) - 1] \\ &= \sigma_E^2(t) \cdot [\exp(R_{A_v}\{t\}) - 1]\end{aligned}\quad (17.6c)$$

These expressions translate a response, R_{A_v} , in the mean breeding value for the environmental variance into the expected change in σ_E^2 for the different transmission models reviewed in Table 17.1. We now consider two different settings by which such a response can occur: as a consequence of direct selection on phenotypic value, z , and as the result of direct selection on σ_E^2 itself. A third possibility—a correlated response in A_v (i.e., in the environmental variance of the trait) due to direct selection on A_m (i.e., the value z of the trait itself) when $\rho(A_v, A_m) \neq 0$ —is examined in Volume 3.

Response From Stabilizing Selection on Phenotypic Value, z

We have previously suggested that selection either for, or against, extreme individuals may also result in some selection for genotypes with higher, or lower, environmental variances. We formalize this by considering how selection on a phenotypic value, z , maps onto selection on A_m and A_v . First consider a quadratic fitness model of stabilizing selection. Here, the expected fitness of an individual with a phenotypic value of z is

$$W(z) = 1 - s(z - \theta)^2 \quad (17.7a)$$

where θ is the optimal trait value and s is the strength of stabilizing selection. This is a weak selection model, as $W \geq 0$ only for sufficiently small s relative to the total variance of z . Note that if we set $s < 0$, Equation 17.7a becomes a model of (weak) disruptive selection. Gavrilets and Hastings (1994c) examined how this phenotypic fitness function translates into selection on (A_m, A_v) under the multiplicative model. To do so, we replace z by $A_m + A_v e$ and take the expectation over e . Noting that $E[e] = 0$, $E[e^2] = \sigma_e^2$, the expected fitness as a function of A_m and A_v becomes

$$\begin{aligned}W(A_m, A_v) &= 1 - s E[(A_m + A_v e - \theta)^2 | A_m, A_v] \\ &= 1 - s [(A_m - \theta)^2 + 2(A_m - \theta)A_v E[e] + A_v^2 E(e^2)] \\ &= 1 - s [(A_m - \theta)^2 + A_v^2 \sigma_e^2]\end{aligned}\quad (17.7b)$$

Similar fitnesses arise under the Gaussian model of weak stabilizing selection (Equation 16.17); see Hill and Mulder (2010), and Example 17.3 for a more exact analysis. Equation 17.7b shows that phenotypic stabilizing selection favors A_v values near zero, thus decreasing σ_E^2 (Hansen et al. 2006), which has two important consequences. First, the reduction in phenotypic variance can be significantly greater than predicted from the simple reduction in the additive variance from the Bulmer effect (Chapter 16). And second, there can be cases where the trait heritability, h_z^2 , will *increase* under stabilizing selection. Because both additive and environmental variances are decreased, if the decrease in environmental variance is sufficiently greater, then h_z^2 increases. Results for quadratic disruptive selection follow by changing the sign on s , which results in selection to increase A_v .

Example 17.3. The quadratic fitness function (Equation 17.7a) is a model for weak stabilizing selection, as it can generate negative (and hence undefined) fitness values when selection is sufficiently strong. An alternative model of stabilizing selection without this constraint is normalizing selection (Equation 16.17), where θ denotes the optimal phenotypic value and ω^2 denotes the strength of selection around this optimum. Devaux and Lande (2009) used this fitness function in their study of selection on the flower-timing variance within an individual. They assumed that the additive model for genetic variation in σ_e^2 (Equation 17.4c) holds and that repeated expressions z of the trait from an individual with breeding values A_m (for the trait) and A_v (for σ_E^2) are drawn from a normal, so that

$$p(z | A_m, A_v) = \frac{1}{\sqrt{2\pi(\sigma_e^2 + A_v)}} \exp \left[-\frac{(z - A_m)^2}{2(\sigma_e^2 + A_v)} \right]$$

Integration of $W(A_m, A_v) = \int W(z) p(z | A_m, A_v) dz$ yields

$$W(A_m, A_v) = \sqrt{\frac{\omega^2}{\omega^2 + \sigma_e^2 + A_v}} \exp \left[-\frac{(A_m - \theta)^2}{2(\omega^2 + \sigma_e^2 + A_v)} \right] \quad (17.8a)$$

When $A_m \simeq \theta$, the exponential term is near one (as its numerator is near zero), and so fitness is largely driven by the square root term. For weak selection ($\omega^2 \gg \sigma_e^2 + A_v$) when $A_m = \theta$, a first-order Taylor series approximation yields

$$W(A_m, A_v) \simeq 1 - \frac{\sigma_e^2 + A_v}{2\omega^2} \quad (17.8b)$$

As was the case for weak quadratic selection, fitness increases as A_v decreases.

The more interesting case is that where the population is far from the equilibrium, so $|A_m - \theta| \gg 1$, and the numerator in the exponential term in Equation 17.8a is large. In this case, fitness can be improved by *increasing* the value of A_v (i.e., moving it closer to θ), which reduces the magnitude of the exponential term. Thus, as also noted by Lande (1980b) and Bull (1987), stabilizing selection can actually favor an *increase* in σ_E^2 when the population is far from its optimum, as the larger variance increases the chance that some phenotypes will be near θ . Svardal et al. (2011) similarly found that selection favors increased values of σ_E^2 when there are strong fluctuations in θ over time.

Response From Directional Selection on z

Now consider directional selection on the trait phenotype, z . We first assume that the multiplicative model holds and that we have a simple linear fitness function

$$W(z) = 1 + sz \quad (17.9a)$$

Taking the expectation over environmental values, Gavrilets and Hastings (1994c) found that

$$W(A_m, A_v) = 1 - sE(A_m + eA_v | A_m, A_v) = 1 - sA_m + A_vE(e) = 1 - sA_m \quad (17.9b)$$

Under this setting, there is no direct selection on A_v .

A rather different outcome was noted by both Hill and Zhang (2004) and Mulder et al. (2007) for truncation selection on a normally distributed trait. As a measure of fitness, Hill and Zhang considered the probability, $P(a, b)$, that a genotype with a mean of $\mu + a$ and a variance of $\sigma^2 + b$ is selected by using a multidimensional Taylor series approximation (Equation A6.6a) for the probability that such a genotype exceeds the truncation threshold when a fraction, p , is saved and $z \sim N(\mu, \sigma^2)$. Keeping only first-order terms in a and b yields

$$P(a, b) \simeq p \left(1 + a \frac{\bar{t}}{\sigma_z} + \frac{b}{2} \frac{\bar{t} x_{[1-p]}}{\sigma_z^2} \right) \quad (17.10a)$$

Here \bar{t} is the selection intensity (Equation 14.3a), and $x_{[1-p]}$ satisfies $\Pr(U \geq x_{[1-p]}) = p$, where $U \sim N(0, 1)$. Thus, truncation selection generates selection pressure, \bar{t} , on A_m and $\bar{t} x_{[1-p]}$ on A_v . When A_m and A_v are uncorrelated, the expected response in the trait mean is simply our standard result from Chapter 13 (Equation 13.6b),

$$R_{A_m} = h_m^2 \bar{t} \sigma_z \quad (17.10b)$$

Under the additive model for the environmental variance (Equation 17.4a), Hill and Zhang found that the response in the mean breeding value for the environmental variance is

$$R_{A_v} = h_v^2 \bar{t} x_{[1-p]} \sigma_z^2 \quad (17.10c)$$

which is also the response in σ_E^2 (Equation 17.6a). Equation 17.10a assumes that the population distribution of the trait value, z , is approximately normal, which breaks down at extreme trait values when there is heritable variation in σ_E^2 (as z is now no longer normally distributed, but rather has become a weighted mixture of normals). Hence, for strong selection these results are potentially biased.

Example 17.4. Consider a trait with $\sigma_z^2 = 100$, $h_m^2 = 0.3$, and $h_v^2 = 0.03$ (the latter a typical value from Table 17.2). Assume that the additive model for the environmental variance (Equation 17.4b) holds. What is the expected response in the mean and σ_E^2 following a single generation of truncation selection with $p = 0.1$? Because $h_m^2 \sigma_z = h_v^2 \sigma_z = 3$, Equations 17.10b and 17.10c show that any difference in response is due entirely to differences in the strength of selection (\bar{t} vs. $\bar{t} x_{[1-p]}$), not the genetic variances of these traits. Noting that $\Pr(U > 1.282) = 0.1$, we have $x_{[1-0.1]} = 1.282$ and (recalling Equation 14.3a) $\bar{t} = \varphi(1.282)/0.1 = 1.755$, with Equations 17.10b and 17.10c yielding

$$R_{A_m} = 0.3 \cdot 1.755 \cdot 10 = 5.265 \quad \text{and} \quad R_{A_v} = 0.03 \cdot 1.755 \cdot 1.282 \cdot 100 = 6.750$$

meaning that a single generation of selection increases the mean by 5.3 and the environmental variance increases by 6.75.

Using these same parameter values, the Bulmer equation (Equation 16.12d) yields the change in the additive genetic variance of the trait, $\sigma^2(A_m)$, after one generation of selection as $d = -3.74$, for (ignoring changes in σ_E^2) a phenotypic variance of $100 - 3.74 = 96.26$ and a heritability of $(30 - 3.74)/(100 - 3.74) = 0.27$. Accounting for changes in σ_E^2 yields a phenotypic variance after one generation of $100 - 3.74 + 6.75 = 103.1$ and heritability of $(30 - 3.74)/103.1 = 0.25$. Because the response in the trait mean is given by $R(t) = h^2(t) \bar{t} \sigma_z(t)$, the decrease in h^2 (from increased σ_E^2) is somewhat offset by the increase in the phenotypic variance. The response in the trait mean in generation 2 becomes $0.27 \cdot 1.77 \cdot \sqrt{96.26} = 4.69$ when ignoring the change in σ_E^2 and $0.25 \cdot 1.77 \cdot \sqrt{103.1} = 4.49$ when including it.

Now consider stronger selection, $p = 0.01$. Here $x_{[1-p]} = 2.326$ and $\bar{t} = 2.666$, yielding

$$R_{A_m} = 0.3 \cdot 2.666 \cdot 10 = 7.998 \quad \text{and} \quad R_{A_v} = 0.03 \cdot 2.666 \cdot 2.326 \cdot 100 = 18.603$$

Relative to $p = 0.1$, this is roughly a 50% increase in the response in the mean, but a 275% increase in the response in the environmental variance. The Bulmer equation yields $d = -4.06$ for one generation of selection and a resulting heritability (ignoring any changes in σ_E^2) of 0.27. If we include the change in environmental variance, the new phenotypic variance is $100 - 4.06 + 18.60 = 114.54$, resulting in a heritability of $25.94/114.54 = 0.23$. As above, the actual trait heritability is less than predicted from the Bulmer equation, but the resulting impact on the response in the mean is again partly offset by the increase in the phenotypic variance, with the expected response in generation two of 7.06 (Bulmer) and 6.78 (Bulmer plus changes in σ_E^2).

Example 17.4 illustrates the fact that as truncation selection becomes stronger, there is a disproportionate change in the variance relative to the mean, as selection is favoring outliers, and hence is more strongly influenced by genotypes associated with larger environmental variances. The effect on σ_E^2 from directional selection on the trait value, z , is thus expected to be greatest under strong selection (Hill and Zhang 2004). We can quantify this assertion by using Equation 17.10a. As shown in Figure 17.1, from moderate to large values of p (i.e., close to 1 and implying weak selection, as most of the population is saved), selection on the mean (\bar{t}) dominates. The two strengths of selection are equal around $p = 0.16$ (as $x_{[1-0.16]} = 1$), below which ($p < 0.16$) selection on the variance ($\bar{t}x_{[1-p]}$) is stronger (as $x_{[1-p]} > 1$). For $p > 0.5$ (more than half the population is saved), $x_{[1-p]} < 0$, implying that weak directional selection results in a slight *decrease* in σ_E^2 (Hill and Zhang 2004). The effect is largest around $p = 0.80$ (only 20% of the population is culled), but even here the strength of selection on σ_E^2 is fairly small, with $\bar{t}x = -0.3$. This slight decrease in σ_E^2 under weak directional selection occurs because only outliers with very low values of z are selected *against*, and such phenotypes arise in genotypes that have higher variances.

As we have seen, there are two very different pathways, through either $\sigma^2(A_m)$ or σ_E^2 , for short-term change in the phenotypic variance, σ_z^2 . Generation of gametic-phase disequilibrium by selection changes $\sigma^2(A_m)$ without requiring significant allele-frequency change (Chapters 16 and 24). Likewise, the presence of heritable variation in σ_E^2 can also generate a short-term response in the total variance. As noted by Bull (1987), “environmental and genetic factors may thus compete to produce a given selected level of phenotypic variance.”

What insights do these results offer on which factor is more important? The general conclusion is that while direct selection pressure on σ_E^2 often has the same sign as the selection on $\sigma^2(A_m)$, this is not *always* the case. Under disruptive selection, there is direct selection for positive disequilibrium, and hence an increase in $\sigma^2(A_m)$, along with direct selection to increase σ_E^2 , so the Bulmer equation is expected to underpredict the increase in phenotypic variance. With stabilizing selection (when the population mean is close to the optimum value), the direct selection pressures on $\sigma^2(A_m)$ and σ_E^2 also align, favoring a decrease in each, and again resulting in an underprediction of the total change in σ_z^2 if only the Bulmer equation is used. However, if the current population mean is far from the optimum, there can be selection pressure to *increase* σ_E^2 (Example 17.3). The most direct conflict between these two potential components of change in the phenotypic variance occurs under directional selection. This always generates a negative disequilibrium value d (Equation 16.2), and hence a reduction in the additive variance, $\sigma^2(A_m)$, of the trait. However, under modest to strong selection, it also favors an *increase* in σ_E^2 which often results in both an increase in the phenotypic variance and a further decrease in the heritability. The net result is that the Bulmer equation underpredicts the expected change in the variance (Example 17.4). With very modest selection (over 50% of the population saved), there is weak selection pressure for a slight *decrease* in σ_E^2 . It is important to stress that all of these

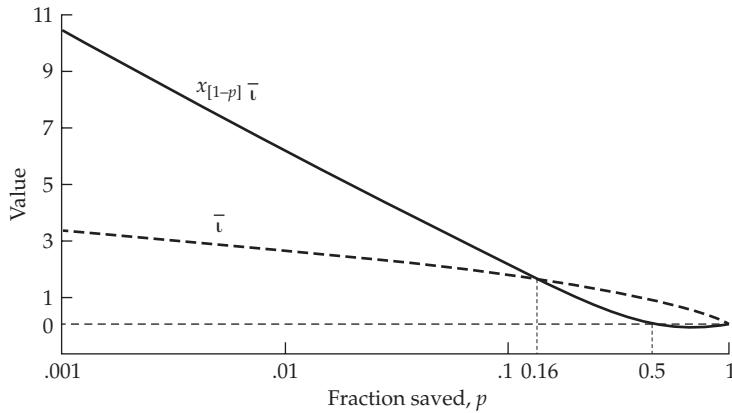

Figure 17.1 The relative strengths of selection on the mean (\bar{t}) and variance ($x_{[1-p]} \bar{t}$) under truncation selection as a function of the fraction, p , saved. The two strengths of selection are equal around $p = 0.16$ (as $x_{[1-0.16]} = x_{[0.84]} = 1$). Note that for $p > 0.5$, there is (weak) selection to *decrease* the variance, as the curve for $x_{[1-p]} \bar{t}$ dips below the horizontal dashed line that indicates a value of zero.

results only consider the *direct* response in σ_E^2 , as it is assumed that $\rho(A_m, A_v) = 0$. When the breeding values for the trait value and its environmental variance are negatively correlated, the sign of response on σ_E^2 can depart from these predictions (examined in Volume 3).

A major distinction in these two potential routes for changing σ_z^2 is that (under the infinitesimal model) changes in $\sigma^2(A_m)$ are transient, and decay away after selection stops. However, change in σ_E^2 are due to changes in the mean breeding value, μ_{A_v} , and this response (being due to changes in allele frequencies) is stable after selection stops. Hence, the genetic variance in the trait value, $\sigma^2(A_m)$, returns to its base population value, while the environmental variance stays at its new population value.

Direct Selection on σ_E^2 Using Repeated Records

While σ_E^2 can change as a consequence of simple selection on the trait value, z , a breeder may wish to target σ_E^2 directly. While simple selection on z can result in direct selection on A_v , it also targets A_m (and hence changes the mean). Through the use of an appropriate selection index, one can directly select on A_v alone (and hence directly target σ_E^2), even with only a single observation per individual. This is possible because A_m is linearly associated with z , while A_v is associated with z^2 . If we rescale z to have a mean of zero, an index of the form $I_i = az_i + bz_i^2$ can be constructed to specifically target individuals with high (or low) A_v values. We examine this index, and the component responses, in Volume 3.

Another approach involves selecting those individuals with the smallest residual variances under a repeated-measures design. We considered this design in Chapter 13 as an approach to reduce environmental noise when selecting on the *mean* trait value of an individual, but here the target is the actual *variation* among the records themselves. Individuals are chosen based on the index

$$V_i = \frac{1}{n-1} \sum_{j=1}^n (z_{ij} - \bar{z}_i)^2 \quad (17.11)$$

where z_{ij} denotes the j th record (observation) from individual i , with selection for uniformity favoring individuals with smaller V_i values. Natural selection can also act in a repeated-records setting, such as on the within-individual variation in flowering time. Depending on the ecological setting, selection can favor individuals with either larger or smaller values of within-individual variances (Example 17.3; Devaux and Lande 2009).

Assuming the exponential model holds for σ_E^2 , San Cristobal-Gaudy et al. (1998) and

Ibáñez-Escriche et al. (2008b) approximated the expected response in the mean breeding value of A_v , given selection intensity, \bar{t} , over the index, V , as

$$R_{A_v} \simeq \bar{t} \frac{\sigma^2(A_v)}{\sqrt{\exp[\sigma^2(A_v)][(n+1)/(n-1)] - 1}}, \quad (17.12)$$

where n is the number of repeated records per individual. Substitution into Equation 17.6c provides the expected response in σ_E^2 . More exact expressions were given in Ibáñez-Escriche et al., who also examined the power and required sample sizes when using repeated-measures selection experiments to detect heritable environmental variation.

Under a strict repeated-records design, all observations in V_i have the same genotype. A related design is to select based on variation in trait value among the *offspring* of an individual. For example, Garreau et al. (2008) selected rabbit dams based upon Equation 17.11, using the weights of offspring (suitably corrected for fixed effects such as litter size and parity). As mentioned at the start of the chapter, offspring mortality is lower within litters with more similar individual weights (Milligan et al. 2002; Garreau et al. 2008), and such selection conceivably occurs in natural populations as well. Under an offspring-based index, the multiple records are based on individuals with potentially different genotypes, and hence a large V score could arise from a high breeding value for σ_E^2 , segregation of a major gene, nonadditive variance, or (most likely) some combination of these. Garreau et al. observed significant responses in the first generation for both the increased- and decreased-variance selected lines. The selection pressure was weaker in subsequent generations in their experiment, and the response was largely flat. While these data are consistent with a response in σ_E^2 , the majority of the initial response may simply have arisen from selection for, or against, females that are heterozygous for major genes influencing weight.

Analysis of Short-term Selection Experiments:

1. Least-squares Approaches

To consult the statistician after an experiment is finished is often merely to ask him to conduct a postmortem examination. He can perhaps say what the experiment died of.
Fisher (1938)

This chapter examines the analysis of short-term selection experiments, whose duration is such that changes in allele frequency (from either selection or drift) are assumed to be relatively negligible. We restrict our attention here to the change in the mean under directional selection. The bulk of the chapter consists of developing least-squares (LS) estimates (and their corresponding standard errors) of **realized heritabilities** from the observed response. We also examine the empirical evidence for the goodness-of-fit of the breeder's equation to short-term artificial selection experiments. This is followed by a discussion of experimental and optimal designs for selection experiments, and we conclude with a detailed discussion of **generation means analysis**, the analysis of response when individuals from different cycles of selection are crossed (e.g., by using remnant seed).

Under the LS framework (LW Chapter 8), the only data required are the sample means (before and after selection) over generations, which are usually straightforward to obtain. Conversely, when one has access to the phenotypic values of essentially *all* of the individuals in the experiment, as well as their complete pedigree, more powerful mixed-model (MM) methods can be used. These are discussed in Chapter 19, while Chapter 20 considers the analysis of response in the much more complex setting of natural populations, where there is little control over either the nature of selection or the environment.

Finally, while our focus here is on phenotypic changes, we would be remiss if we did not point out that an area of very considerable interest is the genetic basis behind any such response. We previously discussed (Chapter 9; LW Chapter 15) a number of tools to aid in this dissection (e.g., QTL mapping using crosses between selected lines; tests of selection on specific loci/markers). The most recent extension of this quest are **evolve & resequence (E&R) experiments** (a term coined by Turner et al. [2011]), wherein a population is allowed to evolve under laboratory conditions and then genomic sequencing is applied in the search for target loci. See Long et al. (2015) for a recent review, and Kofler and Schlötterer (2013) and Bladwin-Brown et al. (2014) for design and power issues. Chapters 25 and 26 discuss the findings of such experiments.

The literature on selection experiments is truly massive, and our goal here is to introduce the important concepts rather than to exhaustively review all experiments. Reviews of selection experiments (mainly on metazoans) include Wilson (1977), Wright (1977), Robertson (1980), Mather (1983), Hill (1984), Sheridan (1988), Eisen (1989), Hill and Mackay (1989), Falconer (1992), Hill and Caballero (1992), Garland and Rose (2009), and Hill (2011). Fueled by the rapid advances in next-generation DNA sequencing, artificial selection experiments have undergone a renaissance, both in the form of **experimental evolution studies** (Kawecki et al. 2012) and in a growing number of experiments involving viral and microbial systems (Chapter 26). Our focus here is on goodness-of-fit to the breeder's equation, while in Chapters 25 and 26 we review empirical trends from long-term selection experiments.

VARIANCE IN SHORT-TERM RESPONSE

As we saw in Chapter 12, the means for a series of initially identical lines will inevitably diverge over time through the action of genetic drift, generating an among-line variance. The same is true for lines under selection, with this among-line variance being manifested

as **variation in response** (Figure 18.1). While the grand mean over a series of replicate lines under pure drift should remain essentially unchanged, the similar mean over a series of replicate selection lines should show a response over time, meaning that any particular realized response equals this expected response plus noise due to the evolutionary process of drift. Because artificial selection usually involves choosing a small number of parents to form the next generation, this among-line variance can be considerable. As we saw in Chapter 12, drift also changes the additive variance, σ_A^2 , within any given line. Our short-term assumption implies that $t/N_e \ll 1$, in which case drift can generate a significant among-line variance in means but with little within-line change in σ_A^2 (Chapters 11 and 12). Our focus on short-term response assumes that selection has only a minor role in changing the genetic variance over the course of the experiment. This is the standard infinitesimal model assumption used throughout Chapters 13–20 (and relaxed in Chapters 24–28). One complication that we initially ignore (addressing it later in the chapter) is that directional selection decreases the additive genetic variance by creating negative gametic-phase disequilibrium (Chapter 16).

Expected Variance in Response Generated by Drift

The expected variation among the means of replicate lines subjected to the same amount of selection was first considered by Prout (1962b) and then examined in detail by Hill (1971, 1972c, 1972d, 1974b, 1977a, 1980, 1986). The variation between the sample means, $\bar{z}_{t,i}$, of a series of replicate lines (in generation t) has two components: an **evolutionary variance** due to differences between the true means, $\mu_{t,i}$, generated by drift and selection, and a sampling (or residual) variance from estimating the true mean, $\mu_{t,i}$, by a sample mean, $\bar{z}_{t,i}$, based on $M_{t,i}$ individuals. Chapter 12 examined these components under pure drift, while here we consider the joint action of drift and selection.

With selection, the M individuals are not chosen at random with respect to their phenotypes, which *decreases* the among-line variance in population means relative to pure drift. This is partly countered by the fact that selection generates a lower effective population size than expected from drift alone (Chapters 3 and 26). Further, selection can increase the among-line variance relative to drift by changing allele frequencies more rapidly than expected from drift alone. It is these opposing (and potentially offsetting) changes in variance that led to suggestions that many of these effects will cancel out, leaving the pure-drift variance (with a suitably adjusted N_e) as an adequate approximation (Hill 1977a, 1980, 1986; Robertson 1977a; Nicholas 1980). Simulations (Robertson 1977a) and experimental results (Falconer 1973; López-Fanjul 1982) suggest that the pure-drift variance is a reasonable approximation.

Using the pure-drift results (Chapter 12), the sample mean in generation t for a particular realization (line) can be decomposed as

$$\bar{z}_t = \mu_t + e_t \quad (18.1a)$$

where μ_t is the true mean of this line and e_t is the residual error in estimating this true mean from a population sample. The true mean can be further decomposed as

$$\mu_t = \mu + g_t + b_t \quad (18.1b)$$

where g_t is the mean breeding value (relative to a base population value of $g_0 = 0$) and b_t is the mean environmental deviation in generation t , yielding an expected value for the sample mean of a random line in generation t of

$$E(\bar{z}_t) = \mu + E(g_t) + b_t \quad (18.2)$$

Under pure drift, $E(g_t) = 0$, while under selection, $E(g_t)$ is given by the breeder's equation, $\sum_i^t h_i^2 S_i = th^2 S$, if the heritability and selection differential remain constant (given the usual

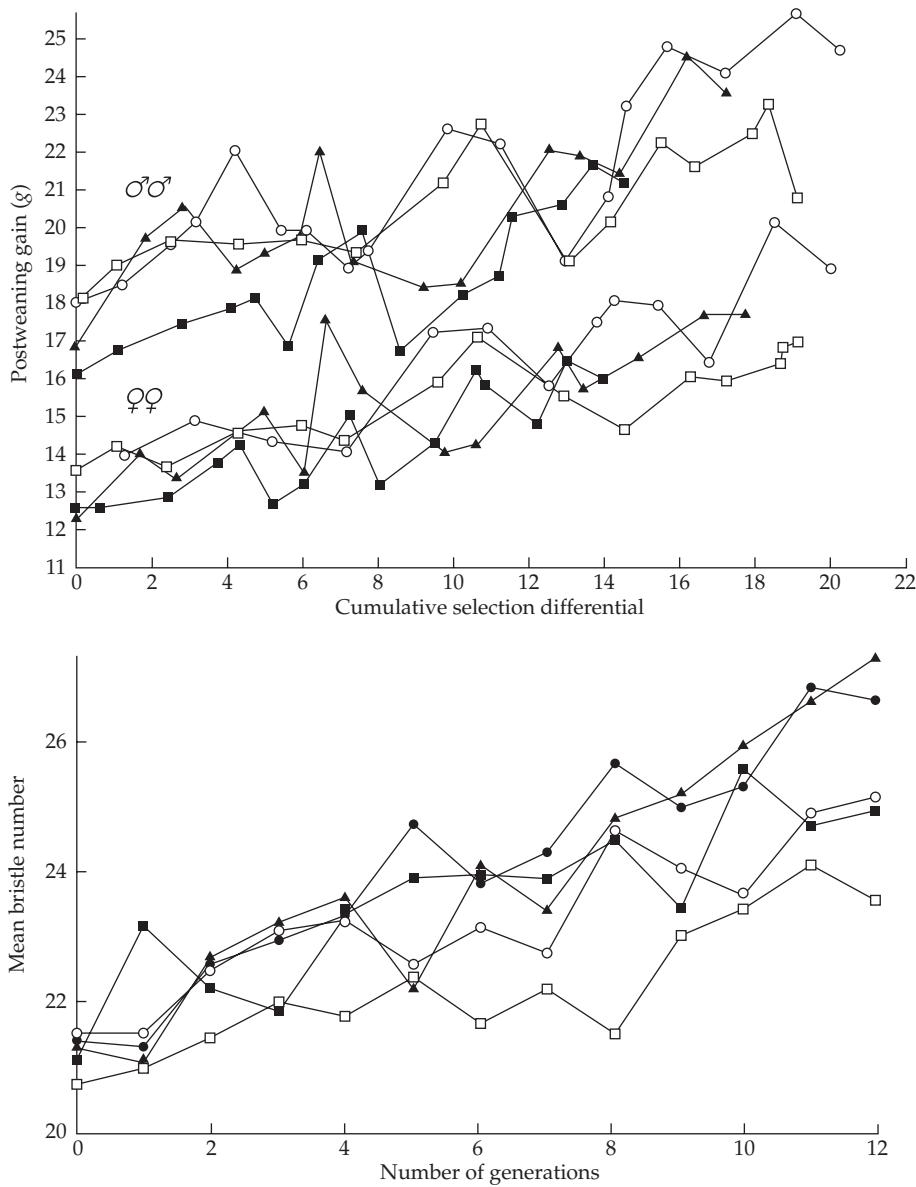

Figure 18.1 Examples of the variance in response to selection among replicate lines. **Top:** Postweaning weight gain in male and female mice (Hanrahan et al. 1973). Each replicate consists of a full-sib single family, which was propagated by selecting the largest pair within each family. **Bottom:** Abdominal bristle number in *Drosophila melanogaster* (Frankham et al. 1968a). Here, 50 pairs of parents were scored and the largest 10 of each sex were used to form the next generation. Notice that these graphs differ in the way the response is plotted. In the upper graph, response is given as a function of the **cumulative selection differential**, which has an expected slope of h^2 under the breeder's equation. On the lower graph, response is a function of the **number of generations**, which can depart from linearity if S varies over time.

caveats summarized in Table 13.2). Assuming $b_t \sim (0, \sigma_b^2)$, the variance about the expected mean value is

$$\sigma_z^2(t) = \sigma_g^2(t) + \sigma_e^2(t) + \sigma_b^2 \quad (18.3)$$

As discussed later in the chapter, comparison between contemporaneous populations, such as a selected and control line in the same generation or an upselected versus downselected line, can remove the shared environmental effect, and hence the σ_b^2 term.

Given our previous comments, we assume the evolutionary sampling variance, $\sigma_g^2(t)$, about the mean breeding value for selected lines is, to a good approximation, the same as that for lines under drift alone. If M_0 individuals are initially sampled to form each line, then from Equation 12.1b

$$\sigma_g^2(t) = \left(\frac{1}{M_0} + 2f_t \right) h^2 \sigma_z^2 \quad (18.4)$$

The M_0 term accounts for variation in mean breeding value among lines in the founding generation, while f_t (the amount of inbreeding at generation t) accounts for variation generated by subsequent drift. If population size remains constant

$$2f_t = 2 \left[1 - \left(1 - \frac{1}{2N_e} \right)^t \right] \simeq t/N_e \quad \text{for } t/N_e \ll 1 \quad (18.5)$$

If different numbers of males (N_m) and females (N_f) are sampled or if N varies over time

$$2f_t \simeq \sum_{k=0}^{t-1} \left[\frac{1}{4N_m(k)} + \frac{1}{4N_f(k)} \right] \quad (18.6)$$

The variance, $\sigma_e^2(t)$, in Equation 18.3, which is associated with estimating the true mean from a sample mean, depends on the relatedness among the M_t individuals chosen to estimate the mean. If these individuals are unrelated, then $\sigma_e^2(t) = \sigma_z^2(t)/M_t$. If some selected individuals are related (such as from the same family), the positive covariance between them reduces the effective sample variance, with the exact form of σ_e^2 depending on the distribution of family sizes within the sample. Hill (1971, 1980) shows that it is bounded by

$$\frac{\sigma_z^2 - \sigma_A^2/2}{M_t} \leq \sigma_e^2(t) \leq \frac{\sigma_z^2}{M_t} \quad (18.7)$$

which corresponds to the range where all individuals are from the same family (lower bound) to all being unrelated (upper bound). Conservatively choosing the upper bound, Equation 18.3 becomes

$$\sigma_{\bar{z}}^2(t) = \left(\frac{1}{M_0} + 2f_t \right) h^2 \sigma_z^2 + \sigma_b^2 + \sigma_z^2/M_t \quad (18.8)$$

Because drift variance accumulates in each generation (via f_t increasing each generation) while the other variance coefficients do not change, when $h^2 \sigma_z^2 > \sigma_b^2$, the drift term in Equation 18.8 is expected to eventually dominate, usually after a few generations. Whereas Equation 18.8 describes the divergence *between* lines due to drift, drift also introduces a positive covariance between the means at different generations *within* a line (Equation 12.2)

$$\sigma(g_t, g_{t'}) = \left(\frac{1}{M_0} + 2f_t \right) h^2 \sigma_z^2 \quad \text{for } t < t' \quad (18.9)$$

Assuming that cross-generational environmental and residual effects are uncorrelated, so that $\sigma(b_t, b_{t'}) = \sigma(e_t, e_{t'}) = 0$, then $\sigma(\bar{z}_t, \bar{z}_{t'}) = \sigma(g_t, g_{t'})$.

The careful reader will notice that neither h^2 or σ_z^2 are indexed by generation, and hence they are assumed to be constant. This treatment is in keeping with our assumption that these parameters remain essentially unchanged over the short time course of the experiment. This is a major assumption and can be violated in several ways. First, changes in the underlying allele frequencies can change these variances (Chapters 5 and 24–28). If alleles of major effect are segregating, large changes in the variance can occur within a few generations. Further, when major alleles are segregating at low frequencies, the sampling to create lines from a base population can result in a substantial increase in the among-line variance over that

predicted by Equation 18.4, as these alleles are absent in some lines and overrepresented (relative to the base population) in others. This results in lines having a larger range of starting additive variances, thus increasing the variance in response (James 1970).

Second, directional selection generates negative gametic-phase disequilibrium, reducing the additive genetic variance within a line over the first few generations before approaching an equilibrium value (Chapter 16). We will deal with this shortly. Third, inbreeding due to finite population size reduces the additive genetic variance within lines. For a completely additive locus, the expected additive genetic variance (in the absence of mutational input) within a line in generation t is expressed by Equation 11.2

$$E[\sigma_A^2(t)] = \left(1 - \frac{1}{2N_e}\right)^t \sigma_A^2(0) \simeq \left(1 - \frac{t}{2N_e}\right) \sigma_A^2(0) \quad \text{for } t \ll N_e$$

where $\sigma_A^2(0)$ is the variance in the base population (the last expression follows from $(1-x)^t \simeq 1 - xt$ for $|xt| \ll 1$). If dominance or epistasis is present, the within-line variance can actually increase (for a time) under drift (Chapter 11), further inflating the among-line variance. Provided $t/2N_e \ll 1$, the error introduced in Equations 18.8 and 18.9 by ignoring the reduction in the within-line variance due to inbreeding is small. Finally, when there is heritable variation in the environmental variance, σ_E^2 is expected to increase under moderate to strong directional selection (Chapter 17), increasing σ_z^2 and thus decreasing h^2 .

Despite all of these potential complications, those few experimental tests of the pure-drift approximation to artificial-selection data have found it to be fairly reasonable (Falconer 1973; López-Fanjul 1982). Mixed-model (REML/BLUP) methods developed in LW Chapters 26 and 28 (and reviewed here in Chapter 19), account for some of these concerns, but they require significantly more information (the phenotypic values of all individuals and their complete pedigree), which may be difficult to obtain.

Variance in Predicted Response Versus Variance in Actual Response

It is important not to confuse the previous expressions for variance in response (the variation about the mean response when the genetic parameters and selection differentials are *known without error*) with variance in the *predicted* response, which has (at least) two *additional* sources of variation. The first is the uncertainty produced by using estimates in place of the true values for the genetic and phenotypic variances. The second is uncertainty in the realized selection intensity. While selecting a preset fraction, p , of the population specifies the *expected* selection intensity, there is variation about this mean value for any particular realization (Chapter 14). For example, *before* selection is performed, we expect that truncation selection saving the uppermost 5% will have an *average* selection intensity of 2.06 (Example 14.1). However, when selecting the largest 5% from a small population (so that the number saved is small, e.g., $N \leq 25$ or so), its realized value can be significantly larger or smaller than the expectation, thus generating additional variation in the predicted response.

Several papers (Tai 1979; Knapp et al. 1989; Bridges et al. 1991) have presented confidence intervals for the expected selection response, but these simply focus on the variance generated by the uncertainty in the initial estimates of additive and phenotypic variances. They do not consider the additional evolutionary variance in response (discussed above), nor do they consider the variance in the particular realization of a prespecified selection intensity (although, retrospectively, we can deal with the latter by using the observed values).

REALIZED HERITABILITIES

The breeder's equation, $R = h^2 S$, immediately suggests that heritability can be estimated as the ratio of the observed response to the observed selection differential

$$\hat{h}_r^2 = \frac{R}{S} \quad (18.10)$$

Falconer (1954) referred to Equation 18.10 as the **realized heritability**, a term now more broadly defined to include any estimate of heritability based on the observed response to selection.

While one can use this approach to estimate h^2 , any complication in predicting response using the breeder's equation (Table 13.2) will usually make \hat{h}_r^2 a biased estimator. Turning this point around suggests that one test for the success of the breeder's equation is to compare how close realized heritabilities are to estimates based on resemblance between relatives in the unselected base population. If the breeder's equation generally provides an accurate model of selection response, we expect these two different estimates to be similar (i.e., within sampling error).

Example 18.1. An interesting example of applying artificial selection in a natural setting is the work of Flux and Flux (1982), who examined response on clutch size in starlings (*Sturnus vulgaris*) in New Zealand. Eggs were laid almost exclusively in nest boxes, allowing for identification of the mothers and careful monitoring of their offspring. Increased clutch size was selected for by removing all eggs from clutches below a specified brood size (artificial truncation selection on clutch size). Pooling all of the single-generation responses over the entire study, the 516 clutches from the offspring of selected females had an average size of 5.60 ± 0.04 , while the average size of 2050 clutches from offspring of unselected females was 5.48 ± 0.02 , yielding an estimated response of $R = 0.12 \pm 0.04$. The mean clutch size of selected female parents was 6.20 versus 5.48 for unselected (control) females, yielding $S_f = 0.72$. Because there is no selection on fathers under this design, $S = S_f/2$ (Chapter 13), yielding an expected response in daughters of $R = h^2 S_f/2$, and a realized heritability of

$$\hat{h}_r^2 = 2R/S_f = 2 \cdot 0.12/0.72 = 0.33$$

This value was in good agreement with the estimated heritability based on mother-daughter regressions of $\hat{h}^2 = 0.34 \pm 0.08$.

Estimators for Several Generations of Selection

While the estimator given by Equation 18.10 is unambiguous for a single generation of selection, two different estimation approaches have been proposed for an experiment of a length of $T > 1$ generations. Both approaches are based on the **cumulative selection response**, $R_C(t)$, and **cumulative selection differential**, $S_C(t)$

$$S_C(t) = \sum_{i=1}^t S_i \quad \text{and} \quad R_C(t) = \sum_{i=1}^t R_i \quad (18.11)$$

where $S_i = \bar{z}_i^* - \bar{z}_i$ and $R_i = \bar{z}_{i+1} - \bar{z}_i$ are the selection differential and single-generation response (respectively) for generation i , and \bar{z}_i and \bar{z}_i^* denoting the preselection and post-selection means in generation i .

The first approach, the simple **ratio estimator** of the realized heritability, is to use the total response divided by the total differential

$$\hat{b}_T = \frac{R_C(T)}{S_C(T)} \quad (18.12)$$

We use the notation throughout the chapter of \hat{b}_x for a particular estimator, as the realized heritability is some multiple of this, $\hat{h}_r^2 = c \cdot \hat{b}_x$, where c depends on the experimental design. For individual selection with only one sex selected, $c = 2$ (Example 18.1), while $c = 1$ when both sexes are selected.

The ratio estimator makes no assumption about a constant heritability, and instead returns an average value over the experiment. When h^2 remains constant, the breeder's equation predicts a linear cumulative response in R as a function of S . This observation leads to the second (and much more widely used) approach of estimating the realized heritability from the slope of the regression of cumulative response on cumulative selection differential

$$R_C(t) = b_C S_C(t) + e_t \quad \text{for } t = 1, \dots, T \quad (18.13)$$

with $\hat{h}_r^2 = b_C$ for individual selection on both sexes (Falconer 1954). Modifications of Equations 18.12 and 18.13 can be used for family selection (Chapter 21) and other designs, such as divergent selection (discussed at the end of this chapter). Because the expected response is zero if there is no selection, the regression line is constrained to pass through the origin and hence lacks an intercept term. Standard linear model approaches (LW Chapter 8) can be used to test for goodness-of-fit, such as testing whether a quadratic regression gives an improved fit (which suggests a changing heritability).

Recall from LW Chapter 8 that a regression estimator depends on the assumed covariance structure of the residuals. Most applications of the regression estimator (Equation 18.13) in the literature have assumed ordinary least-squares (OLS), which requires that the residuals, e_t , be homoscedastic and uncorrelated (LW Chapter 8). However, the careful reader will recall from Equations 18.4 and 18.9 that drift generates heteroscedastic and correlated residuals, thus requiring a generalized least-squares (GLS) solution (LW Chapter 8). We return to this issue after first examining the OLS estimator.

Recalling LW Equation 8.33a, the OLS estimator for the slope is $(\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{y}$. Because the design matrix, \mathbf{X} , for the regression given by Equation 18.13 is simply the vector of cumulative selection differentials, \mathbf{S} , and \mathbf{y} is the vector of cumulative responses, \mathbf{R} , it follows that the OLS estimate of the slope is given by

$$\hat{b}_C(\text{OLS}) = (\mathbf{S}^T \mathbf{S})^{-1} \mathbf{S}^T \mathbf{R} = \frac{\sum_{i=1}^T S_C(i) \cdot R_C(i)}{\sum_{i=1}^T S_C^2(i)} \quad (18.14)$$

We will refer to this as the **OLS regression estimator** of the realized heritability. While this is the most common approach used in the literature, by assuming the wrong residual error structure, the OLS approach substantially *underestimates* the standard error for the slope. Richardson et al. (1968) and Irgang et al. (1985) noted that when the number of individuals, M_t , used to obtain the sample mean varies over generations, sample means based on more individuals contain more information, and thus have smaller residual errors. In this setting, the residual variances (roughly σ_z^2/M_t) are no longer homoscedastic, prompting these authors to suggest that a weighted least-squares method (e.g., LW Example 8.11) be used to correct for this. While it is an improvement over OLS, however, this approach still ignores the very significant impact from additional heteroscedasticity and correlations in the residual errors generated by drift.

The theory for estimating realized heritabilities (via a LS analysis) in populations with overlapping generations is less well-developed. As will be discussed in Volume 3, approaches assuming an asymptotic selection response are flawed in that many generations are required to reach a stable genetic structure when starting from an unselected base population. For nonasymptotic response, see Hill (1974a) and Johnson (1977a) for the relevant theory, and Atkins and Thompson (1986) for an example with Scottish Blackface sheep. Mixed-model approaches (Chapter 19) easily accommodate overlapping generations, but they require the full pedigree of all measured individuals used in making selection decisions. This is often quite feasible with selection on large domesticated animals, and it is becoming increasingly feasible in more general settings using dense-marker estimates of relationships (Chapter 20).

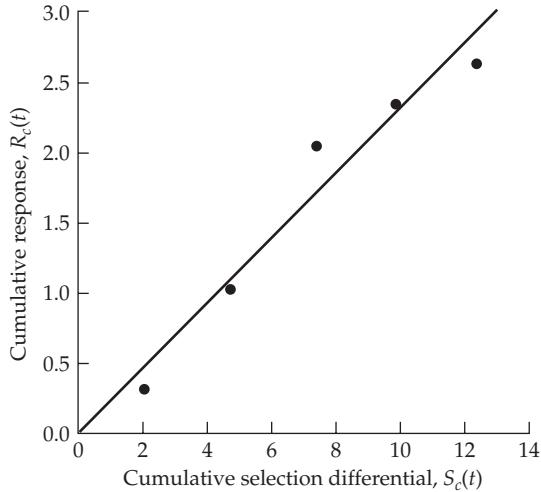

Figure 18.2 Response seen in Mackay's (1985a) divergent selection experiment on abdominal bristle number in *Drosophila melanogaster*. Details are provided in Example 18.2.

Example 18.2. Consider the following data from Mackay (1985a), who performed a divergent selection experiment on abdominal bristle number in replicate lines of *Drosophila melanogaster*. Fifty males and 50 females were measured in each line, with 10 of each sex selected to form the next generation. Her data for the High (up-selected) line from replicate pair 2 for the first five generations of selection are

t	\bar{z}	\bar{z}^*	$S(t)$	$R(t)$	$S_C(t)$	$R_C(t)$
1	18.02	20.10	$20.10 - 18.02 = 2.08$	$18.34 - 18.02 = 0.32$	2.08	0.32
2	18.34	21.00	$21.00 - 18.34 = 2.66$	$19.05 - 18.34 = 0.71$	4.74	1.03
3	19.05	21.75	$21.75 - 19.05 = 2.70$	$20.07 - 19.05 = 1.02$	7.44	2.05
4	20.07	22.55	$22.55 - 20.07 = 2.48$	$20.36 - 20.07 = 0.29$	9.92	2.34
5	20.36	22.95	$22.95 - 20.36 = 2.59$	$20.65 - 20.36 = 0.29$	12.51	2.63
6	20.65					

The ratio estimate of the realized heritability (Equation 18.12) is $\hat{h}_r^2 = 2.63/12.51 = 0.2102$. The regression, forced through the origin, of cumulative response (R_C) on cumulative selection differential (S_C) is plotted in Figure 18.2. Equation 18.14 yields an OLS regression estimator of the realized heritability of

$$\hat{h}_r^2 = \hat{b}_C(\text{OLS}) = \frac{\sum_{i=1}^5 S_C(i) \cdot R_C(i)}{\sum_{i=1}^5 S_C^2(i)} = \frac{78.96}{350.45} = 0.2245$$

Weighted Least-squares Estimates of Realized Heritability

Ordinary least-squares regression assumes that the residuals are homoscedastic and uncorrelated, yielding a covariance matrix for the vector of residuals, e , as $\text{Var}(e) = \sigma_e^2 \cdot \mathbf{I}$ (LW Chapter 8). Genetic drift causes the residual covariance structure of the regression given by Equation 18.13 to depart significantly from this simple form. In particular, the residual variance increases with time (Equation 18.8) and residuals from different generations within a given line are correlated (Equation 18.9). Thus, $\text{Var}(e)$ is not simply $\sigma_e^2 \cdot \mathbf{I}$, and generalized least-squares (GLS) must be used to account for the overall covariance structure. From LW Equation 8.34, the GLS estimator of the regression slope is given by

$$\hat{b}_C(\text{GLS}) = (\mathbf{S}^T \mathbf{V}^{-1} \mathbf{S})^{-1} \mathbf{S}^T \mathbf{V}^{-1} \mathbf{R} \quad (18.15a)$$

where \mathbf{V} is the variance-covariance matrix associated with selection response, with elements

$$V_{ij} = \sigma_e(i, j) = \sigma [R_C(i), R_C(j)] \quad (18.15b)$$

The elements of \mathbf{V} can be obtained from the pure-drift approximation, with the variances, V_{ii} , given by Equation 18.8 and the covariances, V_{ij} , by Equation 18.9, yielding

$$V_{ij} = \begin{cases} \left(\frac{1}{M_0} + 2f_i\right) h^2 \sigma_z^2 + \sigma_z^2/M_i & \text{for } i = j \\ \left(\frac{1}{M_0} + 2f_i\right) h^2 \sigma_z^2 & \text{for } i < j \end{cases} \quad (18.15c)$$

where $2f_i \simeq i/N_e$ (Equation 18.5). If differences in environmental values across generations are not accommodated for by the design, then V_{ii} has an additional term, σ_b^2 , reflecting random changes in the environment that influence the mean trait value (as discussed below, the use of control lines can often remove this term). Even though OLS assumes an incorrect residual structure, it still provides an unbiased estimate of b_C . However, OLS significantly underestimates the standard error of b_C , and it is for this reason that GLS estimators should be used whenever possible (Hill 1971, 1972c, 1972d, 1974b, 1977a, 1980, 1986).

Example 18.3. Computing the GLS regression using the data from Example 18.2 requires the variance-covariance matrix, \mathbf{V} , of the residuals, which is obtained using the pure-drift approximation. From Example 18.2, $M = 100$ and $N = 20$, while the estimated phenotypic variance is $\text{Var}(z) = 3.293$ (Mackay, personal communication). Assuming $N_e = N$, Equation 18.5 yields $f_i \simeq i/20$. Further assuming that both initial sampling and among-generation environmental effects can be ignored (i.e., $M_0 \gg 1$ and $\sigma_b^2 \simeq 0$), Equation 18.8 gives the variance associated with the response in generation i as

$$V_{ii} = 2f_i h^2 \sigma_z^2 + \sigma_z^2/M_i = \left(\frac{i}{20}\right) h^2 \cdot 3.293 + \frac{3.293}{100} = 0.1647 \cdot (i \cdot h^2 + 0.2)$$

Similarly, Equations 18.9 and 18.5 give the covariance between generations as

$$V_{ij} = \left(\frac{i}{N}\right) h^2 \sigma_z^2 = i \cdot h^2 \cdot 0.1647 \quad \text{for } i < j$$

The resulting covariance matrix becomes

$$\mathbf{V} = 0.1647 \cdot \begin{pmatrix} h^2 + 0.2 & h^2 & h^2 & h^2 & h^2 \\ h^2 & 2h^2 + 0.2 & 2h^2 & 2h^2 & 2h^2 \\ h^2 & 2h^2 & 3h^2 + 0.2 & 3h^2 & 3h^2 \\ h^2 & 2h^2 & 3h^2 & 4h^2 + 0.2 & 4h^2 \\ h^2 & 2h^2 & 3h^2 & 4h^2 & 5h^2 + 0.2 \end{pmatrix}$$

Because \mathbf{V} is a function of the unknown heritability, estimation is an iterative process. Starting with some initial estimate of h^2 , each new h_r^2 estimate is used to update \mathbf{V} in subsequent iterations until convergence occurs. Using the ratio estimator $h^2 = 0.21$ (Equation 8.2) as the starting value, Equation 18.15 gives a first estimate as

$$\hat{b}_C(\text{GLS})^{(1)} = (\mathbf{S}^T \mathbf{V}^{-1} \mathbf{S})^{-1} \mathbf{S}^T \mathbf{V}^{-1} \mathbf{R} = 0.2222$$

Substituting this new estimate of h^2 into \mathbf{V} gives, upon a second iteration, $\hat{b}_C(\text{GLS})^{(2)} = 0.2221$, which remains unchanged in subsequent iterations.

Standard Errors of Realized Heritability Estimates

The final pieces of statistical machinery necessary for assessing the success of the breeder's equation are the standard errors associated with the different realized heritability estimators. Consider first the realized heritability estimated from the unweighted (OLS) regression (Equation 18.14). Recalling LW Equation 8.33b for the variance for an OLS estimator

$$\text{Var} [\hat{b}_C(\text{OLS})] = \sigma_e^2 (\mathbf{X}^T \mathbf{X})^{-1} = \sigma_e^2 (\mathbf{S}^T \mathbf{S})^{-1} = \sigma_e^2 \left/ \sum_{i=1}^T S_C^2(i) \right. \quad (18.16a)$$

The residual variance, σ_e^2 , can be estimated from the residual sums of squares divided by the degrees of freedom (see LW Chapter 8). For an experiment lasting for T generations

$$\hat{\sigma}_e^2 = \frac{1}{T-1} \sum_{i=1}^T \hat{e}_i^2 = \frac{1}{T-1} \sum_{i=1}^T (R_C(i) - \hat{h}_r^2 S_C(i))^2 \quad (18.16b)$$

As mentioned, because the OLS estimator assumes that residuals are uncorrelated and have equal variances (both of which are incorrect under drift), it significantly *underestimates* the correct variance (Example 18.4). The GLS regression estimator (Equation 18.15) avoids these problems by properly accounting for the residual variance-covariance structure generated by drift. From standard GLS theory (LW Equation 8.35)

$$\text{Var} [\hat{b}_C(\text{GLS})] = (\mathbf{S}^T \mathbf{V}^{-1} \mathbf{S})^{-1} \quad (18.17)$$

As was done above, the pure-drift approximation is used to obtain the elements of \mathbf{V} , with \hat{h}_r^2 used in place of h^2 .

Finally, consider the variance for the ratio estimator b_T , the total response to total selection (Equation 18.12). Because $\text{Var}(y/c) = \text{Var}(y)/c^2$ for a constant, c , we have

$$\text{Var}(\hat{b}_T) = \frac{\text{Var}[R_C(T)]}{S_C^2(T)} \simeq \frac{(T/N) \hat{h}_r^2 \sigma_z^2 + \sigma_z^2/M_T}{S_C^2(T)} \quad (18.18)$$

The numerator (the variance in response in generation T) follows from the pure-drift approximation (Equation 18.8), assuming that initial sampling can be ignored (e.g., $M_0 \gg 1$) and there is no significant between-generation environmental variance ($\sigma_b^2 = 0$). Hill (1972c, 1972d) noted that $\hat{b}_C(\text{GLS})$ is generally a slightly better estimator (i.e., returning a smaller standard error) than \hat{b}_T when h^2 is small, while \hat{b}_T is a slightly better estimator when h^2 or the number of generations is large.

Example 18.4. Using the data from Examples 18.2 and 18.3, let us compare the standard errors associated with the three different realized heritability estimates. Consider the unweighted regression estimator, $\hat{b}_C(\text{OLS})$, first. The residual sum of squares is

$$\sum_{i=1}^T (R_C(i) - \hat{h}_r^2 S_C(i))^2 = 0.091$$

yielding an estimated residual variance of $\hat{\sigma}_e^2 = 0.091/4 = 0.0228$. Equation 18.16a then yields

$$\text{Var} [\hat{b}_C(\text{OLS})] = \sigma_e^2 \left/ \sum_{i=1}^T S_C^2(i) \right. = \frac{0.0228}{350.45} = 0.0000649$$

Taking the square root yields a standard error of 0.0081.

Turning to the estimate, \hat{b}_T , based on the total response to total selection, Equation 18.18 returns

$$\text{Var}(\hat{b}_T) = \frac{(5/20) \cdot 0.21 \cdot 3.292 + 0.03292}{12.51^2} = 0.00132$$

for a standard error of 0.0363. Finally, if we substitute the GLS estimate of $\hat{h}_r^2 = 0.222135$ (Example 18.3) into \mathbf{V} , Equation 18.17 will yield a variance for this estimate of $(\mathbf{S}^T \mathbf{V}^{-1} \mathbf{S})^{-1} = 1/790.4$, for a standard error of 0.0356.

To summarize, the three approaches give extremely similar estimates

Unweighted least-squares regression, $\hat{b}_C(\text{OLS})$	$\hat{h}_r^2 = 0.2245 \pm 0.0081$
Total response/total differential, \hat{b}_T	$\hat{h}_r^2 = 0.2102 \pm 0.0363$
Weighted least-squares regression, $\hat{b}_C(\text{GLS})$	$\hat{h}_r^2 = 0.2221 \pm 0.0356$

Note that the difference in the standard error between $\hat{b}_C(\text{GLS})$ and \hat{b}_T is very small, with \hat{b}_T considerably more straightforward to compute. Also note that the unweighted regression greatly underestimates the standard error, making it four-fold smaller than the other two standard errors.

Power: Estimation of h^2 from Relatives or Selection Response?

Estimates of heritability from relatives are based on variance components (e.g., LW Chapters 17 and 18), while estimates from selection response are based on ratios of means. Thus, one might expect that realized heritability estimates may have greater power than those based on relatives. Is this indeed the case? Consider the sampling variance for the simple ratio estimator (Equation 18.18)

$$\text{Var}(\hat{h}_r^2) = \frac{\text{Var}[R_C(T)]}{S_C^2(T)} \approx \frac{(T/N) \hat{h}_r^2 \sigma_z^2 + \sigma_z^2/M}{S_C^2(T)} = \frac{(T/N) \hat{h}_r^2 + 1/M}{S_C^2(T)/\sigma_z^2}$$

where T is the number of generations and M individuals are measured per generation, with the most extreme N of these allowed to reproduce. Suppose that the strength of selection is the same in each generation ($S_i = S$), in which case we have that

$$S_C^2(T)/\sigma_z^2 = T^2 S^2/\sigma_z^2 = T^2 \cdot \bar{i}^2$$

and hence

$$\text{Var}(\hat{h}_r^2) \approx \frac{(T/N) \hat{h}_r^2 + 1/M}{T^2 \cdot \bar{i}^2} = \frac{(1/TN) \hat{h}_r^2 + 1/(T^2 M)}{\bar{i}^2} \approx \frac{\hat{h}_r^2}{TN \bar{i}^2} \quad (18.19)$$

where the last step follows by ignoring the $1/(T^2 M)$ term.

Turning to relative-based estimators of h^2 , the optimal midparent-offspring design (N_{mp} sets of parents each with a single offspring) has (LW Equation 17.11b) a standard error of

$$\text{SE}(h_{mp}^2) = \left(\frac{2 - h^4}{N_{mp}} \right)^{1/2}$$

This gives a ratio of sampling variances for the two estimators of

$$\frac{\text{Var}(h_{mp}^2)}{\text{Var}(\hat{h}_r^2)} \approx \frac{(2 - h^4)/N_{mp}}{h^2/(TN \bar{i}^2)} = \left(\frac{TN}{N_{mp}} \right) \left[\bar{i}^2 \left(\frac{2 - h^4}{h^2} \right) \right] \quad (18.20)$$

In applying Equation 18.20 to determine which method (N_{mp} midparent-offspring pairs versus TN total adults over the course of a selection experiment) is more accurate, a few

points are in order. In a selection experiment, one measures M adults in each generation, where N of these reproduce. Hence, if the limiting factor for an investigator is in raising offspring, then the comparison of N_{mp} midparents with TN adults that are allowed to reproduce is a fair one. However, if the limiting factor is in the actual *measurement* of individuals, then the fair comparison should be designs based on TM measured adults versus $3N_{mp}$ midparents (as the latter involves two adults and one offspring measure per pair). As Example 18.5 illustrates, even when T and M are fixed, the choice of N is important, as the standard error (Equation 18.19) is minimized when the product, $N\bar{t}^2$, is maximized. There is a tradeoff in this maximization, as increasing selection decreases N but increases \bar{t} (which is a nonlinear function of N/M).

There are a few final caveats in using a realized heritability estimator in place of a more traditional relative-based one. Clearly, if any of the assumptions of the breeder's equation (Table 13.2) are violated, we obtain a potentially biased estimate. A more subtle issue is the target population for the heritability estimate—is this the entire population or some subset? An example of why this distinction may matter derives from the work of Skibinski and Shereif (1989). These authors initiated lines for selection on sternopleural bristle number in *Drosophila melanogaster* by taking parents from the central part of the distribution versus taking parents with extremely high or extremely low bristle number. The lines founded from the central part of the distribution had higher heritabilities, and larger responses, than lines founded from the extremes of the distribution. This is not expected under the infinitesimal model (Chapter 24), but it is expected if there are alleles of modest (or greater) effect segregating in the population. Thus, the subtle point is that realized heritability estimates may actually be sampling a different part of the population than relative-based estimators (this was also stressed in Chapter 6; see Equations 6.39 and 6.40). For example, if we sample rare alleles of large effect, these will rapidly increase in selected populations, thus inflating the heritability.

Example 18.5. Consider a trait with a true heritability of $h^2 = 0.30$. This trait is expensive to measure, while offspring are inexpensive to rear. With the resources to measure 3000 individuals, two possible designs are to measure 1000 midparent-offspring trios or to measure a total of 3000 individuals over the course of a selection experiment. The expected standard error for the midparent-offspring regression (LW Equation 17.11b) is

$$\text{SE}(h_{mp}^2) = \sqrt{\frac{2 - h^4}{N_{mp}}} = \sqrt{\frac{2 - 0.30^2}{1000}} = 0.044$$

For a T -generation selection experiment, we have $T \cdot M = 3000$ as the design constraint. Thus, if we measure M initial parents to select the most extreme N , and do this for six generations (the parents = generation 0, followed by selected generations 1, 2, 3, 4, 5), with $3000/6 = 500$ individuals being measured in each generation.

Consider three different designs, with $N = 250$ (50% selected), 100 (20%), or 50 (10%). Applying Equation 14.3a, these correspond to selection intensities (not correcting for finite population size) of $\bar{t} = 0.80, 1.40$, and 1.75 , respectively. From Equation 18.19, the standard errors for h_r^2 are given by

$$\sqrt{\frac{h^2}{TN\bar{t}^2}} = \sqrt{\frac{0.3}{5N\bar{t}^2}}$$

or 0.0194, 0.0175, and 0.0197 (for $N = 250, 100$, and 50, respectively). Thus, while all three selection-experiment designs have a smaller standard error than the midparent-offspring estimate, the design with $N = 100$ is the best among the three candidates. Trial and error yields an optimal N of 135, resulting in a standard error of 0.0172. Similar calculations can also be performed assuming experiments of different length (with T varying).

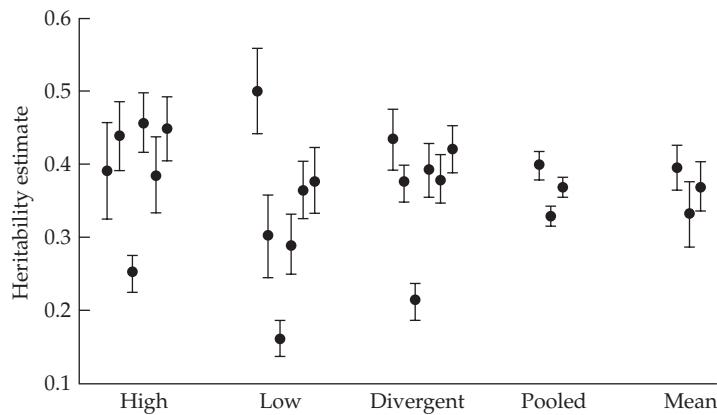

Figure 18.3 Realized heritability estimates (and their associated standard errors) from Falconer's (1973) selection experiment in mice. Six replicate experiments were performed and realized heritabilities within each replicate were estimated by comparing up- and down-selection lines to a control (High and Low, respectively) as well as to each other (Divergent). For each comparison, the estimated heritability plus or minus one standard error (using the OLS regression) is plotted, resulting in six estimates per class. Two combined estimates were also used with each yielding a single estimator for the three classes. The three Pooled estimates (for High, Low, and Divergent) used an OLS regression that took the average value over the six replicates at the data point for any given generation. The three Mean estimates correspond to the mean value of the estimates over the six replicates, with the error bars corresponding to the empirical standard error among the heritability estimates for these six different realizations. While these observed variances were larger than predicted from an OLS regression on the pooled data, this is not unexpected, as the OLS method underestimates the true standard errors.

Empirical Versus Predicted Standard Errors

While the standard error in response can be directly estimated from the among-line variance over a series of replicate lines subjected to identical selection, this approach is generally not cost-effective given the large standard error on such estimates (Chapter 12). As a result, the standard errors reported for most experiments use the pure-drift approximation discussed previously. How closely do the empirical (observed) standard errors match those predicted by the drift approximation? Unfortunately, very few experiments have addressed this issue, and those few that do often use OLS-generated standard errors (which are too small) to compare the fit with the observed among-line variance.

Perhaps the most extensive study is that of Falconer (1973), who performed two-way selection for 6-week weight in mice (Figure 18.3). Six replicate sets of lines were used. Each set consisted of a line selected for larger size, a line selected for smaller size, and an unselected control, for a total of 18 lines in the entire experiment. Realized heritabilities were estimated (by OLS regression) using the three different contrasts available within each replicate set: large versus control (High), small versus control (Low), and large versus small (Divergent).

In addition to these three estimates of \hat{h}_r^2 for each of the six replicates, Falconer also considered two combined estimates, based on all of the lines. First, a regression-based *Pooled estimate* was obtained by using the average of the six means for a given contrast (High, Low, or Divergence) as the data points in a regression. For example, the Pooled High estimate was obtained by regressing the cumulative difference between the mean of all high lines and the mean of all control lines on generations. Second, Falconer also considered a simple *Mean estimate* for the High, Low, and Divergent comparisons, which was computed as the

average of the realized heritability estimates for each comparison over all six replications.

The standard error for the Mean estimate measures the variation seen over the replicates. This is the empirical estimate of the standard error used to compare against the theoretical predictions. The average realized heritability estimates under each of the three different contrasts were very similar: 0.395, 0.331, and 0.369 for High, Low, and Divergent lines (respectively). The three Pooled estimates give very similar estimates. As expected (because OLS estimated standard errors are expected to be downwardly biased), the standard errors for the Mean estimates (based on variation between the replicate lines) were 1.6, 3.3, and 2.3 times larger than the estimated standard error computed using OLS regression of the pooled data.

A second experiment (López-Fanjul and Domínguez 1982; summarized by López-Fanjul 1982) followed 20 replicate *Drosophila* lines selected for sternopleural bristle number. They found that the empirical standard errors were less than OLS-estimated SEs, which in turn were less than GLS-estimated SEs. This is contrary to the expectation that the OLS-estimated SEs are smaller than the true variances, while the empirical and GLS-estimated SEs are expected to be roughly equal. The authors suggested that this may be at least partly due to a scale effect (LW Chapter 11), as the phenotypic variance greatly decreased during selection.

Finally, (Bohn et al. (1983) examined the variance in response to selection on pupal weight in *Triobrium castaneum*, examining three replicates from each of six different base populations. The authors found a poor fit when using Hill's (1971) variance formula, which attempts to correct for the effects of selection. Interestingly, a strong correlation was observed between departures in the predicted variance and departures from normality in the base population. The variance among replicate lines drawn from base populations with increasing (absolute) amounts of kurtosis showed larger departures from the predicted value.

Realized Heritability With Rank Data

Realized heritability estimates are not limited to normally distributed traits. Indeed, the heritability of the liability underlying a threshold trait (Chapter 14) can be computed using a realized heritability estimator, which compared performance of the offspring from different parental classes (Example 14.5; LW Chapter 25). In a similar fashion, Schwartz and Wearden (1959) considered a realized heritability estimator when the data are reduced to ranks, e.g., pecking order. They considered the case where individuals were divided into high- and low-dominance groups, by first ranking the dominance of individuals (in their case, chickens) within a flock, and then assigning those in the upper half to the high group and those in the lower half to the low group. The selection differential was computed as the difference in the mean rank of high and low parents, $a_h - a_l$. Conversely, the selection response was measured as the difference in the mean rank of progeny from high parents versus low parents, $b_h - b_l$, with

$$\hat{h}_r^2 = \frac{b_h - b_l}{a_h - a_l}$$

The authors cleverly noted how this estimator can be related to the Mann-Whitney U statistic (for comparing two sample means based on ranks; Conover 1999), and they used this to develop large-sample confidence intervals for the resulting heritability estimate.

Infinitesimal-model Corrections for Disequilibrium

Our final comment on estimation is that directional selection is expected to decrease the additive variance (and hence the heritability), due to the generation of negative gametic-phase disequilibrium (Chapters 16 and 24). Hence, realized heritability is depressed relative to the (unselected) base population value (Figure 18.4). Under the infinitesimal model, the

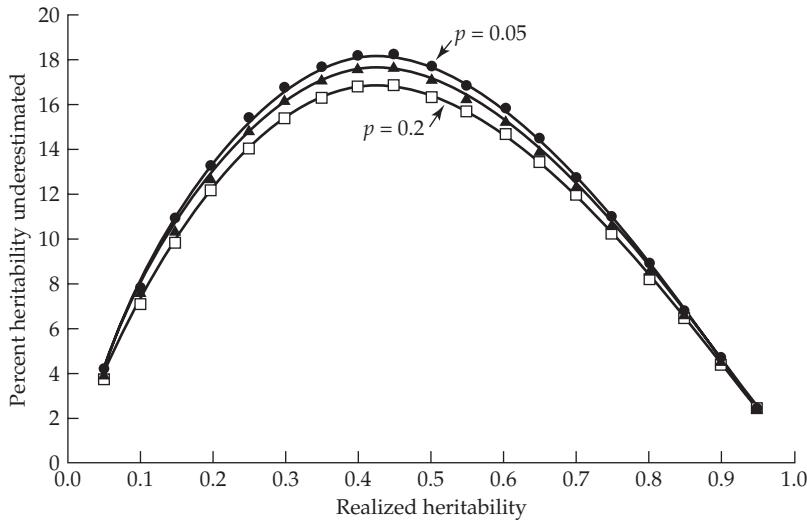

Figure 18.4 The relative percentage by which the base population heritability is underestimated by the realized heritability due to reduction in the additive variance by gametic-phase disequilibrium. The three curves correspond to different levels of directional truncation selection on a normally distributed trait, with 5% (upper curve), 10% (middle curve), and 20% (lower curve) of the population saved (corresponding to \bar{t} values of 2.06, 1.75, and 1.40, respectively). Values were obtained by numerically solving Equation 18.21 and assuming the infinitesimal model (no significant selection-induced changes in allele frequencies) holds.

majority of this decrease occurs over the first few generations, after which the heritability is essentially at its equilibrium value, \tilde{h}^2 , where (from Equations 16.13a and 16.13c)

$$\tilde{h}^2 = \frac{\gamma}{1 + \gamma - h^2} \quad \text{with} \quad \gamma = \frac{2h^2 - 1 + \sqrt{1 + 4h^2(1 - h^2)\kappa}}{2(1 + \kappa)} \quad (18.21)$$

Here h^2 is the (unselected) base population heritability and κ is a measure of the reduction in phenotypic variance due to selection (the variance following selection being $(1 - \kappa) \sigma_z^2$; Equation 16.10a). In particular, $\kappa = \bar{t}(\bar{t} - z_{[1-p]})$ for truncation selection that saves a fraction, p , of the population for a normal trait (Table 16.1). One can thus approximately treat the realized heritability as an estimate of the equilibrium heritability ($\hat{h}_r^2 \simeq \tilde{h}^2$), using Equation 18.21 to numerically solve for the base population heritability (h^2), an approach first used by Atkins and Thompson (1986). Figure 18.4 shows the relative percentage by which the base population heritability is underestimated by the uncorrected realized heritability.

Example 18.6. What are the disequilibrium-corrected estimates for the realized heritability values obtained in Examples 18.2 and 18.3? Recall that for this experiment, $p = 20/100 = 0.2$. From Example 16.3, this value of p yields $\kappa = 0.781$. Substituting this value into Equation 18.21 and using each of the three previous estimates of h_r^2 gives infinitesimal-model corrected realized heritabilities as:

Estimator	Estimate of h_r^2	
	Uncorrected	Corrected
Unweighted least-squares regression, \hat{b}_C (OLS)	0.22	0.25
Total response/total differential, \hat{b}_T	0.21	0.24
Weighted least-squares regression, \hat{b}_C (GLS)	0.22	0.25

If we assume that the infinitesimal model is a reasonable approximation over the course of this experiment, all three methods underestimated the base population heritability by about 13% (see Figure 18.4).

EXPERIMENTAL EVALUATION OF THE BREEDER'S EQUATION

Although the breeder's equation requires a number of assumptions (Table 13.2) and, strictly speaking, holds only for a single generation of selection from an unselected base population, the general claim is that it is usually satisfactory (using the base population h^2 value) over a few (5–10) generations (e.g., Falconer 1981). A slightly more refined statement is that the number of generations should not exceed $N_e/2$ (Hill 1977a), as drift significantly changes the genetic variance within a line after this amount of time has elapsed (Equation 11.2). After a sufficient number of generations, drift and selection change the genetic variances substantially from their base population values, and the breeder's equation (using the initial heritability value) fails (Chapters 24–26).

Our concern here is the adequacy of the breeder's equation for short-term artificial selection experiments, with other empirical trends from selection experiments (both short- and long-term) reviewed in Chapters 25 and 26 and with response in natural populations examined in Chapter 20. Starting with the first formal comparisons by Reeve and Robertson (1953) and Clayton and Robertson (1957), a number of authors have compared their observed short-term responses with those predicted from the breeder's equation. As summarized below, the results are mixed. One complication is that most analyses use ordinary (unweighted) least squares, resulting in significantly underestimated standard errors. Likewise, almost all realized heritability estimates have not been adjusted for the expected decline due to gametic-phase disequilibrium.

Most Traits Respond to Selection

Before delving into the goodness-of-fit of the breeder's equation, it is important to emphasize a fundamental observation in quantitative genetics: ***Most traits in outbred populations respond to selection.*** This is such a fundamental observation that the few exceptions are classic and well-known. The first such exception is sex ratio in chickens. Despite enormous economic incentive to create female-biased lines, to our knowledge this has not happened.

The second exception is selection for **directional asymmetries**, DA, (i.e., “handedness”) in traits in *Drosophila* (Lewontin 1974). While selection to change the *variance* in asymmetry is usually successful (Chapter 17), attempts to select for a consistently higher trait value on one *specific* side of an organism (such as more bristles on the right side) when DA are absent in the base population have historically been unsuccessful (Maynard Smith and Sondhi 1960; Purnell and Thompson 1973; Coyne 1987; Tuinstra et al. 1990; Carter et al. 2009). Because there are numerous examples, such as handedness of the larger claw in fiddler crabs and wing features in many insects (reviewed by Pélabon and Hansen 2008), of such directional asymmetries in nature, this lack of response is intriguing. Two studies offer some potential insight. First, Pélabon et al. (2005) observed changes in DA as a correlated response to selection on an index of wing traits in *Drosophila*. The key difference from previous unsuccessful experiments is that this index itself showed DA in the control population, while the previously cited failures of response in DA occurred in traits that initially were symmetric. Hence, when DA are already present, it may be possible to amplify them via selection. Second, Rego et al. (2006) found significant genetic variation in DA following hybridization of two closely related *Drosophila* species, showing that there is at least between-population genetic variation in DA for some traits.

When we move from univariate to multivariate traits, the notion that each trait usually responds to selection is less clear. There often appear to be serious constraints (i.e., little

Table 18.1 Comparison of realized heritabilities (\hat{h}_r^2) and heritability estimates based on resemblances between relatives (\hat{h}^2). Within each group, the table gives the distribution of the percent absolute disagreement ($|\hat{h}^2 - \hat{h}_r^2|/\hat{h}_r^2$) between the two estimates, where n is the number of experiments considered for each species group. For example, 8% of the 60 *Drosophila* experiments had a percent absolute disagreement between estimates of 30% to 50%. (After Sheridan 1988.)

Species	Distribution of absolute disagreement (relative to \hat{h}_r^2)					n
	0–10%	10–20%	20–30%	30–50%	>50%	
<i>Drosophila</i>	0.48	0.12	0.05	0.08	0.27	60
<i>Tribolium</i>	0.31	0.08	0.12	0.38	0.12	26
Mice and rats	0.23	0.00	0.13	0.23	0.41	39
Poultry and quail	0.20	0.05	0.17	0.05	0.54	41
Swine and sheep	0.20	0.00	0.10	0.20	0.50	10
Summary over all groups						
Laboratory species	0.37	0.07	0.09	0.19	0.28	125
Commercial species	0.19	0.05	0.18	0.11	0.47	62
All species	0.31	0.06	0.12	0.17	0.34	187

genetic variation) for specific combinations of traits, despite significant heritabilities in each component. In such settings, selection on *only* a specific trait results in a response, while selection on that trait as part of a multivariate selection index may not yield any response, or even may yield a response in the opposite direction of selection on that trait (Volume 3).

Sheridan's Analysis

One of the most extensive reviews of the fit of the breeder's equation is that of Sheridan (1988), who examined 198 experiments involving laboratory and domesticated animals and compared realized heritabilities with estimates of heritability based on resemblances between relatives. Sheridan first considered those experiments in which the base populations already had an extensive past history of artificial selection on the target trait. In these populations, the response was very poorly predicted by the breeder's equation, with all 11 experiments (6 in *Drosophila*, 2 in *Tribolium* and 3 in mice) showing greater than 50% disagreement between the realized and estimated (i.e., base population) heritabilities.

Table 18.1 shows the fit for the remaining 187 experiments, namely, for those traits without an extensive past history of artificial selection. As the data show, the fit was rather poor in many experiments—roughly half have a disagreement of at least 30%, and one in three exceeds 50%. In addition to the biological reasons listed in Table 13.2, there are also design issues that could account for the apparently poor fit. First, none of the experiments reviewed by Sheridan corrected for the expected decline in the realized heritability due to gametic-phase disequilibrium. Second, small absolute disagreements can translate into large relative percentages of disagreement for traits with low heritabilities (Hill and Caballero 1992). For example, $|\hat{h}^2 - \hat{h}_r^2| = 0.04$ is a 20% relative disagreement if $\hat{h}_r^2 = 0.2$, but an 80% disagreement if $\hat{h}_r^2 = 0.05$. Third, variance in response will also generate some level of disagreement. This raises the questions as to which differences in the table are significant. As a rough approximation, Sheridan considered the disagreement to be significant if it exceeded two standard errors (which amounts to $p < 0.05$ if the data are normally distributed). Assuming the two estimates are uncorrelated, the variance for their difference is the sum of the variance for each estimate, giving a standard error of

$$\text{SE}(\hat{h}^2 - \hat{h}_r^2) = \sqrt{\left(\text{SE}[\hat{h}^2]\right)^2 + \left(\text{SE}[\hat{h}_r^2]\right)^2} \quad (18.22)$$

Table 18.2 Tests of significance between relative-based estimates of h^2 and realized heritabilities. Differences of more than two standard errors (computed from Equation 18.22) were regarded as significant. Only those experiments (from Table 18.1) with estimated standard errors for both heritability estimates are included. As above, n denotes the number of such experiments. Given that most studies use OLS (resulting in SEs that are too small), the fraction of significant differences is best viewed as an upper bound. (After Sheridan 1988.)

Species	Proportion of Significant Differences	Total
<i>Drosophila</i>	0.23	61
<i>Tribolium</i>	0.27	26
Mice and rats	0.18	34
Poultry and quail	0.45	11
Swine and sheep	0.53	15
Summary over all groups		
Laboratory species	0.21	131
Commercial species	0.37	30
All species	0.25	151

Table 18.3 Agreement between realized and estimated base population heritability as a function of the duration of the experiment. (After Sheridan 1988.)

Generations	Percent absolute disagreement (relative to \hat{h}_r^2)			n
	0–10%	10–30%	> 30 %	
1–5	0.18	0.27	0.55	44
6–10	0.24	0.17	0.59	98
10–15	0.52	0.10	0.38	90

Taking those 131 experiments with standard errors for both \hat{h}_r^2 and \hat{h}^2 , Table 18.2 shows that 25% had realized heritabilities significantly different from \hat{h}^2 . One problem with this approach is that most of the reported standard errors for \hat{h}_r^2 used by Sheridan were based on unweighted least-squares (OLS), which underestimates the true standard error, giving confidence intervals that are too narrow and thereby inflating the level of significance. The overall 25% of experiments reported by Sheridan as showing a significant departure from the predicted response is thus an *upper bound*, suggesting that the breeder's equation may not be doing such a poor job after all.

Finally, Sheridan looked at the goodness-of-fit as a function of the duration of the experiment (Table 18.3). Surprisingly, longer experiments tended to have a better fit. While this is contrary to expectations, it could simply be a design artifact. In many cases, longer experiments employ larger population sizes than experiments of shorter duration, thus reducing the effects of drift.

Realized Heritabilities, Selection Intensity, and Inbreeding

In addition to quantitative differences in the predictions of the breeder's equation discussed above, there are also reported cases of major *qualitative* departures. For example, the breeder's equation predicts that while selection response should increase with selection intensity, the ratio of response to selection differential, R/S , should be constant. Some studies have reported a dependence of realized heritability on the selection intensity, although a survey of selection experiments found no consistent pattern (Table 18.4).

Table 18.4 Summary of experiments examining the effects of selection intensity on \hat{h}_r^2 .

Abdominal bristles in <i>D. melanogaster</i> Clayton and Robertson (1957)	\hat{h}_r^2 decreases with increasing selection intensity.
Abdominal bristles in <i>D. melanogaster</i> Frankham et al. (1986)	Agreement between base population estimate of h^2 and \hat{h}_r^2 is best at highest selection intensity, becoming worse as selection intensity decreases.
Postweaning weight gain in mice Hanrahan et al. (1973)	No consistent effect of selection intensity on \hat{h}_r^2 .
Pupal weight in <i>Tribolium castaneum</i> Meyer and Enfield (1975)	\hat{h}_r^2 decreases with selection intensity in down-selected lines; no effect in up-selected lines.
Kernal oil content in maize Silvela et al. (1989)	No effect of selection intensity on \hat{h}_r^2 .

Table 18.5 Results of experiments examining the effects of finite population size and inbreeding on short-term response. Chapter 26 examines drift and long-term response in more detail.

Wing length in <i>D. melanogaster</i> Tantawy and Reeve (1956)	Short-term response for outbreds > double first cousins > sib mating.
Gonadotrophic hormone level in rats Chung and Chapman (1958)	Outbred and crossbred lines had larger short-term responses than inbred lines.
Body size in mice Lewis and Warwick (1953)	The outbred line had a larger short-term response than an inbred line.
Abdominal bristles in <i>D. melanogaster</i> Frankham et al. (1968a)	Weak trend for larger population sizes to have a greater short-term response.
Postweaning weight gain in mice Hanrahan et al. (1973)	Short-term response increased with increasing population size.
Kernal oil content in maize (Silvela et al. 1989)	Short-term response increased with increasing population size.

There are several reasons why a dependency may arise between realized heritability and selection intensity. First, increasing the selection intensity increases gametic-phase disequilibrium, thus reducing σ_A^2 and hence \hat{h}_r^2 (Chapter 16). As Figure 18.4 shows, the prediction is that (uncorrected) realized heritabilities should decrease with increasing selection intensity (albeit only slightly in many cases). Again, essentially none of the reported selection experiments correct for this expected reduction. Second, allele frequencies are expected to change more rapidly as the strength of selection increases. Whether this results in an increased or decreased response depends on the initial distribution of allele frequencies and effects (see the discussion on genetic asymmetries below).

Finally, N_e decreases as selection intensity increases (Chapter 3 and 26), thus increasing the amount of inbreeding and (generally) reducing the additive variance (Chapter 11). When inbreeding occurs, the short-term response is generally found to be less than that predicted from the breeder's equation when using variance components estimated from the base population (Table 18.5). This is expected, as inbreeding (generally) decreases the additive genetic variance within a line (Chapter 11), thus reducing response. Exceptions can occur if nonadditive genetic variance is present, in which case inbreeding may actually result in an *increase* in the within-line additive variance (Chapter 11), increasing response. The effects of drift on long-term experiments are examined in detail in Chapter 26. Inbreeding depression is another complication, which we will address shortly.

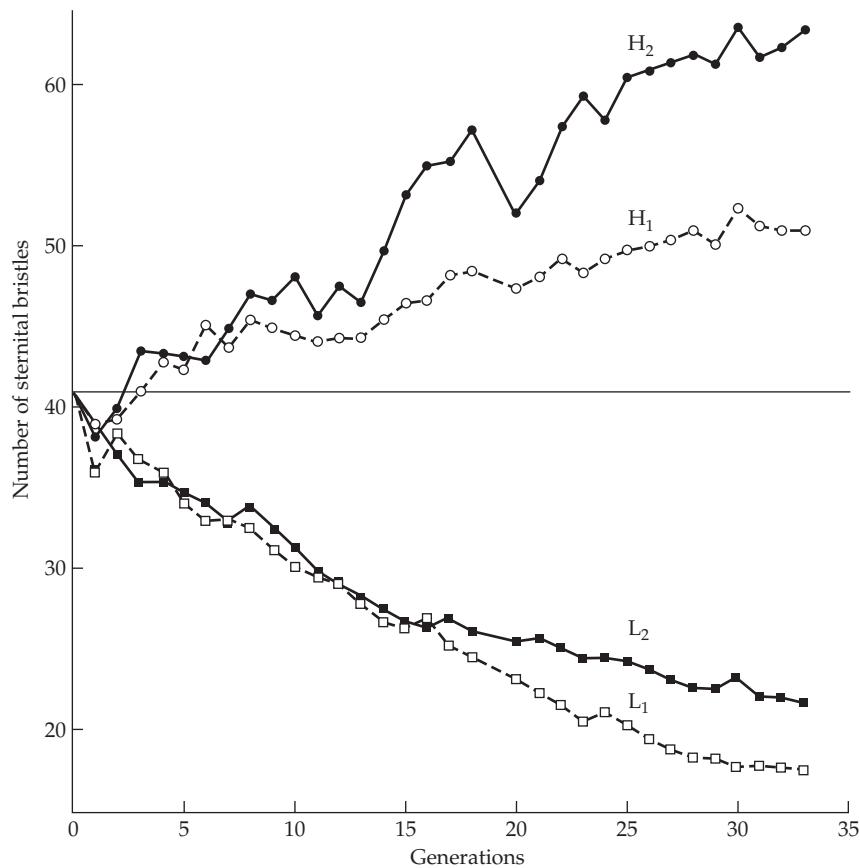

Figure 18.5 Selection response on abdominal bristle number in male *Drosophila melanogaster*. Two replicates in each direction (High and Low) were performed, all with the same selection differential. Contrary to the symmetric response expected under the breeder's equation, an asymmetric selection response was observed. (After Sheldon 1963.)

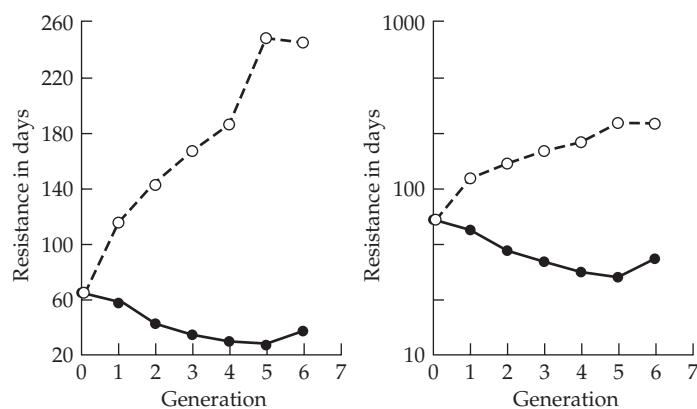

Figure 18.6 An example of a scale effect generating an asymmetric selection response. **Left:** Selection for resistance to dental caries (cavities) in albino rats (*Rattus norvegicus*), response measured as the expected number of days to develop caries on a standard diet. **Right:** The same data presented on a log scale show a symmetric response. (Based on Falconer's 1954 analysis of data from Hunt et al. 1944.)

Table 18.6 Possible explanations for asymmetric response (including reversed response).

Design artifacts	Drift (Chapter 12) Scale effects (LW Chapter 11) Different effective selection differentials (Chapter 13) Undetected environmental trends (Chapter 20) Transient effects from previous selection in the base population, e.g., decay of response from $A \times A$ or genetic maternal effects (Chapter 15) Undetected selection on correlated characters (Chapter 20)
Nonlinear parent-offspring regressions	Major genes with dominance (LW Chapter 17) Genotype \times environment interactions (Volume 3) Departures from normality (Chapter 24)
Other sources	Genetic asymmetries (this chapter) Inbreeding depression (Chapter 23) Maternal effects (Chapters 15 and 22) Associative effects (Chapter 22)

Asymmetric Selection Response

A common design is to perform a **divergent selection experiment**, wherein replicate lines are selected in opposite directions. Many such experiments (e.g., Figures 18.5–18.8) show different amounts of response in the up versus down direction, a phenomenon referred to as an **asymmetric selection response** (Falconer 1954). This is in sharp contrast with the expectation from the breeder's equation, which predicts that the absolute magnitude of response should depend only the absolute value of S , and not on its sign.

There are a variety of possible explanations for asymmetric responses (Table 18.6). They may simply be artifacts of experimental design or analysis. In particular, the prediction of equal positive and negative slopes holds only for plots of cumulative responses versus cumulative *selection differentials*, $R_C(t)$ versus $S_C(t)$. Asymmetry in response based on differences in slope of cumulative response versus *generations* of selection, $R_C(t)$ versus t , can thus be misleading, as the different lines may have experienced different amounts of selection. Likewise, differences in response could simply be scale effects (Figure 18.6; see LW Chapter 11). For example, if the genetic variance increases with the mean, the heritability can also increase with the mean, resulting in a faster response in the upwardly selected lines. Asymmetric differences in selection response can also be due to biological features that were not considered by the design. For example, even if the amount of *artificial* selection is the same in both directions, there may be major differences in *natural* selection (e.g., up-selected lines might experience lower fertility). Using effective selection differentials (Equation 13.9) corrects for this source of bias, but the investigator often lacks the data (e.g., fertilities for each parent) necessary to compute them. Likewise, we have seen that if a population has been under previous selection, its mean can change even after selection has stopped (Chapter 15). If we start a divergent selection experiment using such a nonequilibrium population as our base, we can bias the response in at least one direction, thus generating an asymmetric response even when the true genetic trend from the experiment is symmetric.

Even though lines may have quite different values of \hat{h}_r^2 , there remains the issue of whether these differences are statistically significant. Genetic drift can generate considerable variation between replicate lines, and it is important to distinguish between real differences in the expected response and the variation among realizations of a process with the same (absolute) expected value. Directional trends in the environment can also produce asymmetries, inflating the apparent response in the direction of the trend and retarding it in the opposite direction. An example of this can be seen in the bottom graph in Figure 18.7. If one simply compares the High and Low lines, a clear asymmetric response is seen.

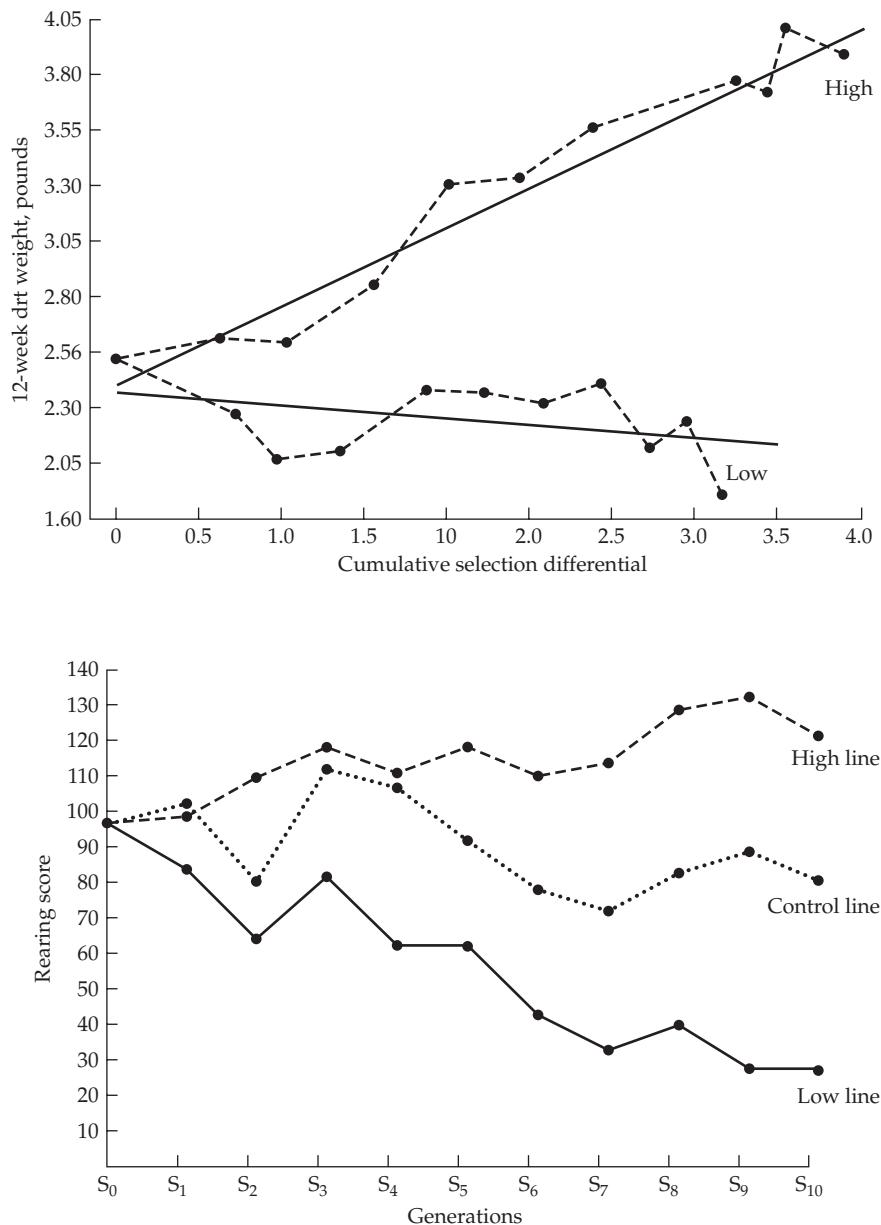

Figure 18.7. Further examples of asymmetric response to selection. **Top:** Twelve-week body weight in chickens (Maloney et al. 1963). **Bottom:** Rearing activity in rats (Sanders 1981).

However, when comparing each line as measured as a deviation from the Control line, the response is much more symmetric.

Although spurious asymmetric responses can result from these defects in design and analysis, true asymmetric responses can be generated by a variety of genetic situations. For example, if the parent-offspring regression is nonlinear, S will not be sufficient to predict the response (Gimelfarb and Willis 1994; Chapters 6, 13, and 24), and it is not surprising that asymmetric responses can be generated in such cases. Failure to initially detect departures from linearity in the base population does not rule out nonlinearity as an explanation for an observed asymmetric response, as the range of variation in the base population may not be sufficient to detect any such departures at the extreme ends of the initial range of phenotypes. As the selected lines diverge, however, differences in the tails of the initial

phenotypic distribution can be revealed. Likewise, as previously mentioned, heritability can be a function of the part of the phenotypic distribution from which individuals are drawn (e.g., Skibinski and Shereif 1989).

Characters displaying inbreeding depression (LW Chapter 10) show an asymmetric selection response, with the change in mean from inbreeding accentuating the response in one direction and retarding it in the other. A simple test for inbreeding as an explanation of an asymmetric response is to see whether the mean of an unselected control population (when inbred) changes in the direction of greater response. The effects of inbreeding depression can be corrected by inbreeding a control population to the same level as the divergent selection lines and using the contrast between selected and control lines to estimate response. However, this process is not necessarily as straightforward as it appears, as selection generally increases the amount of inbreeding within a line by decreasing its effective population size (Chapters 3 and 26). Simply keeping the control line at the same size as the selected lines thus underestimates the amount of inbreeding (and hence any correction for inbreeding depression), especially when selection is intense. An alternative tests is to cross two replicate lines, with heterosis in the resulting F_1 indicating inbreeding depression.

The assumption of negligible allele-frequency change over a few generations of selection can be violated when alleles of major effect are segregating. In this setting, asymmetries can arise as a consequence of allele frequencies changing in different directions in the differentially selected populations. An increase in an allele from its initial frequency nearly always results in a different additive variance from that produced by an equal decrease in frequency. Falconer (1954) refers to this feature as **genetic asymmetry**. This is most easily seen by considering LW Figure 4.6, which shows additive genetic variation as a function of allele frequency for a single diallelic locus. If alleles are completely additive, then σ_A^2 as a function of allele frequency is symmetric about $p = 1/2$. Suppose that the frequency of an allele that increases the character value is initially below 1/2. In upwardly selected lines, σ_A^2 (and h^2) increase as this allele increases to a frequency of 0.5 and decrease when it exceeds this value. Conversely, in downwardly selected lines, the contribution to σ_A^2 from this locus always decreases. If dominance is present, then σ_A^2 will no longer be a symmetric function of allelic frequencies (LW Figure 4.8) and asymmetric changes in the contribution to σ_A^2 from a single locus are almost always expected.

Frankham and Nurthen (1981) provided an interesting example of this phenomena. They started with a base population with the major recessive allele sm^{lab} (which greatly reduces abdominal bristle number in *Drosophila melanogaster*) at low frequency. As shown in Figure 18.8, in two of three down-selected lines, this allele increased in frequency, resulting in a large increase in h^2 as the sm^{lab} allele reached intermediate frequencies. Presumably, this allele was either lost or not sampled when Line 1 was formed, as it does not show this pattern. Heritability returned to the base population value as this allele approached fixation, suggesting much smaller allele-frequency change in the residual polygenic genetic variation that remains once the major allele has been removed.

While we have focused on the effects of a single major gene, the effects of unequal allele frequencies apply to any QTL. Alleles of small effect are expected to have slower changes in allele frequencies (and thus are expected to have smaller effects on asymmetry) over the time scales of most short-term experiments. Hence, if many loci of small effect underlie a character, the effects of genetic asymmetry on selection response are expected to be slight unless the number of generations is large. Further, at least some cancellation is expected between the asymmetries in σ_A^2 generated by allele-frequency changes at different loci. Analogous to directional dominance being required for inbreeding depression (a systematic trend in the direction of dominance over loci; LW Chapter 10), there must also be some systematic trend in the allele frequencies at loci underlying the trait for genetic asymmetries to occur (in the absence of major genes). For example, if most alleles that decrease the trait value tend to be rare, then up-selected versus down-selected lines are expected to show an asymmetric response as allele-frequency changes become significant, with the rare alleles increasing (and increasing variance) in the down-selected, but not the up-selected, lines.

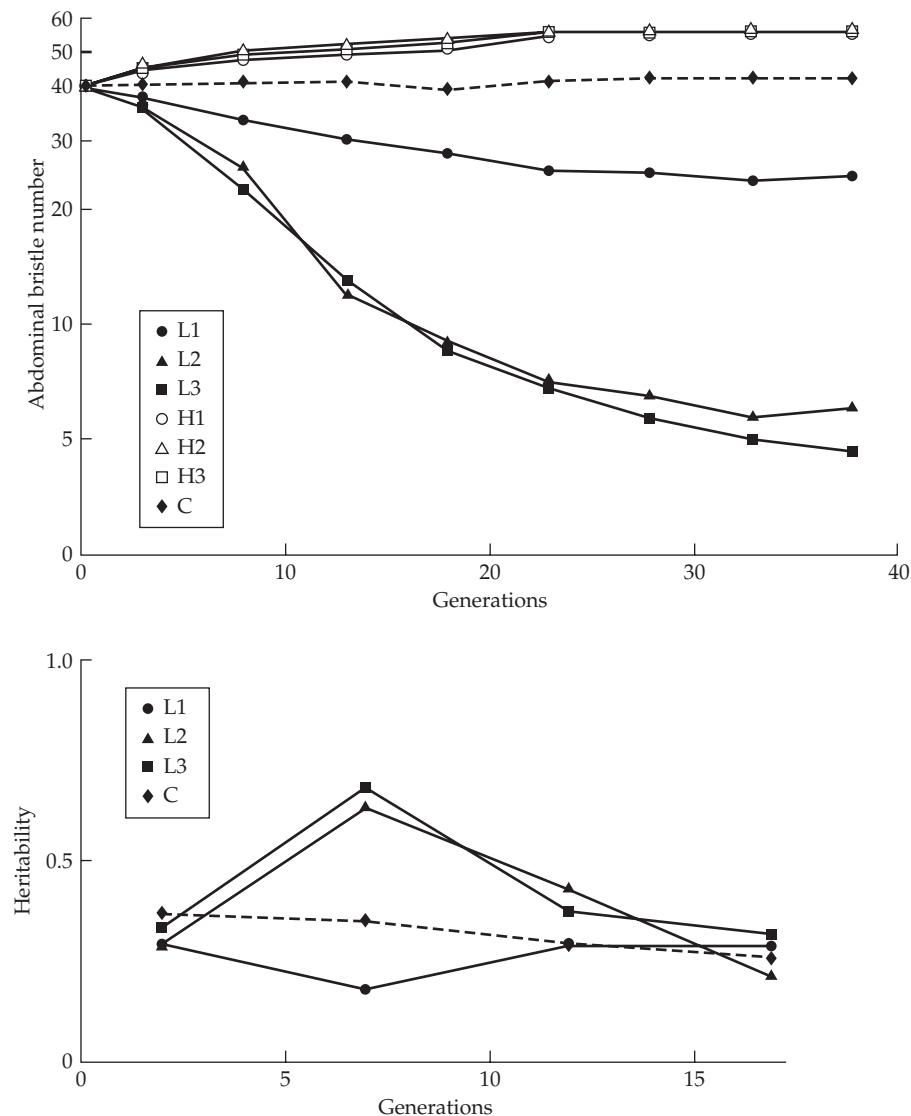

Figure 18.8 **Top:** Asymmetric selection response for abdominal bristle number in *Drosophila melanogaster* from a base population containing a major allele (sm^{lab}) that was initially at low frequency. L1–L3 are three replicate low lines, H1–H3 are three replicate high lines, and C is the control line. Data were log-transformed to remove scale effects, and on this new scale, low line L1 has a symmetric response with high lines H1–H3, while lines L2 and L3 do not. Further, there is also a greater variance in response among the low lines. **Bottom:** Changes in heritabilities in the control (dashed curve) and lines L1–L3. Heritability was estimated from phenotypic correlations between bristle numbers of adjacent segments of the same fly (see Frankham and Nurthen [1981] for details). Note the large increases in heritability for lines L2 and L3, the lines that show an asymmetric selection response (relative to H1–H3), while the heritability is roughly constant in L1, which does not show an asymmetric response. The increase in h^2 reflects an increase in the major allele sm^{lab} due to selection. This allele increased rapidly in frequency after generation 5 and was essentially fixed by generation 10, which is reflected by a rapid increase in h^2 after generation 5, with h^2 returning to normal (the level in the unselected control) as the allele becomes fixed. (After Frankham and Nurthen 1981.)

When might such an asymmetric distribution of allele frequencies be present? One situation is that where there has been a recent history of selection on the trait before the start of the

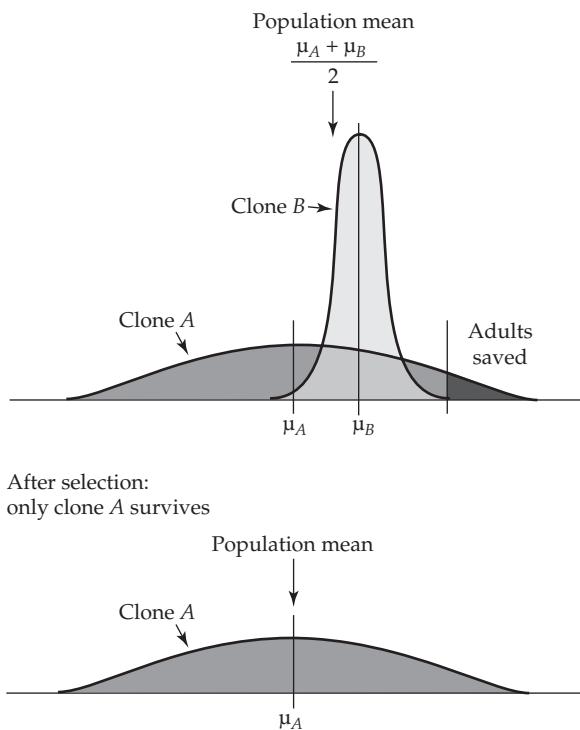

Figure 18.9 Haldane's (1931) example of a reversed response generated by genotype \times environment interaction. The population consists of equal numbers of two asexual clones, *A* and *B*. The mean phenotypic value of *A* (μ_A) is less than the mean phenotypic value of *B* (μ_B). However, clone *A* has a larger environmental variance than *B*. Strong truncation selection culls out all members of clone *B* in the population, leaving only *A*. The new mean in the generation following selection, μ_A , is less than the mean before selection, $(\mu_A + \mu_B)/2$. In this case, selection for *increased* character value z , resulted in a *lowering* of the population mean.

artificial selection experiment.

Components of reproductive fitness, such as fecundity and development time, are expected to have asymmetric allele frequencies, as natural selection increases the frequency of alleles increasing fitness. This condition suggests that asymmetric responses in the selection for reproductive traits are expected, and it further predicts that response should be larger in lines selected for a decrease in reproductive fitness. This was seen in a review by Frankham (1990), who found a larger response in the direction of reduced reproductive fitness in 24 of 30 experiments. Frankham suggested that the presence of rare recessives decreasing reproductive fitness was the most likely cause for this trend. As Figure 25.2 will show, very marked asymmetric responses are expected in such situations.

Reversed Response

The most extreme departure from the breeder's equation is a **reversed response**, a response in the *opposite* direction of selection. Negative maternal effects can result in such a response (Figures 15.3 and 15.4). Likewise, they can arise from sufficiently large genotypic-dependent environmental variances (Haldane 1931; Chapter 17). Haldane's intuition was based on selection with two asexual clones, the first with a higher mean but smaller environmental variance than the second. As shown in Figure 18.9, if the most extreme individuals are selected, there will be an excess of the clone with the smaller mean but higher variance, resulting in a decrease in mean value in the next generation. Wright (1969) expanded Haldane's model to a single diallelic locus. Gimelfarb (1986b) presented a particularly interesting analysis when there is a multiplicative genotype \times environment interaction, showing for this model that

while *phenotypes* are subjected to directional selection, the nature of the interaction between genotype and environment is such that *genotypic* values can actually be under either stabilizing or disruptive selection. The interesting feature of both Haldane's and Gimelfarb's models is that reversed response is most probable when selection is very intense, as this is the setting most favorable to genotypes with high variances (Chapter 17).

Important, and not yet widely appreciated, sources of reversed response are **associative effects** (also called **social effects** or **indirect genetic effects**), of which maternal effects are a special case. As introduced by our discussions on maternal effects in Chapter 15, and more fully developed in Chapter 22, the environment that a focal individual experiences can be strongly influenced by its neighbors. In such cases, an individual's phenotype is the result of both **direct effects**, due to its own intrinsic genes, and **social effects**, from its neighbors. If the latter have a heritable component, these effects can also evolve. If direct and social effects are genetically negatively correlated, a positive response in the direct trait can be overcome by a negative social response, resulting in a net *decrease* in trait value. Consider selection for egg production in caged chickens. Aggressive individuals gather more food in the cage thus producing more eggs. With selection based solely on individual egg production, more aggressive chickens are chosen (i.e., those with negative associative effects), creating a deleterious cage environment that can overshadow any direct genetic advance in terms of number of eggs, resulting in a *reduction* in the number of eggs per cage in the next generation.

CONTROL POPULATIONS AND EXPERIMENTAL DESIGNS

We conclude this chapter by considering several specialized issues in the analysis of selection experiments, topics that may be skipped by the casual reader. We first examine the strengths and weaknesses of different types of designs (such as the use of a control population), then consider optimal designs, and finish with a discussion of a modified line-cross analysis (LW Chapter 9) to examine the genetic components of a selection response.

One complication with estimating realized heritabilities is distinguishing between genetic versus environmental trends. For example, Newman et al. (1973) found that 60% of the increase in yearling weight in a selected line of Shorthorn cattle was due to environmental, rather than genetic, improvement. Using a large unselected **control population** reared under the same environmental conditions as the selected line or lines allows for correction of such between-generation environmental changes (e.g., the bottom graph in Figure 18.7). Hill (1972a, 1972b) reviewed this approach and some of the features seen in control populations from a number of different species. The use of control populations is not a foolproof approach for removing environmental trends, as the control and selected lines can evolve different genotype \times environment interactions. Likewise, extensive genetic drift in the mean of the control population can also result in biases, resulting in the corrected (selection minus control) values underestimating or overestimating the true selection trend. When full pedigree data are available, the powerful methods of mixed-model analysis (Chapter 19) can be used to remove genetic and environmental trends, even in the absence of control populations (although incorporating such controls is preferred). Undetected environmental trends are especially problematic in the analysis of response in natural populations (Chapter 20).

Basic Theory of Control Populations

Assuming no genotype \times environment interaction, the true mean of a line in generation t can be decomposed as $\mu + g_t + b_t$, where μ is the base population mean, g_t is the change in mean breeding value due to selection and drift, and b_t is the change in mean due to environmental change. Under this model, observed means, \bar{z} , for a selected (s) and control (c) population reared in a common environment can be decomposed as

$$\bar{z}_{s,t} = \mu + g_{s,t} + b_{s,t} + e_{s,t} \quad (18.23a)$$

$$\bar{z}_{c,t} = \mu + g_{c,t} + b_{c,t} + e_{c,t} \quad (18.23b)$$

where e_t is the error in estimating the mean breeding value ($\mu + g_t$) from the observed mean, corrected for the change in the environment ($\bar{z}_t - b_t$), and has an expected value of 0.

Assuming that the breeder's equation holds, the expected total (i.e., cumulative) response at generation t is $E[R_C(t)] = E[g_{s,t}] = h^2 S_C(t)$. Under drift alone, there is no expected directional change in the mean breeding value of the control population, $E[g_{c,t}] = 0$. If we assume that there are no genotype \times environment interactions (i.e., $b_{s,t} = b_{c,t}$), the contrast between the selected and control populations has an expected value of

$$E[\bar{z}_{s,t} - \bar{z}_{c,t}] = E[g_{s,t}] - E[g_{c,t}] = h^2 S_C(t) \quad (18.24a)$$

If the control population is small, $g_{c,t}$ can drift significantly away from zero, resulting in an overestimation (or underestimation) of the true selection response. If the goal is simply to remove an environmental trend, control populations should be kept as large as possible so that $g_{c,t}$ is close to zero. However, as previously mentioned, control populations are also used in an attempt to correct for any effects of inbreeding depression. In such cases, the size of the control population is usually on par with that for the selected population, meaning that significant drift has likely occurred. In this setting, the use of a control population may introduce additional uncertainty in the estimate of the response (which may be more than compensated for by the control accounting for inbreeding depression and environmental trends).

If genotype \times environmental interactions are present, then

$$E[\bar{z}_{s,t} - \bar{z}_{c,t}] = h^2 S_C(t) + (b_{s,t} - b_{c,t}) \quad (18.24b)$$

resulting in $\bar{z}_{s,t} - \bar{z}_{c,t}$ being a potentially biased estimator of $h^2 S_C(t)$. In principle, if the environmental trends are positively correlated between populations, then the use of a control will still improve the estimate of the genetic trend. If they are negatively correlated, however, the use of a control can lead to a less accurate estimate than simply using a selected population without a control. As discussed in Chapter 19, mixed-model analyses may be able to provide some insights (as they estimate the $b_{x,t}$), but they require extensive information (full pedigrees) and that the model assumptions hold.

If a control population is used, the (per-generation, R_t , and cumulative, $R_C[t]$) responses and differentials are estimated by

$$R_t = (\bar{z}_{s,t} - \bar{z}_{c,t}) - (\bar{z}_{s,t-1} - \bar{z}_{c,t-1}) \quad (18.25a)$$

$$R_C(t) = \bar{z}_{s,t} - \bar{z}_{c,t} \quad (18.25b)$$

$$S_t = \bar{z}_{s,t-1}^* - \bar{z}_{s,t-1} \quad (18.25c)$$

$$S_C(t) = \sum_{i=1}^t S_i \quad (18.25d)$$

where \bar{z}^* denotes the mean of the selected individuals. If selection differs between the sexes

$$S_t = \frac{S_t(m) + S_t(f)}{2}$$

where $S_t(m)$ and $S_t(f)$ are, respectively, the observed selection differentials on males and females.

Muir (1986a, 1986b) has suggested that an analysis of covariance approach (along the lines of LW Equation 10.12) be used when extensive G \times E is expected. In its simplest form, Muir's idea is to adjust the mean of the selected population in generation i by using the deviation of $\bar{z}_{c,i}$ from its grand mean over the course of the experiment, $\bar{z}_{c,..}$, namely

$$\bar{z}'_{s,i} = \bar{z}_{s,i} - \beta(\bar{z}_{c,i} - \bar{z}_{c,..})$$

If there is no genotype \times environment interaction (so that the environmental effect at time i has the same influence on both the selected and control lines), then $\beta = 1$ and we recover

our previous results. However, if there is $G \times E$, such that the environmental deviation influences the control differently from the selected population, then this expression provides a less biased correction than simply subtracting off the mean of the control. Note that this covariate approach at least partly corrects for the most extreme case, namely that in which the environmental effect results in different signs in the control and selective populations ($\beta < 0$).

Divergent Selection Designs

A related approach is the **divergent** (or **bidirectional**) selection design, wherein one compares lines that were selected in opposite directions. Again assuming there are no significant genotype \times environment interactions between lines, the basic statistical model for this design is

$$\bar{z}_{u,t} = \mu + g_{u,t} + b_{u,t} + e_{u,t} \quad (18.26a)$$

$$\bar{z}_{d,t} = \mu + g_{d,t} + b_{d,t} + e_{d,t} \quad (18.26b)$$

where the subscripts u and d refer to the upwardly and downwardly selected lines, respectively. Using this design (and assuming that $b_{u,t} = b_{d,t}$), the responses and differentials are estimated by

$$R_t = (\bar{z}_{u,t} - \bar{z}_{u,t-1}) - (\bar{z}_{d,t} - \bar{z}_{d,t-1}) \quad (18.27a)$$

$$R_C(t) = \bar{z}_{u,t} - \bar{z}_{d,t} \quad (18.27b)$$

$$S_t = (\bar{z}_{u,t-1}^* - \bar{z}_{u,t-1}) - (\bar{z}_{d,t-1}^* - \bar{z}_{d,t-1}) \quad (18.27c)$$

Again, the expected response (using Equations 18.27a and 18.27c for the response and selection differentials) is simply $R = h^2 S$. More generally, if $S_{x,i}$ denotes the selection differential in line x at generation i , the total (cumulative) expected divergence between lines is

$$R_C(t) = h^2 \sum_{i=1}^t (S_{u,i} - S_{d,i}) = h^2 (S_{C,u} - S_{C,d}) \quad (18.27d)$$

Variance in Response

Recall the pure-drift approximation for the variance (Equation 18.8) and the within-line covariance across generations (Equation 18.9) for the design of a single selected line. Here we present corresponding expressions for the selection plus control and divergence selection designs (assuming there are no genotype \times environmental interactions between lines). For unidirectional selection plus a control population

$$\begin{aligned} R_C(t) &= \bar{z}_{s,t} - \bar{z}_{c,t} = (\mu + g_{s,t} + b_t + e_{s,t}) - (\mu + g_{c,t} + b_t + e_{c,t}) \\ &= (g_{s,t} - g_{c,t}) + (e_{s,t} - e_{c,t}) \end{aligned} \quad (18.28)$$

Similarly, for divergent selection

$$R_C(t) = \bar{z}_{su,t} - \bar{z}_{sd,t} = (g_{su,t} - g_{sd,t}) + (e_{su,t} - e_{sd,t}) \quad (18.29)$$

Because each term in Equations 18.28 and 18.29 is independent, applying Equations 18.4 and 18.5 yields a pure-drift approximation for the variance in response in generation t of

$$\sigma^2 [R_C(t)] = (2f_t + B_0) h^2 \sigma_z^2 + B_t \sigma_z^2 \simeq (t A + B_0) h^2 \sigma_z^2 + B_t \sigma_z^2 \quad (18.30a)$$

and the covariance between generations within the same line

$$\begin{aligned} \sigma [R_C(t), R_C(t')] &= (2f_t + B_0) h^2 \sigma_z^2 \\ &\simeq (t A + B_0) \sigma_z^2 h^2 \quad \text{for } t < t' \end{aligned} \quad (18.30b)$$

Table 18.7 Coefficients for the pure-drift variances and covariances in response (Equations 18.30a and 18.30b). $M_{x,t}$ individuals are sampled in population x at generation t , of which N_x are allowed to reproduce. The subscripts $x = s$ and c refer to the selected and control populations, $x = u$ and d refer to the up-selected and down-selected lines, and $f_{x,t}$ refers to the amount of inbreeding in population x at time t .

Selection in a single direction without a control line. Equation 18.30a has an extra term, σ_b^2 , accounting for the between-generation variation in environmental effects.

$$f_t = f_{s,t}, \quad A = \frac{1}{N_s}, \quad B_t = \frac{1}{M_{s,t}} \quad \text{for } t \geq 0$$

Selection in a single direction with a control line.

$$f_t = f_{s,t} + f_{c,t}, \quad A = \frac{1}{N_s} + \frac{1}{N_c}, \quad B_t = \frac{1}{M_{s,t}} + \frac{1}{M_{c,t}} \quad \text{for } t \geq 0$$

Divergent selection without a control line.

$$f_t = f_{u,t} + f_{d,t}, \quad A = \frac{1}{N_u} + \frac{1}{N_d}, \quad B_t = \frac{1}{M_{u,t}} + \frac{1}{M_{d,t}} \quad \text{for } t \geq 0$$

where the (design-specific) coefficients, A and B_t , are given in Table 18.7. If the number of reproducing individuals varies over time, then the tA term is replaced by the sum over time of the components in A , for example by $\sum_{i=1}^t (1/N_i)$, or related expressions. Finally, recall (Equation 18.3) that for unidirectional selection without a control, the variance in response has an additional term, σ_b^2 , accounting for the between-generation environmental variation.

Control Populations and Variance in Response

When does using a control population in a undirectional selection experiment reduce the variance in response? Equation 18.30a, along with the coefficients from Table 18.7, gives the expected variance with and without the use of a control. Assuming $M = M_s = M_c$ and $N = N_s = N_c$, this equation yields

$$\sigma^2 [R_C(t)]_{control} - \sigma^2 [R_C(t)]_{no\ control} = \left(\frac{t}{N} + \frac{1}{M_0} \right) h^2 \sigma_z^2 + \frac{1}{M} \sigma_z^2 - \sigma_b^2 \quad (18.31a)$$

Assuming the between-line drift variance dominates (terms involving M can be ignored), the condition for the variance in response with a control to be larger than the response without one is approximately

$$t\sigma_z^2 h^2 / N > \sigma_b^2 \quad (18.31b)$$

Hence, regardless of the value of σ_b^2 , if sufficient generations are used, the optimal design (in terms of giving the smallest expected variance in response) is not to use a control. However, this approach runs the risk that an undetected directional environmental trend will

Table 18.8 Coefficients of variation (CV) for various designs, assuming the pure-drift approximation and that $\sigma^2 [R_C(t)] \simeq t Ah^2 \sigma_z^2$. The latter assumes that the selection experiment is of sufficient duration that the among-line drift dominates (i.e., $t A \gg B_0$ and $t Ah^2 \gg B_t$, with these parameters defined in Table 18.7). We assume that the absolute selection intensity in all selected lines is \bar{i} .

Selection in a single direction with a control line.

$$E[R_C(t)] = t h^2 \bar{i} \sigma_z, \quad CV[R_C(t)] \simeq \frac{1}{h\bar{i}} \sqrt{\frac{2}{Nt}} \quad (18.32a)$$

Selection in a single direction without a control line.

$$E[R_C(t)] = t h^2 \bar{i} \sigma_z, \quad CV[R_C(t)] \simeq \frac{1}{h\bar{i}} \sqrt{\frac{1}{Nt}} + \frac{1}{t h^2 \bar{i}} \left(\frac{\sigma_d}{\sigma_z} \right) \quad (18.32b)$$

Divergent selection without a control line.

$$E[R_C(t)] = 2t h^2 \bar{i} \sigma_z, \quad CV[R_C(t)] \simeq \frac{1}{h\bar{i}} \sqrt{\frac{1}{2Nt}} \quad (18.32c)$$

compromise the estimated heritability. Thus, the cost from to an increase in SE when using a control seems very worth enduring in many cases, given the more general benefits of having one or more control lines.

OPTIMAL EXPERIMENTAL DESIGNS

As Equation 18.31b illustrates, it is not entirely obvious which design is optimal. What in general can we say? The coefficient of variation (CV) of the selection response

$$CV[R_C(t)] = \frac{\sigma[R_C(t)]}{E[R_C(t)]} \quad (18.33)$$

is especially useful in comparing efficiencies of different designs, as it is independent of σ_z^2 . Further, it provides an appropriate measure of comparative efficiencies when the expected response differs between designs. Table 18.8 gives expressions for the CV under some simplifying assumptions. The coefficient of variation is a function of tN , the total number of adults selected during the course of the experiment, provided drift variance dominates the error variance. A short experiment with many selected adults per generation thus gives the same expected CV as a longer experiment with fewer adults per generation (provided the total numbers, tN , are the same). However, if the error variance is nontrivial relative to the drift variance (as would be expected if h^2 is small), increasing the duration of the experiment results in some improvement in precision (Hill 1980).

As an example of using the CV of response, consider unidirectional selection without a control population versus divergent selection. Which is more efficient if the same total number of adults are selected (e.g., N under unidirectional selection and $N_d = N_u = N/2$ under divergent selection)? If there is no between-generation environmental variance, then both designs are equally efficient, while divergent selection is more efficient if $\sigma_b^2 > 0$.

Example 18.7. Suppose we plan to select the upper 5% of a population for a normally distributed character with $h^2 = 0.25$. What value of Nt is needed for the expected CV of response to be no greater than 0.01 if no control population is used? From Example 14.1, $E[\bar{i}] = 2.06$ if the population is large, and slightly less in small populations (for simplicity we

assume the large population value applies). To solve for the value of Nt , we use the expression for the CV in response without a control line (Equation 18.32b), and further assume that the drift variance dominates, so that we ignore the contribution from σ_b^2 . This yields

$$CV = 0.01 = \frac{1}{0.5 \times 2.06} \times \sqrt{\frac{1}{Nt}}$$

which has a solution of $Nt \simeq 9426$. Hence, during the entire course of the experiment using a total of at least 9426 selected parents returns an approximate expected CV of less than 1%. If the desired CV is 0.05 or 0.10, then $Nt \simeq 377$ and $Nt \simeq 94$, respectively. It is important to stress that these numbers are somewhat misleading, in that N is the number of *saved* individuals, while $M = N/p$ is the number of *measured* individuals. For $p = 0.05$, the value of Mt is $1/0.05 = 20$ times the value of Nt , so one must measure roughly 18,900, 7540, and 1880 individuals to obtain these desired CVs.

Nicholas' Criterion

An alternative criterion for choosing Nt was suggested by Nicholas (1980). Often the investigator is interested in ensuring that at least a certain response will occur with a preset probability. To a reasonable approximation, the expected mean value in any given replicate selection line after t generations of selection is normally distributed, with a mean of $E[R_C(t)]$ and a variance of $\sigma^2 [R_C(t)]$. Consider the probability that the observed response is at least β of the expected response

$$\begin{aligned} \Pr \left(R_C(t) > \beta E[R_C(t)] \right) &= \Pr \left(\frac{R_C(t) - E[R_C(t)]}{\sigma [R_C(t)]} > \frac{(\beta - 1)E[R_C(t)]}{\sigma [R_C(t)]} \right) \\ &= \Pr \left(U > \frac{\beta - 1}{\text{CV}[R_C(t)]} \right) \end{aligned} \quad (18.34)$$

where U is a unit normal random variable. Note that the probability that the observed response *exceeds* the expected response ($\beta = 1$) is one half, as $\Pr[U > 0] = 1/2$.

Example 18.8. Again suppose that $\bar{t} = 2.06$, $h^2 = 0.25$, and the design is unidirectional selection without a control population. What value of Nt is required in order to obtain a 95% probability that the observed response is at least 90% of its expected response? Here, $\beta = 0.9$ and $\Pr[U > -1.65] = 0.95$. Hence,

$$\frac{\beta - 1}{\text{CV}[R_C(t)]} = \frac{-0.1}{\text{CV}[R_C(t)]} = -1.65$$

Rearranging yields

$$\text{CV}[R_C(t)] = \frac{1}{0.5 \times 2.06} \sqrt{\frac{1}{Nt}} = \frac{0.1}{1.65}$$

implying that $Nt \simeq 257$. As in Example 18.7, the required total number of *measured* individuals is $1/p$ times this value, yielding $Mt = 257/0.05 \simeq 5140$.

Replicate Lines

There is no loss of efficiency when replicate lines are used (Hill 1980). To see this, let $\bar{z}_{i,t}$ for $1 \leq i \leq r$ be the sample mean for replicate population i at time t . The overall mean is

$$\bar{z}_t = \frac{1}{r} \sum_{i=1}^r \bar{z}_{i,t} \quad (18.35a)$$

If we take the variances and assume each line is independent

$$\sigma_z^2(t) = \frac{1}{r^2} \sum_{i=1}^r \sigma_{z_i}^2(t) = \frac{1}{r} \sigma_{\bar{z}_1}^2(t) \quad (18.35b)$$

If the number sampled and number used as parents within a replicate are $M^* = M/r$ and $N^* = N/r$, respectively, then it is easily seen from Table 18.8 that the variance of a replicate line is simply r times the variance of a population with N and M . Hence, variance in the sample mean from r replicate lines with N^* and M^* is the same as the variance with a single line with N and M , provided that the number of individuals within each replicate line is sufficiently large to avoid significant inbreeding. Richardson et al. (1968), Irgang et al. (1985), and Muir (1986a, 1986b) developed regression approaches that correct for between-generation environmental changes when replicate lines are used.

LINE-CROSS ANALYSIS OF SELECTION EXPERIMENTS

Plant-breeding schemes often involve two (or more) generations for each **cycle** of selection (Chapter 23; Volume 3). The amount of selective progress can be examined by growing seeds from different cycles together in a common garden thus offering a direct assessment of the genetic response. For example, one could regress the mean of a line on its selection-cycle number (e.g., Burton et al. 1971). An even more powerful design involves growing *crosses* between remnant seed from different cycles of selection in a common garden. Such a **line-cross analysis** yields summary statistics about the genetic nature of the divergence between lines, such as the role of additive versus nonadditive effects (LW Chapters 9 and 20). As we saw in LW Chapter 20, a large number of parameters are required when one has a collection of *unrelated* lines (i.e., the general and specific combining abilities of each line and each pair, respectively). However, in the analysis of a selection experiment, lines are not unrelated but rather are genetically connected, requiring far fewer parameters to model. The key to connecting lines from different cycles is to assume a constant rate of allele-frequency change over the course of the experiment (Hammond and Gardner 1974; Smith 1979a, 1979b, 1983; Melchinger and Flachenecker 2006), which is referred to as a **generation means analysis (GMA)**. With a large number of loci, each of which has a small effect, this assumption may be reasonable. If there are major alleles present or selection runs long enough such that substantial allele-frequency change occurs, then this model becomes more problematic. While commonly used in plant breeding, GMA is applicable to any organism for which an equivalent of “remnant seed” is available, such as frozen breeding stock or lines extracted from different generations of selection.

The Simple Additive Model

To see the logic behind a GMA, consider the simplest case: two alleles at each locus, with only additive effects and no $G \times E$ present. Focusing on a particular locus, the genotypes contribute values of $0 : a : 2a$ to the overall mean, where we sum contributions across all loci (because we assumed there is no epistasis). If p denotes the frequency of the favorable allele, then the contribution from this locus is $2ap$. If we further assume a roughly constant rate of change in allele frequency (at least over a few generations), then the frequency, $p(k)$, of the favorable allele in cycle k of selection is

$$p(k) \simeq p + k\Delta p$$

where p is the initial frequency and Δp is the per-generation rate of change for this locus. Summing over all loci, the mean following k cycles of selection is

$$C_k = \mu + \sum_i 2a_i p_i(k) \simeq \mu + \sum_i 2a_i(p_i + k\Delta p_i) = \mu + \sum_i 2a_i p_i + k \sum_i 2a_i \Delta p_i$$

Next, we define

$$m = \mu + 2 \sum p_i a_i \quad \text{and} \quad A = 2 \sum \Delta p_i a_i \quad (18.36)$$

where m is the line mean before selection and A is a weighted measure of change in the mean given constant allele-frequency change, Δp_i , at a locus (which can vary over loci). The expected line mean from selection cycle k becomes

$$C_k = m + A \cdot k \quad (18.37a)$$

Now suppose individuals from cycles k and j are crossed. With the frequencies of the favorable allele in these lines being $p(k)$ and $p(j)$, $[1-p(k)][1-p(j)]$ is the chance of getting the 0-valued homozygote, while $p(k)[1-p(j)] + p(j)[1-p(k)]$ is the chance of getting an a -value heterozygote, and $p(k)p(j)$ is the chance of getting a $2a$ homozygote. The resulting contribution from a particular locus to this cross becomes

$$\begin{aligned} 0 \cdot \left\{ [1-p(k)][1-p(j)] \right\} + a \cdot \left\{ p(k)[1-p(j)] + p(j)[1-p(k)] \right\} + 2a \cdot \left\{ p(k)p(j) \right\} \\ = a \cdot [p(k) + p(j)] = a \cdot [2p + (k+j)\Delta p] \end{aligned}$$

Summing over all loci, and recalling Equation 18.36, we get an expected mean for this cross of

$$C_{k \times j} = m + A \cdot \frac{k+j}{2} \quad (18.37b)$$

Under this simple additive model, the mean of any particular population (a line, C_k , or the progeny from a line cross, $C_{k \times j}$) is a function of the constants m and A and the selection cycle number. The goodness-of-fit can be assessed by comparing the predicted and actual mean values (LW Chapter 9).

Equations 18.37a and 18.37b have a simple form because of the assumption of strict additivity (no dominance or epistasis). However, when loci show dominance, the expressions for line and line-cross means are more complex. Line means may then change under selfing (assuming that there is inbreeding depression), although any such change allows us to estimate certain dominance components. Further, when dominance is present, care is required when considering the *progeny* of line crosses. We can regard the progeny from a particular cross (say $C_{k \times j}$) as an F_1 , and can generate an F_2 by either selfing individuals (when possible) or by letting the F_1 randomly mate. Under strict additivity, the means of both types of F_2 offspring (from either selfing or random mating) are still given by Equation 18.37b, the mean value of the F_1 . When loci display dominance, the F_1 mean and the two different types of F_2 all differ from each other. Again, these differences offer opportunities to estimate various dominance components, as we now will describe.

The Hammond-Gardner Model

Motivated by the general diallel analysis of Gardner and Eberhart (1966), Hammond and Gardner (1974) extended the simple additive model to allow for dominance, which requires three additional parameters (D_0 , D , and D_q). Assuming all lines start from the same base population, as derived below in Example 18.10, the **Hammond-Gardner (HG) model** returns means for various lines and line crosses of:

$$C_k = m + A \cdot k + D_0 + D \cdot k + D_q \cdot k^2 \quad (18.38a)$$

$$C_k(s) = m + A \cdot k + \frac{1}{2} (D_0 + D \cdot k + D_q \cdot k^2) \quad (18.38b)$$

$$C_{k \times j} = m + \frac{A}{2}(k+j) + D_0 + \frac{1}{2} [D \cdot (k+j) + 2D_q \cdot kj] \quad (18.38c)$$

$$C_{k \times j}(s) = m + \frac{A}{2}(k+j) + \frac{D_0}{2} + \frac{1}{4} [D \cdot (k+j) + 2D_q \cdot kj] \quad (18.38d)$$

$$C_{k \times j}(rm) = C_{k \times j} + \frac{D_q}{4}(k-j)^2 \quad (18.38e)$$

where (s) and (rm) , respectively, denote the selfed and randomly mated next generations given the cross or line. For example, $C_4(s)$ is the mean among the selfed progeny of individuals from cycle four. Likewise, for $C_{2 \times 6}(rm)$, we cross cycle two and cycle six individuals, let their offspring (the $F_1, C_{2 \times 6}[rm]$) randomly mate, and then measure their resulting progeny (the F_2). As expected, when all of the dominance terms are zero, Equations 18.38a–18.38e reduce to Equations 18.37a and 18.37b. With no dominance, there is no change in the line mean following inbreeding, so $C_k = C_k(s)$, and the F_1 progeny mean from a cross has the same mean as the progeny from either a selfed or randomly mated F_2 , $C_{k \times j} = C_{k \times j}(s) = C_{k \times j}(rm)$.

Five parameters (m, A, D, D_0 , and D_q) are required under the full model, and closer inspection of the coefficients on these model parameters in Equations 18.38a–18.38e reveals what types of crosses are required to estimate parameters of interest. If the investigator only has the unselfed line means, C_k , and their F_1 crosses, $C_{k \times j}$, A and D are not separately estimable, as they appear as $k(A + D)$ in expressions for these means (see Equations 18.38a and 18.38c). Obtaining separate estimates requires having different coefficients on the A and D terms, as occurs with either selfed lines or selfed F_2 crosses (Equations 18.38b and 18.38d). These particular crosses provide additional information on the genetic nature of the between-generation divergence that is not given by the simple line means, or their F_1 s, alone. Likewise, one cannot obtain separate estimates of m and D_0 unless there is at least one selfed line in the study. These terms enter as $m + D_0$ in all randomly mating populations, but they enter as $m + D_0/2$ in selfed lines.

As with the strictly additive model, we can express the parameters of the Hammond-Gardner model in terms of locus-specific parameters, with m and A as defined by Equation 18.36. Letting d_i be the dominance for locus i , which now makes the genotypic values $0 : a_i + d_i : 2a_i$, the dominance-related parameters, D_0, D , and D_q , in Equations 18.38a–18.38e are as follows. D_0 is the contribution (to the mean) from dominance in the initial (cycle-zero) population

$$D_0 = 2 \sum p_i(1 - p_i)d_i \quad (18.39a)$$

The role of dominance in response in the line means enters through D and D_q , which are the linear and quadratic regression coefficients on cycle number. D is calculated by

$$D = 2 \sum \Delta p_i(1 - 2p_i)d_i \quad (18.39b)$$

and it appears in Equations 18.38a–18.38e as terms of the form $D \cdot k$, namely, D times the appropriate selection cycle number, k . Recalling (LW Equation 4.10b) that the average effect, α , of an allelic substitution (replacing an unfavorable allele by a favorable one) is given by $\alpha = a + d(1 - 2p)$, we have

$$\begin{aligned} A + D &= 2 \left(\sum \Delta p_i a_i + \sum \Delta p_i(1 - 2p_i)d_i \right) \\ &= 2 \left(\sum \Delta p_i [a_i + (1 - 2p_i)d_i] \right) = 2 \sum \Delta p_i \alpha_i \end{aligned} \quad (18.39c)$$

with $A + D$ representing the per-generation change in the trait mean as a linear regression on cycle number (e.g., $k[A + D]$ for line k). This is also twice the average effect of substituting the unfavorable allele with the favorable one weighted by the allele-frequency change.

The final dominance term

$$D_q = -2 \sum (\Delta p_i)^2 d_i \quad (18.39d)$$

appears as a quadratic function of cycle number, with terms of the form $k^2 D_q$ for cycle k and $kj D_q$ for crosses between lines from cycles j and k . This is perhaps the most interesting dominance term, as it measures both inbreeding depression and the expected heterosis when two lines are crossed. As discussed below, D_q has also been interpreted as the component of change in the mean due to the effects of drift, with $A + D$ representing the response from

selection (the expected deterministic change). Recall (LW Chapter 10) that the heterosis, H , between two lines

$$H = \mu_{1\times 2} - \frac{\mu_1 + \mu_2}{2}$$

is the difference between the mean of the F_1 and the average of its parental lines. In the absence of epistasis

$$H = \sum (\delta p_i)^2 d_i \quad (18.39e)$$

where δp_i is the between-line difference in allele frequency for the favorable allele at the i th locus and d_i is the associated dominance term. Because the expected difference, δp_i , in allele frequency between lines separated by a single cycle of selection is Δp_i , comparing Equations 18.39d and 18.39e shows that D_q is the negative of twice the heterosis generated by a single generation of selection, namely, $D_q = -2H$.

The composite parameters (m , A , D , D_0 , and D_q) are typically estimated by OLS, with the vector of estimates given by $(\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{y}$, with \mathbf{y} being the vector of population means and the design matrix, \mathbf{X} , containing the appropriate coefficients for the parameters of interest (Example 18.9). The machinery introduced in LW Chapter 9 for standard line-cross analysis, such as hypothesis testing, testing goodness-of-fit, and estimation via GLS when the standard errors vary over means, can all be applied in a straightforward fashion. As with a standard line-cross analysis, one starts a GMA with the simple additive model and then tests whether adding additional model terms significantly improves the fit (LW Chapter 9). Typically one ends up with a reduced model, as some of the parameters turn out to be nonsignificant.

GMA can be extended to situations where some of the crosses are between lines from different base populations (Smith 1979b, 1983; Helms et al. 1989; Butruille et al. 2004; Melchinger and Flachenecker 2006). The same logic holds as before, with the frequency of the favorable allele in cycle k from base population j being $p_j(k) \simeq p_j + k\Delta p_j$, and with associated parameters m_j , A_j , D_j , $D_{0,j}$, and $D_{q,j}$. Additional terms are required to account for any initial heterosis (cycle-zero crosses between base populations j and i) which, from Equation 18.39e, is a function of the square of the difference in their allele frequencies, $\delta_{i,j}^2 = (p_i - p_j)^2$. Finally, terms for any additional heterosis that has accrued during selection are required, and again these are functions of the squared allele-frequency differences. For a cycle- k line from base population i crossed to a cycle- ℓ line from base population j , this is

$$[\delta_{i,j}(k, \ell)]^2 = [p_j(k) - p_i(\ell)]^2 = [(p_j + k\Delta p_j) - (p_i + \ell\Delta p_i)]^2$$

The motivation for this type of analysis is examined in our final volume, where we discuss the breeding of superior hybrids between lines. Basically, one tries to improve the performance of both selected lines, as well as that of their resulting hybrid. Generation means analysis can help partition any observed improvement into components of within-line and between-line (hybrid) improvement.

Example 18.9. As a simple worked example of the Hammond-Gardner model, consider eight populations (cycles 0, 4, 7 and their crosses) from a much larger sample generated by a selection experiment for yield in maize analyzed by Smith (1983). Suppose we wish to estimate the parameters in the Hammond-Gardner model, fitting a reduced model where D_q is excluded. The crosses (which include two selfed populations), their means, and the resulting coefficients (in Equation 18.38) for the parameters to estimate are as follows:

Line/cross	Mean	Coefficients			
		m	A	D_0	D
C_0	59.7	1	0	1	0
C_4	63.4	1	4	1	4

Line/cross	Mean	Coefficients			
		m	A	D_0	D
C_7	68.9	1	7	1	7
$C_7(s)$	42.3	1	7	$\frac{1}{2}$	$\frac{7}{2}$
$C_{0 \times 4}$	61.2	1	$\frac{0+4}{2}$	1	$\frac{0+4}{2}$
$C_{0 \times 7}$	79.6	1	$\frac{0+7}{2}$	1	$\frac{0+7}{2}$
$C_{4 \times 7}$	72.3	1	$\frac{4+7}{2}$	1	$\frac{4+7}{2}$
$C_{4 \times 7}(s)$	40.3	1	$\frac{4+7}{2}$	$\frac{1}{2}$	$\frac{4+7}{4}$

The resulting vector, \mathbf{y} , of means and the design matrix, \mathbf{X} , become

$$\mathbf{y} = \begin{pmatrix} 59.7 \\ 63.4 \\ 68.9 \\ 42.3 \\ 61.2 \\ 79.6 \\ 72.3 \\ 40.3 \end{pmatrix}, \quad \mathbf{X} = \begin{pmatrix} 1 & 0 & 1 & 0 \\ 1 & 4 & 1 & 4 \\ 1 & 7 & 1 & 7 \\ 1 & 7 & 0.5 & 3.5 \\ 1 & 2 & 1 & 2 \\ 1 & 3.5 & 1 & 3.5 \\ 1 & 5.5 & 1 & 5.5 \\ 1 & 5.5 & 0.5 & 2.75 \end{pmatrix}$$

Solving for the vector of parameter estimates yields

$$\begin{pmatrix} \hat{m} \\ \hat{A} \\ \hat{D}_0 \\ \hat{D} \end{pmatrix} = (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{y} = \begin{pmatrix} 4.266 \\ 1.072 \\ 57.402 \\ 0.523 \end{pmatrix}$$

Based on this subset of data, we note that there is considerable initial dominance ($\hat{D}_0 = 57.402$) influencing the initial value of the trait. Of the per-generation change of $A + D = 1.595$ per generation, roughly two-thirds are from A (1.072), and one-third is from D (0.5223). Standard errors for these estimates follow using standard OLS machinery (LW Chapter 9).

Example 18.10. Here we derive the line and cross means when dominance is present. Because the focus is on the contribution from a specific locus, for ease of presentation we suppress the subscript (on a , d , and p) denoting the locus being followed. Assuming no epistasis, the mean is derived by summing the contributions over all loci. To allow for dominance, the genotypic values at our target locus become $0 : a + d : 2a$. With p being the frequency of the favorable allele, the mean contribution from this locus is

$$0 \cdot (1 - p^2) + (a + d) \cdot 2p(1 - p) + (2a) \cdot p^2 = 2ap + 2dp(1 - p)$$

Notice that the contribution from a is a linear function of the allele frequency (and hence a linear function of allele frequency change), while the contribution from d has both linear (p) and quadratic (p^2) components. The contribution from this locus to the line mean in cycle k follows by replacing p with $p(k) \simeq p + k\Delta p$ in Equation 18.36b to yield

$$\begin{aligned} C_k &= \mu + 2ap(k) + 2dp(k)[1 - p(k)] \\ &= \mu + 2a[p + k\Delta p] + 2d[p + k\Delta p][1 - (p - k\Delta p)] \\ &= (\mu + 2ap) + k \cdot 2a\Delta p + 2dp(1 - p) + k \cdot 2d\Delta p \cdot (1 - 2p) - k^2 \cdot 2d(\Delta p)^2 \\ &= m + k \cdot A + D_0 + k \cdot D + k^2 \cdot D_q \end{aligned}$$

Now suppose that this line is selfed. Homozygotes replicate themselves, while segregation of genotypes occurs when heterozygotes are selfed, with half of the offspring being $a + d$ heterozygotes, one-quarter of the offspring being $2a$ homozygotes, and the final one-quarter

being 0-valued homozygotes. The resulting mean value following a generation of selfing is the sum of these contributions,

$$p^2 [2a] + 2p(1-p) \left[(1/4)(2a) + (1/2)(a+d) + (1/4) \cdot 0 \right] + (1-p)^2 \cdot 0 = 2ap + dp(1-p)$$

Note that all terms involving d are exactly half of their random-mating values, yielding

$$C_k(s) = m + k \cdot A + \frac{1}{2} (D_0 + k \cdot D + k^2 \cdot D_q)$$

Now consider the mean of the cross of lines from cycles k and j . As above, the chance of a 0-valued homozygote is $[1-p(k)][1-p(j)]$, whereas it is $p(k)[1-p(j)]+p(j)[1-p(k)]$ for an $a+d$ heterozygote, and $p(k)p(j)$ for a $2a$ homozygote, yielding a resulting mean of

$$\begin{aligned} C_{k \times j} &= \mu + (a+d) \cdot \left(p(k)[1-p(j)] + p(j)[1-p(k)] \right) + 2a \cdot p(k)p(j) \\ &= \mu + a \left(p(k) + p(j) \right) + d \cdot \left(p(k) + p(j) - 2p(k)p(j) \right) \\ &= (\mu + 2ap) + (k+j)a\Delta p + d \left(2p(1-p) + (k+j) \cdot \Delta p(1-2p) - k j \cdot 2(\Delta p)^2 \right) \\ &= m + \frac{k+j}{2} \cdot A + D_0 + \frac{k+j}{2} \cdot D + k j \cdot D_q \end{aligned}$$

If we self these individuals to form an F_2 , by the same argument used above for selfing a line, each of the dominance terms is reduced by one-half, recovering Equation 18.38d.

Finally, when we form an F_2 by randomly mating the F_1 progeny from a line cross, the new allele frequency is

$$\frac{p(k) + p(j)}{2} \simeq p + \frac{k+j}{2} \Delta p$$

yielding a mean of

$$\begin{aligned} C_{k \times j}(rm) &= \mu + 2a \left(p + \frac{k+j}{2} \Delta p \right) + 2d \left(p + \frac{k+j}{2} \Delta p \right) \left(1-p - \frac{k+j}{2} \Delta p \right) \\ &= (\mu + 2ap) + \frac{k+j}{2} 2a\Delta p + 2dp(1-p) + \frac{k+j}{2} 2d\Delta p(1-2p) - \left(\frac{k+j}{2} \right)^2 2d(\Delta p)^2 \\ &= m + \frac{k+j}{2} \cdot A + D_0 + \frac{k+j}{2} \cdot D + \left(\frac{k+j}{2} \right)^2 \cdot D_q \end{aligned}$$

Recalling Equation 18.38c, we can express this as

$$C_{k \times j}(rm) = C_{k \times j} - kj \cdot D_q + \left(\frac{k+j}{2} \right)^2 \cdot D_q = C_{k \times j} + \frac{(k-j)^2}{4} \cdot D_q$$

The additional term is due to the decay in heterosis following random mating, as the heterosis in the F_1 cross between lines from cycles j and k is

$$\begin{aligned} H &= \sum (p_i(k) - p_i(j))^2 d_i = \sum (p + k\Delta p - p - j\Delta p)^2 d_i \\ &= (k-j)^2 \sum (\Delta p)^2 d_i = -(k-j)^2 D_q / 2 \end{aligned}$$

Recall (LW Chapter 9) that the amount, H , of heterosis from the F_1 is reduced to $H/2$ in the (random-mating generated) F_2 . Hence

$$C_{k \times j}(rm) - C_{k \times j} = -\frac{H}{2} = (k-j)^2 \frac{D_q}{4}$$

as found above.

Accounting for Inbreeding Depression and Drift

The deterministic assumption of a constant rate of allele-frequency change in the Hammond-Gardner model requires large population sizes. Because a typical selection experiment often involves small populations, genetic drift can also be important and thus needs to be taken into account. Smith (1979a, 1979b, 1983) was the first to incorporate drift and inbreeding depression in a GMA, while the most general treatment is from Melchinger and Flachenecker (2006). The latter authors' key idea was to separate allele frequency at cycle k into deterministic and drift components

$$p(k) = p(0) + k\Delta p + \delta p_k \quad (18.40)$$

where the Δp represents the expected large-population change (i.e., the Hammond-Gardner model), while δp_k accounts for the additional change due to drift. Recall from Chapter 2 that under drift $E[\delta p_k] = 0$, so that $E[(\delta p_k)^2] = \sigma^2(\delta p_k)$. Under pure drift, Equation 2.14a yields an allele-frequency variance after k generations of

$$\sigma^2(\delta p_k) = p(0)[1 - p(0)]f_k \quad (18.41a)$$

where $f_k \simeq k/(2N_e)$ is the amount of inbreeding in cycle k . Melchinger and Flachenecker suggested that, with selection, Equation 18.41a can be approximated by using the average frequency over the k cycles

$$E[(\delta p_k)^2] \simeq \left(\frac{p(0)[1 - p(0)] + p(k)[1 - p(k)]}{2} \right) f_k \quad (18.41b)$$

Using the deterministic approximation $p(k) = p(0) + k\Delta p$, this reduces to

$$E[(\delta p_k)^2] \simeq p(0)[1 - p(0)]f_k + \frac{k}{2} \cdot (1 - 2p)\Delta p f_k - \frac{k^2}{2} (\Delta p)^2 f_k \quad (18.41c)$$

Notice the close similarity of these three terms to D_0 , D , and D_q (c.f. Equations 18.39a–18.39d). Using Equation 18.40 as the model for allele frequency and following the logic used in Example 18.10, the adjustment in the mean for inbreeding due to drift becomes

$$I_k = \left(D_0 + \frac{k \cdot D}{2} - \frac{k^2 \cdot D_q}{2} \right) f_k \quad (18.42a)$$

Assuming $f_k = k\Delta f$ (typically, with $\Delta f = 1/[2N_e]$), this simplifies to

$$I_k = k \left(D_0 + \frac{k \cdot D}{2} - \frac{k^2 \cdot D_q}{2} \right) \Delta f \quad (18.42b)$$

The resulting line means are

$$C_k = C_k(HG) - I_k \quad \text{and} \quad C_k(s) = C_k(s, HG) - I_k/2 \quad (18.43a)$$

while the line-cross means become

$$C_{k \times j} = C_{k \times j}(HG) - I_k \quad \text{for } j > k \quad (18.43b)$$

where HG denotes the value under the Hammond-Gardner model (Equations 18.38a–18.38e).

Equations 18.42 and 18.43 define the **Melchinger-Flachenecker model**. The presence of drift ($f_k > 0$) modifies the contributions from the three dominance terms, resulting in a reduction in mean (relative to the HG model) when both D_0 and D are positive (as D_q is ≤ 0 when directional dominance is present). Smith (1979a, 1983) equated this reduction to inbreeding depression, which arises from drift causing some favorable alleles to decrease in frequency. On average, drift is equally likely to increase or decrease the change in frequency of an allele over its deterministic value, Δp . Thus, under drift, some alleles have a greater-than-deterministic increase in frequency, but this is countered by (on average) others having a less-than-expected increase. For additive genes, the expected value of these changes exactly cancel (as $E[\delta p_k] = 0$). However, with dominance, this variance in allele-frequency change around Δp does not cancel out, as the mean is a quadratic function of d .

While Melchinger and Flachenecker's analysis is exact, the approximate results of the work by Smith (1979a, 1983) had a significant influence on the GMA literature, so a few comments on his approximations are in order. Smith's (1979a) model was

$$C_k(s, S) = C_k(s, HG) + k \cdot I \quad (18.44)$$

namely, it added a term, kI , to the Hammond-Gardner model expression for $C_k(s)$ (Equation 18.38b) to account for inbreeding, with $I = (D_0 + D)$. Note by comparison to the exact result (Equation 18.42b) that this is only correct when $D_0 \gg D$, and D_q is negligible (as Smith assumed). Further, Smith neglected to include I in his expressions for the line-cross means, instead using the HG expression for $C_{k \times j}(s)$, Equation 13.38d. Equation 18.43b shows this to be incorrect. Smith (1979a) ignored the D_q term, as he felt that Δp was expected to be small, and hence its square was likely to be negligible (or in any case, potentially difficult to estimate with precision).

In a later paper, Smith (1983) instead ignored the inbreeding correction, I , and suggested that for experiments with very small effective population size, $E[(\delta p_k)^2] \gg (\Delta p)^2$, and thus D_q was a surrogate measure for drift, as most of its value was due to the drift variance. Equations 18.42b and 18.43 show that both of these ideas, while correct in spirit, are approximations of the more general solution (Equation 18.42b). However, they can often yield a fairly good approximation. For example, Flachenecker et al. (2006) found that both the Smith (1983) and Melchinger-Flachenecker models gave rather similar parameter estimates. The critical insight offered by Smith's analysis was that by adjusting for the effects of drift, one could estimate the potential response if a larger population size was used, as the following two examples illustrate.

Example 18.11. Helms et al. (1989) obtained an estimate of $\hat{D}_q = -0.024$ (which was significant at the 1% level) in an analysis of a maize line selected for yield. Assuming small effective population size, how much was the population mean at cycle ten reduced due to drift-generated inbreeding depression? Recalling from Equation 18.38a that the contribution from D_q in cycle k is $D_q \cdot k^2 = -0.024 \cdot 10^2 = -2.4$, then the observed mean (provided the assumptions of the Smith [1983] model hold) is expected to be reduced by 2.4 units (relative to a randomly mating population) by the effects of drift generating inbreeding depression.

Example 18.12. Smith (1979b) examined the relative effectiveness of two different selection schemes (using half sib [HT] versus S_1 [S] family selection; both procedures are examined in Chapters 21 and 23) for yield in maize using the cultivar BSK. Both the Hammond-Gardner and Smith (1979a) models were fit to the data, yielding the following values

		Hammond-Gardner	Smith (1979a)
BSK(HT)	A	0.7 ± 0.15	1.22 ± 0.15
	I	—	-1.83 ± 0.28
D, D_q		not significant	—

		Hammond-Gardner	Smith (1979a)
BSK(S)	A	1.42 ± 0.15	1.97 ± 0.15
	I	—	-1.83 ± 0.28
	D, D_q	not significant	—

By ignoring inbreeding, the Hammond-Gardner model resulted in a significant *underestimation* of A in both experiments. Smith's GMA shows that both selection schemes result in significant amounts of inbreeding depression (-1.83 in both cases), but also significant gains (1.22 and 1.97). Increasing the effective population size is expected to decrease $\Delta f = 1/(2N_e)$, and thus the magnitude of I , in turn enhancing response. Both the Smith and Hammond-Gardner analyses showed that S_1 selection was more effective than half-sib selection, as measured in terms of average genetic gain ($A + D$) per cycle ($1.42/0.7 = 203\%$ and $1.97/1.22 = 160\%$, respectively).

Finally, a rough calculation suggests the conditions under which $\sigma^2(\delta p) \gg (\Delta p)^2$, i.e., when the variance in allele-frequency change from drift exceeds the square of the deterministic change from selection. Equation 5.2b shows that $\Delta p \simeq sp(1-p)$ for a very weakly selected additive locus, while Equation 5.21 yields $s \simeq \bar{t}a/\sigma_z$, where \bar{t} is the selection intensity on the trait, yielding $\Delta p_i \simeq (\bar{t}a_i/\sigma_z)p_i(1-p_i)$. Recalling that $\sigma^2(A_i) = 2a_i^2p_i(1-p_i)$ is the additive genetic variance associated with locus i

$$\begin{aligned} (\Delta p_i)^2 &\simeq (\bar{t}a_i/\sigma_z)^2 p_i^2 (1-p_i)^2 = \bar{t}^2 p_i (1-p_i) \left(\frac{a_i^2 p_i (1-p_i)}{\sigma_z^2} \right) \\ &= \bar{t}^2 p_i (1-p_i) \left(\frac{\sigma^2(A_i)/2}{\sigma_z^2} \right) = \frac{\bar{t}^2 p_i (1-p_i)}{2} h_i^2 \end{aligned}$$

where h_i^2 is the heritability due to locus i . Assuming that n loci underlying the trait contribute roughly the same to the overall heritability, h^2 , then

$$(\Delta p_i)^2 \simeq \frac{p_i(1-p_i)}{2} \frac{\bar{t}^2 h^2}{n} \quad (18.45a)$$

Drift dominates the expected quadratic change when $\sigma^2(\delta p) \gg (\Delta p)^2$, or

$$\frac{p(1-p)}{2N_e} \gg \frac{p(1-p)}{2} \frac{\bar{t}^2 h^2}{n}$$

which reduces to

$$n \gg N_e (\bar{t}^2 h^2) \quad (18.45b)$$

For example, for a trait with $h^2 = 0.25$ under truncation selection to save the largest 5% ($\bar{t} = 2.06$; Example 14.1), $\bar{t}^2 h^2 \simeq 1$, so drift dominates the quadratic term when the number of loci is much greater than the effective population size (assuming loci have roughly equal effects). Expressed in another way, the fractional contribution to the expected square in allele-frequency change from drift is

$$\frac{\sigma^2(\delta p)}{\sigma^2(\delta p) + (\Delta p)^2} \simeq \frac{1/N_e}{1/N_e + \bar{t}^2 h^2/n} = \frac{1}{1 + \bar{t}^2 h^2 N_e/n} \quad (18.45c)$$

or

$$\frac{\sigma^2(\delta p)}{\sigma^2(\delta p) + (\Delta p)^2} \simeq 1 - \bar{t}^2 h^2 N_e/n, \quad \text{when } n \gg N_e \quad (18.45d)$$

For $h^2 = 0.25$, $\bar{t} = 2.06$, $n = 100$, and $N_e = 25$, Equation 18.45c returns a value of 0.79, while the approximation given by Equation 18.45d yields 0.74. Hence, in this setting almost 80% of the expected squared allele-frequency change is due to drift.

Analysis of Short-term Selection Experiments:

2. Mixed-model and Bayesian Approaches

Unnecessarily complex analysis should not be used as a foil to disguise lower quality datasets: estimates of genetic parameters are only as good as the data on which they are based.

Kruuk (2004)

While a least-squares (LS) analysis of a selection experiment distills the data down to the trait mean and variance for each generation, one often has more information. In the extreme, one has measurements (or **records**) for all individuals throughout the course of the experiment (or breeding program) as well as their complete pedigree. When such additional data are available, an LS analysis simply ignores them. A **mixed-model (MM) analysis** (LW Chapters 26 and 27), on the other hand, fully considers the covariances between *all* observations. By virtue of using this additional information, an MM is potentially far more powerful. It is also more flexible, easily incorporating complicated fixed effects and highly unbalanced designs. Finally, breeders and evolutionary biologists are especially concerned with the realized genetic gain from selection, which, due to shifting environments, may be different from the change in mean phenotype. LS estimates the latter, while MM, by estimating the mean breeding value in each generation, estimates the former. An important application of the analysis of selection experiments is in the **evaluation of breeding programs**, and the success of almost all animal, and increasingly many plant, breeding programs is gauged by examining the response using a mixed-model framework.

There are two different frameworks for a mixed-model analysis. The first is the **two-step approach**, wherein one first employs **REML** (LW Chapter 27) or some other method to estimate the appropriate variance components, and then uses these with **BLUP** (best linear unbiased predictor) to estimate breeding values (LW Chapter 26). With BLUPs for individual breeding values in hand, one can estimate the mean breeding value for any particular generation and directly follow *genetic*, as opposed to *phenotypic*, change. This allows for the separation of genetic versus environmental change, even in the absence of a control population. While straightforward, the two-step approach does not account for the uncertainty in BLUP estimates that arises from using estimates of the variances (as opposed to their true values). In contrast, **Bayesian approaches** provide for an exact accounting of the uncertainty in the estimation of the breeding values by integrating over the uncertainty from the confounding effects of nuisance parameters, such as the variance components.

By building around applications to the analysis of selection experiments (including applied breeding), we use this chapter to review some of the basic statistical machinery behind mixed models (which is also used extensively in Chapters 20 and 22) and to more formally introduce the Bayesian framework (briefly touched upon in Chapter 10, and more fully developed in Appendices 2 and 3). We start with a brief review of the theory of mixed models and then consider various applications of the **animal (or individual) model** to the analysis of selection experiments. We conclude by briefly examining mixed models under a Bayesian framework.

MIXED-MODEL VERSUS LEAST-SQUARES ANALYSIS

Figure 19.1 illustrates the result of a mixed-model analysis of selection response. Note that instead of measuring response from the *observed phenotypic means* (the LS approach), response is measured from the *estimated mean breeding values* obtained from BLUP. Further, instead of estimating a realized heritability, a mixed-model (REML) analysis estimates the

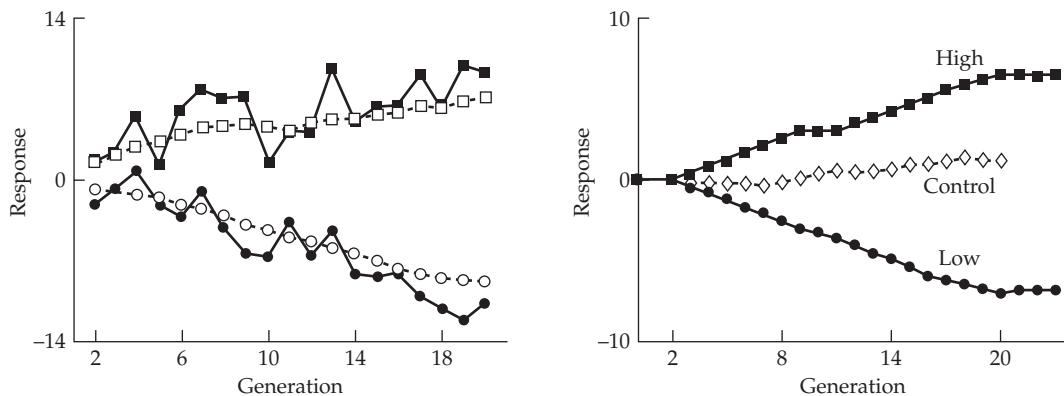

Figure 19.1 Results from high and low selection on 6-week weight in mice. **Left:** Observed (filled boxes and circles) and predicted (open boxes and circles) mean phenotypic values in the up- and down-selected lines, expressed as deviations from the control population. The predicted mean for a specific generation is given by the estimated mean breeding value plus the estimated environmental value. **Right:** Estimated mean breeding values for both selected populations and the control. See Examples 19.2 and 19.7 for more details on this experiment. (After Meyer and Hill 1991.)

additive genetic variance in the *base population*.

Mixed-models readily allow records to be adjusted for any number of **fixed effects** (differences between the expected value of individuals from different categories). For example, one might correct for trait differences between sexes, trait differences between individuals from different litter sizes, age effects, known environmental factors, etc. Such adjustments result in a more accurate prediction of an individual's genetic value, and thus a more accurate estimate of the population's genetic response. Further, a properly formatted MM analysis can separate phenotypic changes into genetic and environmental components without using a control population. In contrast, an LS analysis cannot separate genetic from environmental trends when only a single line is considered. Under a mixed model, such a separation is possible because the covariance structure associated with the pedigree of all individuals in the experiment allows information to be borrowed from relatives across generations.

Another advantage of a mixed-model analysis is its enormous flexibility in handling almost any selection design. For example, an MM analysis easily allows for overlapping generations (when a parent contributes offspring over several different years of selection), while analysis of response in overlapping generations under LS can be difficult to formulate correctly. Further, as detailed below, a properly designed MM analysis can also account for assortative mating, drift, and selection-induced gametic-phase disequilibrium (provided we can assume that the infinitesimal model holds).

Nonetheless, despite its power, an MM analysis has tradeoffs relative to a simpler LS analysis. First, an MM analysis requires far greater record keeping (e.g., following all individuals and their relatives) and is more computationally demanding. Second, an MM analysis can be rather model-sensitive. In particular, assumption of the infinitesimal model is critical. If selection-induced changes in allele frequencies are significant during the course of the experiment, the assumptions of an MM analysis will be violated. Finally, MM analysis *critically* depends on the covariance structure of the random effects. If this is incorrectly specified, an MM analysis can lead to highly biased results.

BLUP Selection

A previously introduced MM application is **BLUP selection** (Chapter 13), wherein a mixed

model is used to find those individuals with the highest estimated breeding values, which are then used as parents to form the next generation. This is the main route of selection used by animal and tree breeders, and to a growing extent, by plant breeders working with outcrossing species. BLUP selection uses all of the information up to a given generation to choose the parents for the next cycle of selection.

Conversely, an MM analysis of selection response is a *retrospective* analysis of the genetic gain of a population, wherein we start at some final time point and infer the trajectory of past genetic gain during the experiment or breeding program. The actual scheme used to choose parents (such as mass, index, or BLUP selection) is irrelevant to the MM analysis of the final genetic gain, which is solely based on the values of all individuals, and their relationships (pedigree), over the course of the experiment.

BASICS OF MIXED-MODEL ANALYSIS

Here, we start with a quick review of some of the key theoretical results of mixed-model analysis and then examine specific applications. We encourage the reader to review LW Chapters 26 and 27 (either before, or after, reading this short introduction). These chapters provide additional worked examples to give a better feel for mixed models and also consider advanced topics in MM analysis in greater detail.

Mixed models are so named because they consider both fixed and random effects. Recall that fixed effects are unknown constants, while random effects have values that are drawn from some underlying distribution (LW Chapters 8 and 26). Hence, any particular value for a random effect represents just one possible realization from this underlying distribution, which is usually assumed to be normal with a mean of zero and an unknown (yet to be estimated) variance.

A brief example will remind the reader of a powerful feature of random-effects models. Suppose we have T time points and include an environmental value, E_i , for each time point in our model. Treating these values as fixed effects makes no assumption as to how the E_i from different generations are related to each other, but the cost is T degrees of freedom. Conversely, if we make a random-effects assumption that the E_i values are drawn from some underlying distribution, we use far fewer degrees of freedom. If we assume the E_i are independent draws from an underlying normal, then we only need a single degree of freedom (the variance, σ_E^2 , of this distribution, as the mean value of a random effect is zero), no matter the value of T . More generally, one could make additional assumptions about the distribution of the E_i values, at the cost of additional degrees of freedom. For example, one could assume that all the E_i values for adjacent generations are autocorrelated by the same amount, ρ , which introduces an additional parameter to be estimated.

Typically, statisticians speak of *estimating* fixed effects and *predicting* the realized values of random effects. Both LS and MM analyses estimate the fixed effects in a model, while MM analysis also predicts the values of the random effects by using the covariances between observations (after adjusting for fixed effects). (Note that under a Bayesian analysis, as will be discussed later, every effect is assumed to be random, and this distinction between fixed and random effects is more subtle.) The standard mixed model for a vector, y , of n observations is

$$y = \mathbf{X}\beta + \mathbf{Z}\mathbf{a} + \mathbf{e} \quad (19.1)$$

where β is a $q \times 1$ vector of q fixed effects, \mathbf{a} is a $p \times 1$ vector of p random effects (in our case, the breeding values of the individuals in our experiment), and \mathbf{e} is the $n \times 1$ vector of n residuals (which is also random). The matrices \mathbf{X} and \mathbf{Z} are, respectively, the $n \times q$ **design matrix** and the $n \times p$ **incidence matrix** associated with the fixed and random effects, respectively.

In the absence of the vector, \mathbf{a} , of random effects, Equation 19.1 reduces to a least-squares model, $y = \mathbf{X}\beta + \mathbf{e}$, and whether ordinary (unweighted) least-squares (OLS) or generalized (weighted) least-squares (GLS) analysis is used to estimate β depends on our assumption about the covariance structure of the vector, \mathbf{e} , of the residuals. OLS assumes

that residuals are uncorrelated and homoscedastic, yielding $\text{Var}(\mathbf{e}) = \sigma_e^2 \mathbf{I}$. More generally, if $\text{Var}(\mathbf{e}) = \mathbf{V}$, where the only constraint is that \mathbf{V} be symmetric and positive-definite, then generalized GLS is used (Equation 19.3a).

In order to solve Equation 19.1, we need to specify the covariance structure for the vectors of random effects, \mathbf{a} and \mathbf{e} . As just noted, it is generally assumed that the residuals are uncorrelated and homoscedastic, so $\text{Var}(\mathbf{e}) = \sigma_e^2 \mathbf{I}$. The covariance of \mathbf{a} (the vector of breeding values) has a more complicated structure, which is given by the pedigree, $\text{Var}(\mathbf{a}) = \sigma_A^2 \mathbf{A}$, with $\sigma(a_i, a_j) = \sigma_A^2 A_{ij}$. Here \mathbf{A} is a matrix of known constants (the **numerator relationship matrix**, often abbreviated as simply the **relationship matrix**), whose elements are given by the pedigree structure (or, more recently, from sufficiently dense marker information). The resulting $n \times n$ covariance matrix, \mathbf{V} , for the vector of observations, \mathbf{y} , becomes

$$\mathbf{V} = \sigma_A^2 \mathbf{Z} \mathbf{A} \mathbf{Z}^T + \sigma_e^2 \mathbf{I} \quad (19.2a)$$

For the case of a single phenotypic measurement for each individual with no missing phenotypic data, $\mathbf{Z} = \mathbf{I}$ and Equation 19.2a reduces to $\mathbf{V} = \sigma_A^2 \mathbf{A} + \sigma_e^2 \mathbf{I}$. More generally, when there are multiple observations per individual, or individuals with missing phenotypic data, then \mathbf{Z} departs from an identity matrix (e.g., Example 19.5).

The covariance matrix, \mathbf{V} , is thus a function of the (usually unknown) variance components (σ_A^2 and σ_e^2) and matrices of known constants (\mathbf{Z} , \mathbf{A} , and \mathbf{I}). Because \mathbf{a} is a vector of breeding values, we can alternatively express \mathbf{V} as a function of the heritability (h^2) and the (fixed-effect-adjusted) phenotypic variance ($\sigma_z^2 = \sigma_A^2 + \sigma_e^2$) of the trait of interest

$$\mathbf{V} = \sigma_z^2 \cdot \left(h^2 \mathbf{Z} \mathbf{A} \mathbf{Z}^T + (1 - h^2) \mathbf{I} \right) \quad (19.2b)$$

as $\sigma_e^2 = \sigma_z^2 - \sigma_A^2 = \sigma_z^2(1 - h^2)$. Because our focus is generally on breeding values, any dominance variance gets swept into σ_e^2 . This potentially results in e_i values within families being correlated (due to full sibs sharing $\sigma_D^2/4$), and we will discuss corrections for this shortly.

Assuming \mathbf{V} is known exactly, estimation of the vector, $\boldsymbol{\beta}$, of fixed effects follows from GLS (LW Chapter 8)

$$\hat{\boldsymbol{\beta}} = \left(\mathbf{X}^T \mathbf{V}^{-1} \mathbf{X} \right)^{-1} \mathbf{X}^T \mathbf{V}^{-1} \mathbf{y} \quad (19.3a)$$

Equation 19.3a is called the **best linear unbiased estimator (BLUE)** of the vector, $\boldsymbol{\beta}$, of fixed effects. The **estimability** of the fixed effects can be an issue, as the structure of the data (indicated by the number of independent columns—the **column rank**—of \mathbf{X}) may not allow for unique estimates of all fixed effects. In such cases, generalized inverses can be used to obtain unique estimates of certain linear combinations of the fixed effects (LW Appendix 2). If \mathbf{X} has a column rank of $\ell \leq q$, then exactly ℓ combinations of the q fixed effects can be estimated; see LW Chapter 26, and LW Appendix 2, for further details. Finally, note that although the BLUES are a function of \mathbf{V} (and hence of σ_A^2 and σ_e^2), applying Equation 19.2b shows that the phenotypic variance, σ_z^2 , in \mathbf{V} cancels out in Equation 19.3a (\mathbf{V}^{-1} scales as $1/\sigma_z^2$, while the inverse of \mathbf{V}^{-1} scales as σ_z^2), leaving the BLUE estimate (for Equation 19.1) as a function of the heritability alone.

If we again assume that \mathbf{V} is exactly known, the **best linear unbiased predictor (BLUP)** of the vector of random effects is given by

$$\hat{\mathbf{a}} = \text{Var}(\mathbf{a}) \mathbf{Z}^T \mathbf{V}^{-1} \left(\mathbf{y} - \mathbf{X} \hat{\boldsymbol{\beta}} \right) = \sigma_A^2 \mathbf{A} \mathbf{Z}^T \mathbf{V}^{-1} \left(\mathbf{y} - \mathbf{X} \hat{\boldsymbol{\beta}} \right) \quad (19.3b)$$

The BLUPs for breeding values are often called **PBs** or **EBVs**, for **predicted** or **estimated breeding values**. Equation 19.3b is the regression of \mathbf{a} on $(\mathbf{y} - \mathbf{X} \hat{\boldsymbol{\beta}})$, the vector of observations, \mathbf{y} , adjusted for their expected mean values, $\mathbf{X} \hat{\boldsymbol{\beta}}$. Recall that for the univariate regression predicting a from y , the scaling of $(y - \hat{y})$ is given by the regression slope, $\sigma(a, y)/\sigma^2(y)$. In Equation 19.3b, this scaling is of the form of the covariance matrix, $\sigma(\mathbf{a}, \mathbf{y}) = \sigma(\mathbf{a}, \mathbf{Z}\mathbf{a}) =$

$\sigma_A^2 \mathbf{A} \mathbf{Z}^T$ times the inverse of $\mathbf{V} = \sigma(\mathbf{y}, \mathbf{y})$. Even if the number of random effects exceeds the number of actual observations (i.e., $p > n$), Equation 19.3b still provides unique estimates of each (provided \mathbf{V}^{-1} exists). This occurs because the $p \times p$ covariance structure (\mathbf{A}) of the vector, \mathbf{a} , is incorporated in the model. As with the BLUEs, BLUPs are simply functions of h^2 as $\sigma_A^2 = h^2 \sigma_z^2$, while \mathbf{V}^{-1} scales as $1/\sigma_z^2$. An alternative expression, due to Kennedy and Trus (1993), is

$$\hat{\mathbf{a}} = (\mathbf{Z}^T \mathbf{M} \mathbf{Z} + \lambda \mathbf{A}^{-1})^{-1} \mathbf{Z}^T \mathbf{M} \mathbf{y} \quad (19.3c)$$

where $\lambda = \sigma_e^2 / \sigma_A^2 = (1 - h^2) / h^2$, and

$$\mathbf{M} = \mathbf{I} - \mathbf{X} (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \quad (19.3d)$$

is the **absorption matrix** for the fixed effects, and the design matrix, \mathbf{X} , assigns the fixed effects associated with any particular observation (Equation 19.1). As an aside

$$\mathbf{H} = \mathbf{X} (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \quad (19.3e)$$

is referred to as the **hat matrix** (Hoaglin and Welsch 1978), because for an OLS estimate

$$\hat{\mathbf{y}} = \mathbf{X} \hat{\beta} = \mathbf{X} (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{y} = \mathbf{H} \mathbf{y} \quad (19.3f)$$

and \mathbf{H} maps the observed \mathbf{y} values onto those predicted, $\hat{\mathbf{y}}$, by the fixed effects. Hence

$$\mathbf{M} \mathbf{y} = (\mathbf{I} - \mathbf{H}) \mathbf{y} = \mathbf{y} - \hat{\mathbf{y}} = \mathbf{y} - \mathbf{X} \hat{\beta} \quad (19.3g)$$

are the adjusted values for \mathbf{y} after the fixed effects have been removed, namely, the vector of the deviations of the observations, \mathbf{y} , from their expected values, $\hat{\mathbf{y}}$ (based on fixed effects only).

In practice, Equations 19.3a–19.3c are often not used, as they require the inversion of the potentially very large ($n \times n$) matrix, \mathbf{V} . As an alternative, $\hat{\beta}$ and $\hat{\mathbf{a}}$ can be obtained without computing an inverse by numerically solving (e.g., by applying Gaussian elimination to) **Henderson's mixed-model equations**, (derived in Example A6.5)

$$\begin{pmatrix} \mathbf{X}^T \mathbf{X} & \mathbf{X}^T \mathbf{Z} \\ \mathbf{Z}^T \mathbf{X} & \mathbf{Z}^T \mathbf{Z} + \lambda \mathbf{A}^{-1} \end{pmatrix} \begin{pmatrix} \hat{\beta} \\ \hat{\mathbf{a}} \end{pmatrix} = \begin{pmatrix} \mathbf{X}^T \mathbf{y} \\ \mathbf{Z}^T \mathbf{y} \end{pmatrix} \quad (19.4)$$

The careful reader might wonder why we worried so much about avoiding computing the inverse of \mathbf{V} , given that the mixed-model equations contain \mathbf{A} , which at first blush looks just as complicated to invert as \mathbf{V} . In fact, however, \mathbf{A} turns out to be very easy to invert, as a slight modification of the recursive approach used to compute \mathbf{A} from a pedigree can be used to directly compute \mathbf{A}^{-1} (Henderson 1976; Quaas 1976).

The sampling variance-covariance matrices for $\hat{\mathbf{a}}$ and $\hat{\beta}$ also follow from the mixed-model equations. First we partition the inverse of the $(p+q) \times (p+q)$ matrix in Equation 19.4 as

$$\begin{pmatrix} \mathbf{X}^T \mathbf{X} & \mathbf{X}^T \mathbf{Z} \\ \mathbf{Z}^T \mathbf{X} & \mathbf{Z}^T \mathbf{Z} + \lambda \mathbf{A}^{-1} \end{pmatrix}^{-1} = \begin{pmatrix} \mathbf{C}_{11} & \mathbf{C}_{12} \\ \mathbf{C}_{12}^T & \mathbf{C}_{22} \end{pmatrix} \quad (19.5a)$$

where \mathbf{C}_{11} , \mathbf{C}_{12} , and \mathbf{C}_{22} are, respectively, $q \times q$, $q \times p$, and $p \times p$ submatrices. Henderson (1975) showed that the $q \times q$ covariance matrix for the BLUE vector of fixed effects, β , is given by

$$\text{Var}(\hat{\beta}) = \sigma_e^2 \mathbf{C}_{11} \quad (19.5b)$$

The variance of the predicted breeding values, $\hat{\mathbf{a}}$, is a bit more subtle, as our real interest is not $\text{Var}(\hat{\mathbf{a}})$, but rather the **prediction error variances (PEVs)**, $\text{Var}(\hat{\mathbf{a}} - \mathbf{a})$. These are the variances and covariances among the vector of prediction errors ($\hat{\mathbf{a}} - \mathbf{a}$), and they are given by the $p \times p$ matrix

$$\text{Var}(\hat{\mathbf{a}} - \mathbf{a}) = \sigma_e^2 \mathbf{C}_{22} \quad (19.5c)$$

Note that

$$\text{Var}(\hat{\mathbf{a}}) = \text{Var}(\hat{\mathbf{a}} - \mathbf{a}) + \text{Var}(\mathbf{a}) = \sigma_e^2 \mathbf{C}_{22} + \sigma_A^2 \mathbf{A} \quad (19.5d)$$

Following Equation 19.3c, Kennedy and Trus (1993) showed that we can also express Equation 19.5c as

$$\text{Var}(\hat{\mathbf{a}} - \mathbf{a}) = \sigma_e^2 \left(\mathbf{Z}^T \mathbf{M} \mathbf{Z} + \lambda \mathbf{A}^{-1} \right)^{-1} \quad (19.5e)$$

The prediction error variances for *individual* EBVs are not of serious interest in this chapter, as we measure selection response by taking the average of the EBVs over all individuals within each generation. However, individual EBVs can be important when we try to disentangle selection in natural populations, and we will revisit PEVs in Chapter 20.

Finally, the covariances between estimated fixed effects and prediction errors are

$$\sigma(\hat{\beta}, \hat{\mathbf{a}} - \mathbf{a}) = \sigma_e^2 \mathbf{C}_{12} \quad (19.5f)$$

Equations 19.5b–19.5f assume that both σ_e^2 and $\lambda = \sigma_e^2/\sigma_A^2$ are known without error. When BLUP estimates are obtained using *estimated* values (e.g., $\hat{\sigma}_e^2$), this additional source of error further inflates the sampling variances. Bayesian methods (discussed below) accommodate this additional uncertainty.

One concern is that the BLUPs and BLUEs obtained using these procedures may be biased by selection. However, Henderson (1975) showed that, provided variances are known, the estimates will be unbiased by selection when two conditions hold. First, selection decisions must be based on linear combinations of data (such as truncation selection based on individual phenotypes or a linear index based on the phenotypes of an individual and its relatives). Second, that the model must use estimates of fixed effects that are unbiased when selection is absent. These conditions hold under many reasonable forms of artificial selection.

REML Estimation of Unknown Variance Components

The variance components (σ_A^2 and σ_e^2), or, at a minimum, the heritability $h^2 = \sigma_A^2/(\sigma_A^2 + \sigma_e^2)$, must be specified to obtain $\hat{\beta}$ and $\hat{\mathbf{a}}$. Although these variances are generally unknown, they can be estimated, for example, by using **restricted maximum likelihood (REML)**. REML is closely related to BLUP, with (roughly speaking) REML estimates obtained from iterating and updating BLUP estimates until there is suitable convergence (LW Chapter 27). REML maximizes that part of the likelihood function that is unaffected by fixed effects (Patterson and Thompson 1971). Harville (1977) coined the term **restricted ML**, but Thompson (2008) noted that REML maximizes a *residual* likelihood, and hence preferred the term **residual maximum likelihood**. One advantage of REML estimates (over those obtained by other estimation procedures) is that they are unbiased by the estimates of fixed effects (Patterson and Thompson 1971). For further details, we refer the reader to the extensive discussion of REML variance estimation in LW Chapter 27, and to Hofer (1998), Thompson and Mäntysaari (2004), Thompson et al. (2005), Misztal (2008), Thompson (2008), and Gianola and Rosa (2015) for a review of more recent developments, including computational issues.

For much of this chapter, we assume that BLUP variance components are first obtained by REML (although we relax this assumption when discussing Bayesian mixed-model analysis). This two-stage approach of BLUP using estimated variance components (in place of their true values) is called **empirical BLUP or REML/BLUP** (Sorensen and Kennedy 1986; Kennedy and Sorensen 1988; Harville 1990). Kackar and Harville (1981) and Gianola et al.

(1986, 1988) showed that using REML estimation does not result in biased values for BLUPs, but that the resulting predictors may not be “best” (there may be other linear predictors with smaller mean-squared errors).

The matrix of sample variances and covariances for the REML variance component estimates can be approximated by using the best quadratic fit of the restricted likelihood surface, centered at the REML estimates (Smith and Graser 1986; Graser et al. 1987). If σ is a vector of m estimated variance components (σ_A^2 and σ_e^2 in the models thus far considered), we compute the restricted likelihood, $L(\sigma)$, for a grid of values close to the REML solution and then fit the best quadratic surface to the data, using

$$L(\sigma) = \mathbf{b}_0 + \sigma^T \mathbf{b}_1 + \sigma^T \mathbf{Q} \sigma \quad (19.6a)$$

With v variance components, \mathbf{b}_0 and \mathbf{b}_1 are $v \times 1$ vectors, and \mathbf{Q} is an $v \times v$ symmetric matrix of quadratic regression terms (in Chapter 30 we discuss the fitting of such quadratic surfaces in the context of fitness surface estimation). The approximate covariance matrix for the vector of REMLs, $\hat{\sigma}$, is calculated by

$$\text{Var}(\hat{\sigma}) \simeq (-2\mathbf{Q})^{-1} \quad (19.6b)$$

The rationale for this approach is that, for large samples, the inverse of the matrix of second-order partial derivatives of the likelihood surface (evaluated at the maximum likelihood estimate, MLE) approaches the covariance matrix of these estimates (LW Appendix 4). Equation 19.6a is a (second-order) multidimensional Taylor series (Equation A6.7b), with $2\mathbf{Q}$ corresponding to the matrix of second-order partial derivatives (the **Hessian matrix**) of the likelihood function. Alternatively, Meyer (2008) suggested that the use of the likelihood profile function can often return more appropriate estimated confidence intervals than those based on these large-sample variances (see her paper for details).

Although Equation 19.6b returns a large-sample approximation for the uncertainty in REML variance estimates, this cannot be easily translated into how much additional uncertainty is introduced into BLUP estimates by using REML estimates of variance components in place of their true values. These concerns can be addressed in a Bayesian framework (see below), as Bayesian approaches are exact for any sample size (rather than large-sample approximations). Further, they fully incorporate any uncertainty in the variance estimates into the uncertainty in the BLUP estimates.

REML Often Returns Variance Estimates Unbiased by Selection

As with BLUPs and BLUEs (which assume the presence of known variances), REML variance estimates are often unbiased by selection. As we will show, under the infinitesimal model, the relationship matrix, \mathbf{A} , fully accounts for any change in σ_A^2 from disequilibrium, inbreeding, and drift. As a result, if the base population consists of unselected and noninbred individuals in linkage equilibrium and phenotypic data are available for all selected and unselected individuals, then under the infinitesimal model, REML yields essentially unbiased estimates of the additive genetic variance in the base population (Henderson 1949; Henderson et al. 1959; Curnow 1961; Thompson 1973; Rothschild et al. 1979; Sorensen and Kennedy 1984b; Gianola and Fernando 1986; Gianola et al. 1988; Juga and Thompson 1989; Gianola et al. 1989; Im et al. 1989; Fernando and Gianola 1990; Piepho and Möhring 2006). Simulations by van der Werf and de Boer (1990) showed that if the model includes the pedigree information for all individuals but is missing records (trait values) for some, then REML does not necessarily yield unbiased estimates of σ_A^2 , and in this case bias increases with heritability (Jeyaruban and Gibson 1996).

When the base population consists of previously selected individuals, REML no longer provides protection from biased estimates of the additive genetic variance in the population prior to selection, even if the entire pedigree of individuals back to the base population is included (van der Werf 1990; van der Werf and de Boer 1990; van der Werf and Thompson 1992). This arises because of disequilibrium, $d(0) \neq 0$, in the base population (recall from

Equation 16.2 that d is the difference between the additive genetic and genic variances). While Equation 16.7a allows us to predict the dynamics of $d(t)$, it requires the value of $d(t-1)$, so without knowledge of the actual value of the base population, $d(0)$, the relationship matrix cannot fully account for the dynamics of d . Finally, if selection acts on a suite of unmeasured characters whose breeding values are correlated with characters included in the model, REML can generate biased estimates of the variances and covariances of the measured characters (Schaeffer and Song 1978).

ANIMAL-MODEL ANALYSIS OF SELECTION EXPERIMENTS

The basic building block of a mixed-model analysis of selection experiments is the **animal model** (Quaas and Pollak 1980), which estimates the breeding (or additive-genetic) values of all individuals measured during the course of the experiment. We examine its simplest version first, and consider various elaborations in later sections (also see Chapter 22 and LW Chapter 26). While this model has its origin in the animal-breeding literature, it has very widespread applicability. We trust that plant scientists will not be greatly offended, as the “animal” (or better yet, the “individual”) model can be used to analyze plant-selection experiments as well (e.g., Piepho et al. 2008; Bernardo 2010).

The Basic Animal Model

Mixed-models easily allow for overlapping generations by simply predicting breeding values at discrete time points (e.g., every year or at each natural cohort) rather than in each generation. Hence, in the discussion that follows, one can easily replace “generation” by “year” or some other time measure.

To apply the animal model to a selection experiment, one first vectorizes the observations from the entire experiment by letting y_{ij} denote the trait measurement on the j th individual from generation i , where $0 \leq i \leq t$ (generation 0 represents the unselected base population) and $1 \leq j \leq n_i$, where n_i is the number of measured individuals in generation i . Let the vector \mathbf{y} denote the observations on all measured individuals from the entire experiment

$$\mathbf{y} = \begin{pmatrix} \mathbf{y}_0 \\ \mathbf{y}_1 \\ \vdots \\ \mathbf{y}_t \end{pmatrix} \quad \text{where} \quad \mathbf{y}_i = \begin{pmatrix} \mathbf{y}_{i1} \\ \vdots \\ \mathbf{y}_{in_i} \end{pmatrix}$$

The vector \mathbf{y}_i includes the values for all measured individuals from generation i , *including* those culled as well as those that were allowed to reproduce. The simplest animal model for these data is

$$y_{ij} = \mu + a_{ij} + e_{ij} \tag{19.7a}$$

where μ is an overall mean, a_{ij} is the breeding value of the j th measured individual from generation i , and e_{ij} , the deviation between breeding and phenotypic values. Equation 19.1 gives the mixed model as $\mathbf{y} = \mathbf{X}\beta + \mathbf{Z}\mathbf{a} + \mathbf{e}$. With exactly one record per individual, $\mathbf{Z} = \mathbf{I}$. In this simple model, the only fixed effect is the mean, returning $\beta = (\mu)$ and $\mathbf{X} = \mathbf{1}$ (a vector of ones) thus reducing Equation 19.1 to

$$\mathbf{y} = \mu \cdot \mathbf{1} + \mathbf{a} + \mathbf{e} \tag{19.7b}$$

where \mathbf{a} is the vector of breeding values for all individuals measured during the course of the experiment, with $\text{Var}(\mathbf{a}) = \sigma_A^2 \mathbf{A}$.

The relationship matrix, \mathbf{A} , is the key to the animal model, as it includes all of the pedigree information. Because of this information, the animal model is easily extended to allow breeding values to be estimated for individuals without records, *provided* they have measured relatives in the analysis (see Example 19.5). The diagonal elements of \mathbf{A} describe

the amount of inbreeding, with $A_{ii} = (1 + f_i) = 2\Theta_{ii}$, while the off-diagonal elements given by $A_{ij} = 2\Theta_{ij}$ (twice the coefficient of coancestry; see LW Chapters 7 and 26) describe the relatedness of individuals i and j . Recursive methods for obtaining the elements of \mathbf{A} (and \mathbf{A}^{-1}), given a pedigree, are discussed in LW Chapter 26. The simple animal model assumes that all genetic variance is additive, so there is no genetic covariance between residuals. In this case, it is generally assumed that $\text{Var}(\mathbf{e}) = \sigma_e^2 \mathbf{I}$, and the mixed-model equations (Equation 19.4) simplify to

$$\begin{pmatrix} \hat{\mu} \\ \hat{\mathbf{a}} \end{pmatrix} = \begin{pmatrix} n & \mathbf{1}^T \\ \mathbf{1} & \mathbf{I} + \lambda \mathbf{A}^{-1} \end{pmatrix}^{-1} \begin{pmatrix} n \bar{y} \\ \mathbf{y} \end{pmatrix} \quad (19.7c)$$

where n is the total number of individuals in the experiment, $\lambda = \sigma_e^2 / \sigma_A^2 = (1 - h^2) / h^2$, $\hat{\mathbf{a}}$ is the n -dimensional vector of the predicted breeding values of all measured individuals, and $\mathbf{1}$ is an n -dimensional vector of ones. Likewise, the covariance matrices for the fixed effects estimates, \mathbf{C}_{11} , the predictor errors for the BLUPs of breeding values, \mathbf{C}_{22} , and the covariances, \mathbf{C}_{12} , between these estimates are given by

$$\begin{pmatrix} \mathbf{C}_{11} & \mathbf{C}_{12} \\ \mathbf{C}_{12}^T & \mathbf{C}_{22} \end{pmatrix} = \begin{pmatrix} n & \mathbf{1}^T \\ \mathbf{1} & \mathbf{I} + \lambda \mathbf{A}^{-1} \end{pmatrix}^{-1} \quad (19.7d)$$

Response Is Measured by Change in Mean Breeding Values

Under a mixed-model analysis, response is measured by the change in the mean breeding value of a selected population over time. The estimated mean breeding value in generation k (or, alternatively, at time point k) is simply obtained by calculating the average of individual breeding-value estimates for that generation

$$\hat{\bar{a}}_k = \frac{1}{n_k} \sum_{j=1}^{n_k} \hat{a}_{kj} \quad (19.8a)$$

Because the predicted mean breeding value in generation 0 (the unselected base population) is zero by construction ($\bar{a}_0 = 0$), the total (cumulative) response at generation k is $\bar{a}_k - \bar{a}_0 = \bar{a}_k$. In matrix notation, the vector, $\bar{\mathbf{a}}$, of mean breeding values is estimated by

$$\hat{\bar{\mathbf{a}}} = \begin{pmatrix} \hat{\bar{a}}_0 \\ \vdots \\ \hat{\bar{a}}_{t-1} \end{pmatrix} = \mathbf{K}^T \hat{\mathbf{a}} \quad (19.8b)$$

where elements in the k th row of \mathbf{K} are $1/n_k$ when the column corresponds to an individual from generation k and otherwise are zero (see Example 19.1). Thus, for t generations of data (corresponding to $t - 1$ generations of selection, as the analysis includes the unselected base population, generation 0), \mathbf{K} is an $n \times t$ matrix that satisfies $\mathbf{K}^T \mathbf{1}_n = \mathbf{1}_t$ (a $t \times 1$ vector of ones).

From Equation 19.5a, and recalling that $\text{Var}(\mathbf{Bx}) = \mathbf{B} \text{Var}(\mathbf{x}) \mathbf{B}^T$ (LW Equation 8.21b), the sampling covariance matrix for the vector of estimated genotypic means becomes

$$\text{Var}(\bar{\mathbf{a}}) = \sigma_e^2 \mathbf{K}^T \mathbf{C}_{22} \mathbf{K} \quad (19.8c)$$

where the $n \times n$ matrix, \mathbf{C}_{22} , is the solution to Equation 19.7d (under the simple animal model), or more generally, Equation 19.5a. Again, these expressions assume that the residual variance is known without error, and using an estimate for σ_e^2 adds an additional uncertainty by increasing the sample variance.

Example 19.1. As an example of how one performs a mixed-model analysis of a selection experiment, consider the following, very simple, situation. From a base population of unrelated and noninbred individuals, four (indexed by 1–4) are measured and have trait values of 3, 6, 5, and 2, respectively. The two largest individuals are mated, and their resulting offspring (individuals 5–8) have values of 4, 5, 6, and 5. Now suppose that we have either a REML-based estimate of the heritability (which is not advisable here given the very small sample size) or have previous knowledge of its value. Our goal is to estimate the size of the genetic response. Assuming the only fixed effect is the mean, the resulting animal model is $\mathbf{y} = \mathbf{1}\beta + \mathbf{a} + \mathbf{e}$, where

$$\mathbf{y} = \begin{pmatrix} y_1 \\ y_2 \\ y_3 \\ y_4 \\ y_5 \\ y_6 \\ y_7 \\ y_8 \end{pmatrix} = \begin{pmatrix} 3 \\ 6 \\ 5 \\ 2 \\ 4 \\ 5 \\ 6 \\ 5 \end{pmatrix}, \quad \mathbf{a} = \begin{pmatrix} a_1 \\ a_2 \\ a_3 \\ a_4 \\ a_5 \\ a_6 \\ a_7 \\ a_8 \end{pmatrix}, \quad \boldsymbol{\beta} = (\mu), \quad \mathbf{X} = \mathbf{1} = \begin{pmatrix} 1 \\ 1 \\ 1 \\ 1 \\ 1 \\ 1 \\ 1 \\ 1 \end{pmatrix}$$

What is the relationship matrix, \mathbf{A} ? Because individuals 2 and 3 are the parents and all offspring are full sibs, all related individuals have values of $A_{ij} = 1/2$, as $2\theta_{ij} = 1/2$ for both parent-offspring pairs and full sibs. The resulting numerator relationship matrix becomes

$$\mathbf{A} = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 1/2 & 1/2 & 1/2 & 1/2 \\ 0 & 0 & 1 & 0 & 1/2 & 1/2 & 1/2 & 1/2 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 1/2 & 1/2 & 0 & 1 & 1/2 & 1/2 & 1/2 \\ 0 & 1/2 & 1/2 & 0 & 1/2 & 1 & 1/2 & 1/2 \\ 0 & 1/2 & 1/2 & 0 & 1/2 & 1/2 & 1 & 1/2 \\ 0 & 1/2 & 1/2 & 0 & 1/2 & 1/2 & 1/2 & 1 \end{pmatrix}$$

For example, individuals 2 and 5 are parent and offspring, so $A_{5,2} = A_{2,5} = 1/2$, as the parent-offspring covariance $\sigma_A^2/2$. Similarly, individuals 7 and 8 are full-sibs, so $A_{7,8} = A_{8,7} = 1/2$. Note that the relationship matrix for the founders (base population members) is given by the 4×4 identity submatrix in the upper left of \mathbf{A} . This identity matrix implies that noninbred individuals (diagonal elements are one) and unrelated individuals (off-diagonal elements are zero) formed the base population.

Turning to the covariance matrix of the residuals, we make the standard assumption that $\text{Var}(\mathbf{e}) = \sigma_e^2 \mathbf{I}$, or in other words, that all residuals are uncorrelated with common variance, σ_e^2 . However, if there is dominance, the residuals among full-sibs will be inflated by $\sigma_D^2/4$. Likewise, if there are common-family effects (e.g., maternal effects or other shared environmental effects), the residuals are inflated by σ_c^2 , where c is the common-family effect. For now we will ignore these possible complications, which are easily accommodated by adding additional vectors of random effects to the model (see below).

Suppose (from REML or prior knowledge) that the heritability of the trait is $h^2 = 0.3$. Applying Equation 19.3a yields

$$\hat{\mu} = (\mathbf{1}^T \mathbf{V}^{-1} \mathbf{1})^{-1} \mathbf{1}^T \mathbf{V}^{-1} \mathbf{y} = 4.22$$

where we have computed \mathbf{V} using Equation 19.2b as scaled to remove the phenotypic variance σ_z^2 , for example, $\mathbf{V} = 0.3 \mathbf{A} + 0.7 \mathbf{I}$ (note that σ_z^2 cancels in the above expression, as it appears in both \mathbf{V} and \mathbf{V}^{-1}). Substituting into Equation 19.3b yields the 8×1 vector, $\hat{\mathbf{a}}$, of BLUPs for

the individual genetic values, and the resulting 2×1 vector, $\mathbf{K}^T \hat{\mathbf{a}}$, of genetic means

$$\hat{\mathbf{a}} = \begin{pmatrix} -0.366 \\ 0.666 \\ 0.366 \\ -0.666 \\ 0.386 \\ 0.562 \\ 0.739 \\ 0.562 \end{pmatrix} \quad \mathbf{K} = \frac{1}{4} \begin{pmatrix} 1 & 0 \\ 1 & 0 \\ 1 & 0 \\ 1 & 0 \\ 0 & 1 \\ 0 & 1 \\ 0 & 1 \\ 0 & 1 \end{pmatrix} \quad \mathbf{K}^T \hat{\mathbf{a}} = \begin{pmatrix} 0 \\ 0.562 \end{pmatrix} \quad \mathbf{K}^T \mathbf{1}_8 = \begin{pmatrix} 1 \\ 1 \end{pmatrix}$$

Note that (by construction) the mean breeding value in the base population is zero. Hence, the estimated response (for $h^2 = 0.3$) is 0.562. The estimated genetic gain (response) for different assumed heritabilities is found to be as follows

h^2	Estimated response	h^2	Estimated response
0.0	0	0.6	0.940
0.1	0.211	0.7	1.026
0.2	0.398	0.8	1.083
0.4	0.707	0.9	1.095
0.5	0.833	1.0	1.000

The estimated gain increases with the assumed h^2 until it reaches a maximum of ≈ 1.098 for $h^2 = 0.86$, after which it decreases as the assumed h^2 increases. A Bayesian analysis removes this dependency of the estimated response on h^2 by computing a weighted average of response over all possible h^2 values (weighted by their posterior values), yielding a marginal posterior distribution for the response that fully accounts for any uncertainty introduced from estimating the heritability.

Turning to a more standard analysis, the selection differential is the mean of the selected parents minus the mean of all parents, $S = 5.5 - 4 = 1.5$. Likewise, the selection response is the mean of the offspring minus the mean in the previous generation, $5 - 4 = 1$, which yields a realized heritability of $R/S = 1.0/1.5 = 0.67$. Using this value for h^2 in the MM analysis returns a genetic gain of 1.000.

As is apparent from the above example, a mixed-model analysis of a selection experiment has a very different character than an LS analysis. In the latter, one estimates the realized heritability from a suitable regression of phenotypic means on selection differentials. Under a REML/BLUP analysis, however, one first estimates the heritability in the base population (using REML), and then uses (empirical) BLUP to estimate breeding values for all individuals. The genetic response in a given generation is given by the mean of the elements in the estimated vector, $\hat{\mathbf{a}}$, of breeding values in that generation, allowing for the separation of genetic from environmental response, even in the absence of a control population. Thompson and Atkins (1994) noted a fundamental difference between the two approaches in separating genetic from environmental change: an LS analysis typically uses *between-population* information (e.g., contrasts of the means of selection vs. control, or up-vs. down-selected lines), while a REML/BLUP analysis uses *within-population* information (the connections between relatives across generations contained within \mathbf{A}).

Under an MM analysis, the estimate of heritability should be based on REML estimates of the base population variance components, $\hat{h}^2 = \hat{\sigma}_A^2 / (\hat{\sigma}_A^2 + \hat{\sigma}_e^2)$. One must avoid the temptation to estimate realized heritabilities using estimated mean breeding values. For example, Blair and Pollak (1984) regressed the BLUP mean breeding values on cumulative selection differentials to obtain a realized heritability estimate. The problem with this approach is that these mean estimates depend on the *assumed*, rather than the *actual*, heritability (Thompson 1986; Sorensen and Johannsson 1992; Ollivier 1999). In contrast, under a Bayesian analysis, the marginal posterior estimate of mean breeding value in any particular generation averages over all possible h^2 values and is independent of the heritability (Example 19.10).

Hence, a regression of Bayesian-derived mean breeding values on generations can return an unbiased estimate of realized heritability.

Fixed Effects Alter Heritabilities

Variance components in a mixed model are estimated *after* any variation introduced by fixed effects is removed, and this has an impact on the estimated heritability. Under the mixed-model framework, $h^2 = \sigma_A^2 / (\sigma_A^2 + \sigma_e^2)$, where σ_e^2 is the *residual* variance. Here, the denominator is the **fixed-effects-adjusted** phenotypic variance (the sum of the variance components). This is potentially different from the more standard $h^2 = \sigma_A^2 / \sigma_z^2$, which is a function of the (total) phenotypic variance, σ_z^2 . In the absence of fixed effects that differ over individuals (such as sex- or age-specific means), $\sigma_z^2 = \sigma_A^2 + \sigma_e^2$, meaning that the total and fixed-effects-adjusted phenotypic variances are equivalent, as are the two definitions of h^2 . However, if such class-specific differences exist and are explicitly modeled in the analysis, then the variation they contribute to the overall phenotype is *removed*, and the resulting residual variance reduced, so $\sigma_z^2 > \sigma_A^2 + \sigma_e^2$. For example, if a trait mean varies over the sexes, the variance of the trait in the entire population is greater than the variance of the trait within each sex. Consequently, for a model with sex added as a fixed effect, this source of variation is removed, resulting in a smaller residual variance and a larger heritability.

As a result, mixed-model heritability estimates should be larger than estimates that ignore fixed effects. A related issue is that mixed models using the same data but assuming different fixed effects can differ significantly in their estimated residual variances, σ_e^2 , and thus, their resulting heritabilities (Wilson 2008). The implication is that comparison of heritabilities for different traits or populations estimated under a mixed-model framework can be somewhat problematic due to differences in the incorporated fixed effects.

Model Validation

Given the sensitivity of a mixed-model analysis to the validity of the assumptions (in particular, the infinitesimal model), some form of model validation is required to be able to apply these methods with confidence. One approach is to test the infinitesimal-model prediction that estimates of the base population, σ_A^2 , should remain stable as additional generations of selection are considered. If the infinitesimal model holds, A completely accounts for changes in the additive variance in these later generations from both drift and selection-generated LD (a point that will be more fully developed shortly). If, on the other hand, σ_A^2 changes during selection in ways that are not predictable from the infinitesimal model (e.g., significant allele-frequency change occurs), using data from additional generations of selection may result in rather different estimates of the base-population additive variance.

Example 19.2. One of the first REML/BLUP analyses of a selection experiment was performed by Meyer and Hill (1991), who examined the response to selection for adjusted food intake (AFI) in mice (Figure 19.1). AFI is defined as food intake between 4 and 6 weeks, corrected for 4-week weight. Meyer and Hill had three replicate sets, each consisting of high, low, and control lines, for a total of almost 11,000 mice over the course of the experiment. Within-family selection (Chapter 21) on AFI was followed for 23 generations. Meyer and Hill included a number of fixed effects in their model, as well as adding a random effect to control for common litter (i.e., family) effects (see Example 19.7 for details).

As a check of the validity of the MM assumptions (in particular, the infinitesimal model), Meyer and Hill compared variance estimates based on data from generations 5–7 with estimates based on generations 14–23. In both cases, the full pedigree structure was incorporated into the relationship matrix. While incorporation of the complete pedigree information reduces the bias in estimates of the base-population additive variance, some bias will remain if records from some of these individuals are missing (van der Werf and de Boer 1990). In other words, knowledge of the pedigree is not sufficient; the phenotypic values of these individuals (even if not selected) are also needed to remove bias. Meyer and Hill observed a dramatic

decline in the estimated additive variances (from 19.2 based on generations 5–7 to 2.5 based on generations 14–23). Under the infinitesimal model, both estimates should infer the base-population variance, so this large decrease suggests that the infinitesimal model may not be appropriate for assessing this trait. It is interesting to note that this decrease in the estimate of σ_A^2 occurred even as the total variance increased dramatically (from 23.88 to 33.93). This increase resulted mainly from an increase in the estimated environmental variance (from 12.9 to 25.5), although there was also a slight increase in the litter-effects variance (from 4.78 to 5.96).

Several other REML/BLUP analyses of selection experiments in mice also found differences between estimates of base-population additive variance when comparing data from early and late generations. Beniwal et al. (1992a and 1992b) observed decreases in the estimated additive variance (in body weight, litter size, and lean mass), while Heath et al. (1995) observed an increase in the additive variance in body weight.

In contrast, Martinez et al. (2000) found no changes in estimates of σ_A^2 over 20 generations of selection for body composition (fat pad to body weight ratio) in mice. These authors examined REML estimates of the additive variance (and heritability) using various subsets of the full 20 generation data. Consistent estimates of the additive variance were obtained (i) using the set of all records and the complete pedigree from generations 0–20; (ii) using records from generations 9–20, but with pedigree information from generation 0; and (iii) using only three-generation blocks of the phenotypic data as the entire dataset. They concluded that the selection response, while resulting in a roughly four-fold change in mean, was still well-fit by the infinitesimal model. Finally, Holt et al. (2005) observed no changes in base-population additive variance estimates over time for a high line of mice selected for litter size, but did see a variance reduction in the low line.

Separating Genetic and Environmental Trends

Observed improvement in a trait over time (such as milk yield) may be due entirely to improvement in the environment (better husbandry and nutrition), entirely from genetic changes (response from selected breeding), or (most likely) a combination of both. Thus, it is critical to partition an observed phenotypic change into genetic and environmental components. For example, Southwood and Kennedy (1991) showed that the improvement in several litter-size-related traits in pigs over a 10-year period in Quebec was entirely due to environmental, rather than genetic, changes. Recent plant examples are given by Laidig et al. (2014, 2017) and Piepho et al. (2014).

In a least-squares analysis, any underlying environmental trend is assumed to be removed by contrasting selected and control populations (or contrasting populations selected in opposite directions). The rationale is that the k th individual from population j in generation t can be described as

$$y_{j,tk} = \mu + b_{j,t} + a_{j,tk} + e_{j,tk} \quad (19.9)$$

where $b_{j,t}$ is the environmental trend in population j . If the common environmental value is the same in both the selected and the control populations ($b_{s,t} = b_{c,t}$), then the difference in phenotypic means in generation t between these populations is

$$\bar{y}_{s,t} - \bar{y}_{c,t} = (\bar{a}_{s,t} - \bar{a}_{c,t}) + (e_{s,t} - e_{c,t}) \quad (19.10)$$

Because the residuals, e , have an expected value of zero, this contrast provides an unbiased estimate of $\bar{a}_{s,t}$ provided there is no significant drift in the mean breeding value of the control population (meaning that $\bar{a}_{c,t} \approx 0$). However, if genotype-environment interactions are present, the environmental values can differ between populations, in which case Equation 19.10 has an additional term, $(b_{s,t} - b_{c,t})$. Hence, even when a control population is used, a least-squares analysis can still give biased results if there is significant drift in the mean of the control population ($|\bar{a}_{c,t}| \gg 0$) or significant $G \times E$.

Insight into another way in which the use of a control in an LS analysis can be misleading was offered by Su et al. (1997), who examined response in body weight in chickens starting

from a base population with a known previous history of selection on this trait. Because of prior selection, the base population showed a slippage of the mean back to the original (unselected) value. If this population was used as a control, this slippage would be taken as a decay in the environment over time, resulting in an overestimation of the selection response when using an LS analysis. Because of this concern, Su et al. used a mixed model to estimate the genetic response.

A mixed-model analysis estimates the mean *breeding value*, rather than the *phenotypic mean*, of the population, which allows for this separation of the genetic change from any environmental change (Henderson et al. 1959; Blair and Pollak 1984; Sorensen and Kennedy 1984a; Kennedy 1990). Such a separation is possible because \mathbf{A} tracks the flow of genes through the population, which allows us to make estimates of breeding values independent of environmental effects by borrowing information from relatives across generations. This is dependent on the model assumptions holding, but when they do, a mixed-model analysis does not require a control population. This being said, Sorensen et al. (2003) showed that the inclusion of a control in an MM analysis generally improves the efficiency of estimates (resulting in smaller standard errors).

Common-environment effects are incorporated into the basic animal model by simply adding a fixed effect, b_t , for the common environmental effect in generation t

$$y_{tk} = \mu + b_t + a_{tk} + e_{tk} \quad (19.11)$$

For T generations, there are T estimable fixed effects (μ and all but one b_t). Typically, one either constrains the b_t to sum to zero or arbitrarily sets one of the b_t equal to zero. We do the latter with b_1 , so the vector of fixed effects becomes

$$\boldsymbol{\beta} = (\mu, b_2, \dots, b_T)^T$$

and the corresponding design matrix, \mathbf{X} , has zeros or ones in columns 2 though T , corresponding to the generation in which the individual was scored

$$\mathbf{X} = \begin{pmatrix} 1 & 0 & \cdots & 0 \\ 1 & 0 & \cdots & 0 \\ \vdots & & & \vdots \\ 1 & 1 & \cdots & 0 \\ 1 & 1 & \cdots & 0 \\ \vdots & & & \vdots \\ 1 & 0 & \cdots & 1 \\ 1 & 0 & \cdots & 1 \end{pmatrix}$$

To remind the reader how \mathbf{X} is obtained, recall that $\mathbf{X}\boldsymbol{\beta}$ returns a vector that adjusts each observation for the fixed effects. From the rules of matrix multiplication, the adjustment for observation i is the inner product, $\mathbf{x}_{i\cdot}^T \boldsymbol{\beta}$, where the row vector $\mathbf{x}_{i\cdot}^T$ corresponds to the i th row of \mathbf{X} . Likewise, the j th column of \mathbf{X} corresponds to the vector of weights (over all observations) for the j th fixed effect. Here, the first column is all ones, as all observations contain the mean, μ . Entries in column 2 (corresponding to b_2) are zero, unless an observation is from generation 2 (and hence has a mean of $\mu + b_2$), in which case the entry is 1, and so forth. Hence, the first two displayed rows of the above \mathbf{X} correspond to observations from generation 1, which have means of μ , the second pair of displayed rows to generation 2 (with means of $\mu + b_2$), and the last pair to generation T (with means of $\mu + b_T$).

An alternative approach is to treat the b_i as random (as opposed to fixed) effects, drawn independently (i.e., uncorrelated across generations) from a normal distribution with a mean of zero and an unknown variance, σ_b^2 . The assumption of no environmental correlation between adjacent generations can be questionable (at best), and treating the b_i as fixed, rather than random, removes these concerns (although at a cost of absorbing more degrees of freedom than with a random-effects analysis).

Example 19.3. To examine the potential bias from $G \times E$ and drift in the control population, Blair and Pollak (1984) examined a seven-generation selection experiment on 14-month greasy fleece weight in sheep. The model they assumed was that the m th individual in generation t , with fixed sex effect (male/female), v_i , fixed age of dam effect (mature/immature), d_j , rearing rank effect (single/twin), r_k , and year effect, b_t , had a phenotypic value of

$$y_{ijktm} = v_i + d_j + r_k + b_t + a_{tm} + e_{tm}$$

In matrix form, $\mathbf{y} = \mathbf{X}\beta + \mathbf{Z}\alpha + \mathbf{e}$, where the vector, β , contains the fixed effects for sex (v), dam age (d), and rearing rank (r), in addition to the effects for years (b). Both the selected and control lines were subjected to separate BLUP analyses using this model, and three different estimates of selection response were considered:

- (i) $\widehat{\bar{y}}_{s,t} - \widehat{\bar{y}}_{c,t}$, the estimated phenotypic means following adjustment for the fixed effects (v , d , and r), obtained by $\widehat{\bar{y}}_{x,t} = \widehat{\bar{a}}_{x,t} + \widehat{b}_{x,t}$, where $x = c$ or s , corresponding to the control and selection lines, respectively. This is an unbiased estimate of the response if there is no drift in the control population ($\bar{a}_{c,t} \simeq 0$) and no $G \times E$, so that $b_{c,t} = b_{s,t}$.
- (ii) $\widehat{\bar{y}}_{s,t} - \widehat{b}_{c,t}$, the (fixed-effects-adjusted) phenotypic mean of the selected population minus the common environmental effect, as estimated from the control population.
- (iii) $\widehat{\bar{a}}_{s,t}$, the BLUP estimate of the mean breeding value in the selected population.

Estimate (i) mimics the estimate used in a least-squares analysis, and Blair and Pollak showed that it is independent of the assumed heritability. Estimates (ii) and (iii) are highly dependent on the assumed (or estimated) heritabilities in the control and selected populations. As Figure 19.2 reveals, all three estimates show a positive genetic trend (following a reversed response over the first few generations). As expected, the estimated response using only the predicted mean breeding value is smoother than the other two estimates.

The potential biases in a least-squares analysis of these data based on the contrast between the control and selected phenotypic means are seen in the two lower graphs in Figure 19.2. The lower left graph plots the difference in the estimated common environmental effects between selected and control populations ($\widehat{b}_{ct} - \widehat{b}_{st}$). Ignoring the inherent variance in estimating the \widehat{b} , the average difference (via a paired t test) is not significantly different from zero. The right-hand graph plots the predicted mean breeding value of the control population, which is assumed to be zero under the least-squares analysis. As can be seen, there is a slight, but positive, trend in the mean. When the selected mean is adjusted by subtracting from the control mean, the net result is that the LS analysis slightly underestimates the true response, $\bar{a}_{s,t}$. Thus, there is no evidence of error being introduced by $G \times E$ differences between the control and selected lines, but error is introduced if the mean breeding value of the control population departs significantly from zero.

Validation That a Trend Is Indeed Genetic

The estimated common-environmental (b) and additive-genetic (a) effects are highly dependent on the estimated (or assumed) base population heritability, h^2 . Hence, using BLUP to separate genetic from environmental values is highly dependent on the heritability used being close to its true value. Other departures from mixed-model assumptions (e.g., the infinitesimal model and assuming that BLUP and REML estimates are unaffected by selection) can also result in incorrect assignment of the relative importance of environmental versus genetic values. Thus, achieving some sort of validation of a detected trend is critical.

We have already discussed validation of the general animal model, namely, by examining the consistency of the estimated additive variance over different subsets of the data. Similar validation that a trend is indeed genetic can be performed by again examining the consistency across an analysis. For example, if a control population is used, a BLUP

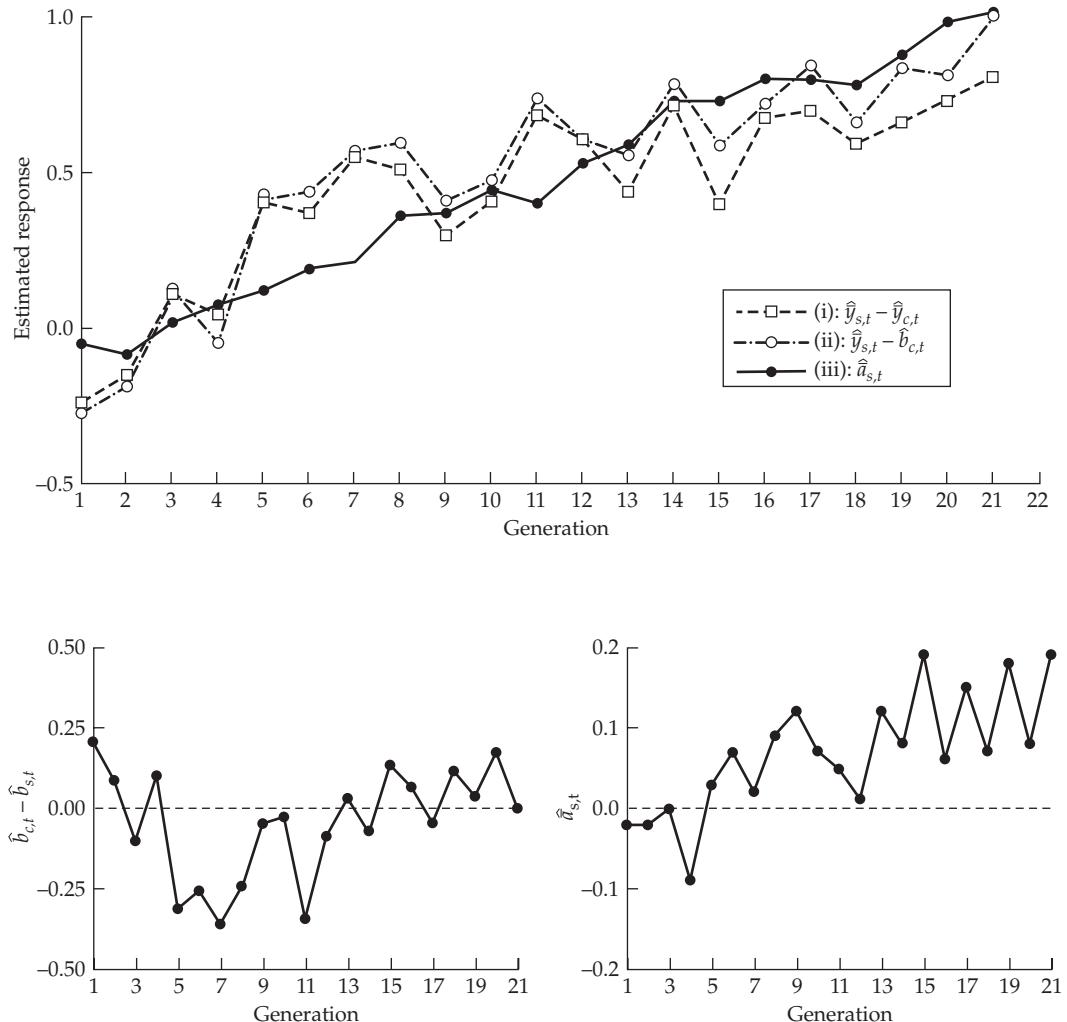

Figure 19.2 Trends for the selection experiment in Example 19.3. See the example for details.

analysis can estimate the amount of drift in the mean breeding value from its expected value of zero. Likewise, estimates of the selection and control environmental effects can be compared (Figure 19.2), and if these are reasonably consistent, then a joint analysis (assuming the same environmental values in both populations) may yield more precise estimates of the generational common-environmental values. Likewise, if the common-environmental estimates are significantly different between selected and control populations, the possibility of $G \times E$ needs to be seriously considered. Even when using a control population, there is still much to be gained by subjecting each group to a mixed-model (e.g., BLUP) analysis (Sorensen et al. 2003).

Even in the absence of a control population, one can still attempt to validate a trend. For example, Boichard et al. (1995) examined several different methods to attempt to validate genetic trends in dairy cattle, all of which involved the comparison of predicted trend values using different subsets of the data. The authors were interested in comparing the performance of a mixed model (AM90) used for French Holsteins from 1990 to 1992 with a more recent model (AM93), whose use started in 1993 (the models differed in their choice of included fixed and random effects). For a variety of reasons, there was concern that the older AM90 model yielded biased trend estimates. One check was based on the fact that milk yield data are in the form of multiple records per individual, so a repeatability model was appropriate (Example 19.6). The authors compared EBVs based only on the

first lactations with estimates using all records. They found that the trends estimated from the first versus all lactations agreed well under the AM93 model, but differed dramatically under the AM90 model. Other measures of consistency (for example, looking at the stability of estimated breeding values of individuals as more information is added) also showed that the newer AM93 model seemed relatively robust, while the older AM90 model seemed to produce biased estimates of the trend.

Replicate Lines

It is straightforward to jointly analyze multiple lines simultaneously. For n lines, we write the total vector of observations as $\mathbf{y}^T = (\mathbf{y}_1^T, \mathbf{y}_2^T, \dots, \mathbf{y}_n^T)$, where \mathbf{y}_k is the vector of all observations from line k . If the generational environmental effects are assumed to be the same across the lines, the model for the i th individual in generation t from line k is

$$y_{k,ti} = \mu + b_t + a_{k,ti} + e_{k,ti} \quad (19.12a)$$

Alternatively, if the environmental effects are potentially different in each line

$$y_{k,ti} = \mu + b_{k,t} + a_{k,ti} + e_{k,ti} \quad (19.12b)$$

The power of combining multiple lines arises when environmental effects can be assumed to be the same across the lines. In this case, the effective sample size for estimating each effect is increased, and (presumably) the resulting sampling variance is decreased, improving the precision of the estimates.

The assumed covariance matrix for the vector of joint breeding values over a set of replicates can take several forms. If the founding members for each line are drawn from the same base population (but otherwise unrelated), then the covariance matrix for the vector of breeding values \mathbf{a} has a block-diagonal form, with the i th block corresponding to $\sigma_A^2 \mathbf{A}(i)$, the relationship matrix for line i times the base population additive variance. If the founding members of some lines are related, then \mathbf{A} is more complex, reflecting these relationships. Further modifications for joint analysis were proposed by Visscher and Thompson (1990), and extended by Beniwal et al. (1992a, 1992b) and Heath et al. (1995) by allowing the additive *genic* variance to change over time (discussed below; recall from Chapter 16 that the additive genic variance is the value for σ_A^2 in the absence of LD). For example, one might assume that the additive genic variance remains constant for the first few generations of selection, after which it assumes a different value. This is a reasonable, but still ad hoc, approach for attempting to deal with potential departures from the infinitesimal model.

Estimating the Additive Variance at Generation t

Even under the infinitesimal model, the additive variance changes over time by the generation of disequilibrium (Chapter 16) and inbreeding (Chapters 3 and 24), a point more fully explicated in the next section. While REML provides an estimate of the base population additive genic variance, $\sigma_a^2(0)$ (which is unbiased provided the model assumptions hold), it does not immediately provide estimates of the actual additive variance, $\sigma_A^2(t) = \sigma_a^2(t) + d(t)$, in any particular generation of selection. The most straightforward approach is to use the parent-offspring regression for each generation of selection to estimate the additive genetic variance in the parents. With parents from generation t and offspring in generation $t+1$, the regression estimates the heritability of the parents, $h_A^2(t)$ (Robertson 1977b). The drawback with this approach is the typically small sample size associated with each generation (resulting in large standard errors for each heritability or variance estimate). Ideally, one would like to be able to combine information across generations in such a way as to improve the variance estimates.

Sorensen and Kennedy (1984b) suggested one approach, which is to use a mixed-model analysis treating generation t as the base population. In particular, one considers only the data from generation t onward (say, to generation T), and the relationship matrix is adjusted

to assume that generation t is the base population. The resulting covariance matrix for the breeding values becomes

$$\text{Var} \begin{pmatrix} \mathbf{a}_t \\ \mathbf{a}_{t+1} \\ \vdots \\ \mathbf{a}_T \end{pmatrix} = \sigma_A^2(t) \begin{pmatrix} \mathbf{I} & \mathbf{A}_{t,t+1} & \cdots & \mathbf{A}_{t,T} \\ \mathbf{A}_{t,t+1} & \mathbf{A}_{t+1,t+1} & \cdots & \mathbf{A}_{t+1,T} \\ \vdots & \ddots & \vdots & \vdots \\ \mathbf{A}_{t,T} & \mathbf{A}_{t+1,T} & \cdots & \mathbf{A}_{T,T} \end{pmatrix} \quad (19.13)$$

where \mathbf{a}_k is the vector of breeding values in generation k , and $\mathbf{A}_{j,k}$ is the relationship matrix of associations between individuals in generations j and k . By taking $\text{Var}(\mathbf{a}_t) = \sigma_A^2(t)\mathbf{I}$, we are assuming that all individuals in generation t are unrelated and noninbred, as this is now our base population. All measured individuals from generation t (including those not leaving offspring) are included in the base population. While this approach seems logical, it is still somewhat ad hoc and not exact. Simulation studies by van der Werf and de Boer (1990) showed that Sorensen and Kennedy's approach tends to overestimate the true additive-genetic variance.

Another potential approach to estimating the additive variance in generation t would be to use the variance among the predicted breeding values within a generation

$$\text{Var}(A_t) = \frac{1}{n-1} \sum_{i=1}^{n_t} (\hat{a}_{ti} - \bar{\hat{a}}_t)^2 \quad (19.14)$$

Again, however, there are complications. One is that the assumed genetic variance used to obtain the BLUP estimates has a strong influence on the values of the estimated \hat{a}_{ti} . Another is that Equation 19.14 estimates $\sigma^2(\hat{a})$, which is different from σ_A^2 , as the former estimates $\rho^2\sigma_A^2$, where $\rho^2 < 1$ is the accuracy of the predicted breeding values (Equation 20.23c). Hence, Equation 19.14 is expected to underestimate the true variance, σ_A^2 . Sorensen et al. (2001) noted that the use of Equation 19.14 in a *Bayesian* framework (wherein the uncertainty in variance estimates is naturally incorporated into the analysis) avoids both of these problems.

THE RELATIONSHIP MATRIX, A, ACCOUNTS FOR DRIFT AND DISEQUILIBRIUM

There are three potential sources of change in the additive-genetic variance, σ_A^2 , during a selection experiment: allele-frequency change from selection; allele-frequency change from drift; and gametic-phase disequilibrium generated by selection (Chapters 5 and 16). Under the infinitesimal model, selection does not change allele frequencies, leaving only drift and disequilibrium as potential agents of change. If the average effect for any allele is small, allele-frequency changes (from selection) are also small, at least for a modest number of generations (Chapters 5 and 25), and the infinitesimal assumption can be approximately correct. In these settings, the relationship matrix, \mathbf{A} , in an MM analysis accounts for the effects of gametic-phase disequilibrium as well as genetic drift (Sorensen and Kennedy 1983, 1984a), and hence for all changes in σ_A^2 , provided the base population consists of unrelated, noninbred individuals in linkage equilibrium. As a result, as long as selection-induced allele-frequency change is negligible, the variance-covariance matrix of the vector of breeding values remains the product of the base population additive-genetic variance and the relationship matrix, $\text{Var}(\mathbf{a}) = \sigma_A^2 \mathbf{A}$.

To both see this point and provide connections among these three potential agents of change, recall two important concepts from Chapter 16. First, the additive-genetic variance can be decomposed as $\sigma_A^2 = \sigma_a^2 + d$, the sum of the additive *genic* variance, σ_a^2 , and the disequilibrium contribution, d (Equation 16.2). The former is the additive variance under linkage equilibrium and Hardy-Weinberg. Under drift and assuming only additive effects, the expected genic variance at generation t is simply $\sigma_a^2(t) = \sigma_a^2(0)(1 - f_t)$, where f_t is the inbreeding coefficient in generation t (Equation 16.9c). Second (Equation 16.8a), the regression of the breeding value, A_i , of an individual on the breeding values, A_{m_i} and A_{f_i} ,

of its parents is

$$A_i = \frac{1}{2} A_{f_i} + \frac{1}{2} A_{m_i} + s_i \quad (19.15a)$$

where the **segregation residual**, s , results from Mendelian sampling due to the segregation of alleles at heterozygous loci in the parents (Example 16.2).

The critical idea in this section—that the conditional independence of the covariance relationships of the vector, \mathbf{a} , from selection and drift (given \mathbf{A})—follows as a consequence of the behavior of the segregation residuals under the infinitesimal model. To see this, note that if the joint distribution of breeding values for parent and offspring is multivariate normal (as occurs under the standard infinitesimal model), the regression given by Equation 19.15a is linear and homoscedastic, meaning that s is *independent* of the parental breeding values. Its variance, $\sigma_{s_i}^2$, for individual i is also independent of parental breeding values, but it does depend on the average inbreeding, \bar{f}_i , of its parents, such that

$$\sigma_{s_i}^2 = (1 - \bar{f}_i) \sigma_a^2 / 2 \quad (19.15b)$$

Provided the vector, \mathbf{s} , of Mendelian sampling residuals remains multivariate normal, then $\mathbf{s} \sim \text{MVN}(\mathbf{0}, [\sigma_a^2 / 2] \mathbf{F})$, with \mathbf{F} representing a diagonal matrix whose i th element is $(1 - \bar{f}_i)$, namely, one minus the average inbreeding of the parents of i . If k and j are the parents of i , then

$$F_{ii} = (1 - \bar{f}_i) = \left(1 - \frac{f_k + f_j}{2}\right) = \left(2 - \frac{A_{kk} + A_{jj}}{2}\right) \quad (19.16)$$

where $A_{kk} = (1 + f_k)$ denotes the k th diagonal element of the relationship matrix, \mathbf{A} . Thus, the distribution of the Mendelian sampling terms, \mathbf{s} , is unaffected by the breeding values of the parents (and hence by selection or assortative mating), while the effects of drift are fully accounted for by \mathbf{F} .

The final key concept is that when we have the complete pedigree of all individuals in the selection experiment, any breeding value can be expressed as a linear function of the base population breeding values and Mendelian sampling terms (Sorensen and Kennedy 1984a; Kennedy et al. 1988). This is an extension of the idea of ancestral regressions discussed in Chapter 15. Example 19.4 shows a critical consequence of this: because the mean breeding value in the base population is zero (by construction), *most of the response in a selection experiment comes, not from base individuals with exceptional breeding values, but rather from Mendelian sampling (i.e., segregation) generating new variation.*

Example 19.4. Suppose individuals 1 through 4 are from the base population (and assumed unrelated), while individuals 5 and 6 are the offspring from 1 and 2, and 3 and 4, respectively. The offspring breeding values can be written as

$$A_5 = \frac{1}{2} A_1 + \frac{1}{2} A_2 + s_5 \quad \text{and} \quad A_6 = \frac{1}{2} A_3 + \frac{1}{2} A_4 + s_6$$

If individual 7 is the offspring of parents 5 and 6, its breeding value is

$$\begin{aligned} A_7 &= \frac{1}{2} A_5 + \frac{1}{2} A_6 + s_7 = \frac{1}{2} \left(\frac{1}{2} A_1 + \frac{1}{2} A_2 + s_5 \right) + \frac{1}{2} \left(\frac{1}{2} A_3 + \frac{1}{2} A_4 + s_6 \right) + s_7 \\ &= \frac{1}{4} (A_1 + A_2 + A_3 + A_4) + \frac{1}{2} (s_5 + s_6) + s_7 \end{aligned}$$

Note that as individuals become increasingly more distant from the base population, the majority of their breeding value is determined by Mendelian sampling, rather than the base population breeding values of their ancestors.

This linear relationship, highlighted in the last example, between the $n \times 1$ vector, \mathbf{a} , of all breeding values and the $m \times 1$ vector, \mathbf{a}_b (breeding values for the m base population founders), and the $(n - m) \times 1$ vector, \mathbf{s} (Mendelian segregation values), can be formally expressed as follows. Defining $\mathbf{w}^T = (\mathbf{a}_b^T, \mathbf{s}^T)$, we can write

$$\mathbf{a} = \mathbf{T}\mathbf{w} = \mathbf{T} \begin{pmatrix} \mathbf{a}_b \\ \mathbf{s} \end{pmatrix} \quad (19.17a)$$

where the $n \times n$ matrix, \mathbf{T} , describes the flow of genes from ancestors to relatives. Indexing the elements in \mathbf{a} so that ancestors precede their relatives, \mathbf{T} is a lower-triangular matrix (all above-diagonal elements are zero) with diagonal values of one. Further, the upper-left $m \times m$ submatrix of \mathbf{T} , corresponding to the base population (and thus, no known ancestors), has all below-diagonal elements with value zero. For descendants of the base population founders, the off-diagonal element of \mathbf{T} associated with (descendant) individuals i, j is

$$T_{i,j} = \frac{1}{2} (T_{f,j} + T_{m,j}) \quad \text{for } j < i \quad (19.17b)$$

where f and m correspond to the index for the father and mother of i . Equations 19.17a and 19.17b formalize the decomposition (highlighted in Example 19.4) of a current breeding value into base population and segregation contributions.

From Equation 19.17a

$$\mathbf{Var}(\mathbf{a}) = \mathbf{Var}(\mathbf{T}\mathbf{w}) = \mathbf{T} \mathbf{Var}(\mathbf{w}) \mathbf{T}^T \quad (19.18a)$$

Because we assume that the base population consists of unrelated individuals ($\mathbf{A}_b = \mathbf{I}$) in gametic-phase equilibrium (so that $\sigma_A^2 = \sigma_a^2$), $\mathbf{Var}(\mathbf{a}_b) = \sigma_a^2 \mathbf{I}$, while $\mathbf{Var}(\mathbf{s}) = (\sigma_a^2/2) \mathbf{F}$. Under multivariate normality, \mathbf{a}_b and \mathbf{s} are independent, and hence uncorrelated, yielding

$$\mathbf{Var}(\mathbf{w}) = \mathbf{Var} \begin{pmatrix} \mathbf{a}_b \\ \mathbf{s} \end{pmatrix} = \sigma_a^2 \begin{pmatrix} \mathbf{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{F}/2 \end{pmatrix} = \sigma_a^2 \mathbf{\Lambda} \quad (19.18b)$$

where $\mathbf{\Lambda}$ is a diagonal matrix with elements of one when both parents are unknown (base population) and $0.5(1 - f)$ when both parents are known. If, due to missing data, only a single parent is known, the diagonal element becomes $(3 - f)/4$, where f is the inbreeding in the known parent (Kennedy et al. 1988). Putting Equations 19.18a and 19.18b together yields

$$\mathbf{Var}(\mathbf{a}) = \sigma_A^2 \mathbf{A} = \mathbf{T} \mathbf{Var}(\mathbf{w}) \mathbf{T}^T = \sigma_a^2 \mathbf{T} \mathbf{\Lambda} \mathbf{T}^T$$

Assuming $\sigma_A^2 = \sigma_a^2$ (no disequilibrium in the base population), then

$$\mathbf{A} = \mathbf{T} \mathbf{\Lambda} \mathbf{T}^T \quad (19.18c)$$

as obtained by Henderson (1976) and Thompson (1977). As an aside, this expression, coupled with the simple form for \mathbf{T} , is what allowed Henderson (1976) to obtain a very rapid way of computing \mathbf{A}^{-1} . The critical feature of Equation 19.18c is that $\mathbf{\Lambda}$, which describes the Mendelian sampling residuals, is *independent of selection and assortative mating* (under the infinitesimal model), and also accounts for the reduction in additive variance from genetic drift.

If the infinitesimal model does not hold, then residual values may vary with parental breeding values, and hence selection can influence the distribution of residuals. Provided that the change in allele frequencies over the course of the experiment is small, this bias may not be too serious (e.g., Maki-Tanila and Kennedy 1986). Another key assumption from the infinitesimal model is that the distribution of residuals does not significantly deviate from normality. Chapter 24 examines this rather technical issue in some detail.

When the genic variance, σ_a^2 , itself is changing due to selection, knowledge of \mathbf{A} is no longer sufficient to account for all changes in σ_A^2 . Beniwal et al. (1992a) suggested that this

complication might be (somewhat) accommodated by a modification of the additive-genetic covariance matrix. Consider the simple case of two time blocks with different (unknown) genic variances: the breeding values, \mathbf{a}_1 , in the first block have a base genic variance, $\sigma_a^2(1)$, while the vector of breeding values, \mathbf{a}_2 , from the second block start with a genic variance of $\sigma_a^2(2)$. First we decompose the diagonal matrix Λ into two blocks

$$\Lambda = \begin{pmatrix} \Lambda_1 & \mathbf{0} \\ \mathbf{0} & \Lambda_2 \end{pmatrix}$$

where Λ_i represents block i . The covariance matrix for the breeding values can be written as

$$\text{Var}(\mathbf{a}) = \text{Var} \begin{pmatrix} \mathbf{a}_1 \\ \mathbf{a}_2 \end{pmatrix} = \sigma_a^2(1)\mathbf{T} \begin{pmatrix} \Lambda_1 & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{pmatrix} \mathbf{T}^T + \sigma_a^2(2)\mathbf{T} \begin{pmatrix} \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \Lambda_2 \end{pmatrix} \mathbf{T}^T \quad (19.19)$$

The variances $\sigma_a^2(1)$ and $\sigma_a^2(2)$ can be estimated separately using REML, and they correspond to the genic variances at the start of each block, which may be reduced by drift within the block. Heath et al. (1995) generalized this approach to allow the genic variance to change in each generation.

MODIFICATIONS OF THE BASIC ANIMAL MODEL

In many cases, it is prudent to modify the simple animal model by considering additional fixed and random effects to more fully accommodate any relevant biological features. For example, genetic and environmental effects can be separated without a control population by adding fixed effects to account for environmental trends. Likewise, as we will discuss shortly, it is often reasonable to include additional random effects, such as maternal or litter effects, to reduce potential correlations between the residuals.

Another modification of the basic model occurs when the phenotypic scores (records) of the parents are unknown. Example 19.5 shows how we can estimate these as random effects, but likely with bias (when selection occurs). As we will cover shortly, an alternative is to treat these breeding values of unmeasured parents as fixed, rather than random.

Example 19.5. A feature of mixed models is that they can often predict the values of random effects (in this case, a breeding value) for an individual with no records (but whose relatives have records). Let 0 (unmeasured) and 1 (measured) index parents that each have a measured offspring (indexed as 2 and 3, respectively), via unrelated and unmeasured individuals. If we assume that there is a single fixed effect (the mean, μ), the resulting mixed model becomes

$$\begin{pmatrix} y_1 \\ y_2 \\ y_3 \end{pmatrix} = \begin{pmatrix} 1 \\ 1 \\ 1 \end{pmatrix} \mu + \begin{pmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} a_0 \\ a_1 \\ a_2 \\ a_3 \end{pmatrix} + \begin{pmatrix} e_1 \\ e_2 \\ e_3 \end{pmatrix}$$

where y_1 through y_3 denote the values of the three measured individuals. Notice that there is no y_0 in this model (as there is no observed value for individual 0), but that parent 0's breeding value, a_0 , is included. To complete the mixed-model analysis, we need the relationship matrix, \mathbf{A} . Because all parents are assumed to be unrelated, so are the two measured offspring, yielding

$$\mathbf{A} = \begin{pmatrix} 1 & 0 & 1/2 & 0 \\ 0 & 1 & 0 & 1/2 \\ 1/2 & 0 & 1 & 0 \\ 0 & 1/2 & 0 & 1 \end{pmatrix}$$

Provided unmeasured individuals have measured relatives, \mathbf{A} allows us to estimate their breeding values. In this case, we can estimate the breeding value, a_0 , for the unmeasured

parent (for example, by using Equation 19.3b to estimate the vector, \mathbf{a} , of the four breeding values), as \mathbf{A} shows that information on a_o is provided from its observed offspring value, y_2 .

Connections between relatives are often referred to as **links**, and the number and strengths of links (or the **connectiveness**) in a relationship matrix is one measure of its precision in estimating breeding values (i.e., the prediction error variance; see Kennedy and Trus 1993). The breeding value of an unmeasured individual with few measured relatives will have much less precision than that of an individual with a large number of measured, and close, relatives. Despite this flexibility in predicting breeding values for individuals with missing records, it is important to again stress that the simple inclusion of all pedigree relationships appears *not* to be sufficient to yield unbiased BLUP/REML estimates when selection occurs. The records (measured values) of all individuals upon which selection decisions have been based must also be included (van der Werf 1990; van der Werf and de Boer 1990; van der Werf and Thompson 1992).

Models with Additional Random Effects

We have assumed that residuals of a mixed model are uncorrelated and homoscedastic, making their covariance matrix $\text{Var}(\mathbf{e}) = \sigma_e^2 \mathbf{I}$. When additional random effects are present but ignored by the model, they are inadvertently subsumed into the residuals, introducing correlations and heteroscedasticity, which, in turn, may bias the BLUP estimates. For example, if sibs share a common maternal environment, this introduces correlations between them beyond those accounted for by \mathbf{A} . If the model only includes \mathbf{a} and \mathbf{e} , this additional covariance appears between the residuals of sibs, and the true covariance matrix for \mathbf{e} is no longer the assumed diagonal, which leads to biased estimates of the BLUEs and BLUPs. By suitably incorporating additional random effects, we can develop a new model, in which the residuals again have the simple OLS covariance structure, $\text{Var}(\mathbf{e}) = \sigma_e^2 \mathbf{I}$.

Suppose there is a second vector, \mathbf{u} , of m random effects (e.g., the common effects from the m families in our sample) in addition to the vector, \mathbf{a} , of p breeding values, and vector of residuals, \mathbf{e} . Equation 19.1 becomes

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{a} + \mathbf{W}\mathbf{u} + \mathbf{e} \quad (19.20a)$$

where \mathbf{X} , \mathbf{Z} , and \mathbf{W} are $n \times q$ (n observations and q fixed effects), $n \times p$, and $n \times m$ incidence matrices. Assuming that common-family effects are *not* shared across different families (even if the families are related), the assumed covariance structures for the three vectors of random effects become $\text{Var}(\mathbf{a}) = \sigma_A^2 \mathbf{A}$, $\text{Var}(\mathbf{u}) = \sigma_u^2 \mathbf{I}$, and $\text{Var}(\mathbf{e}) = \sigma_e^2 \mathbf{I}$, where \mathbf{a} , \mathbf{u} , and \mathbf{e} are uncorrelated. This can be compactly written as

$$\text{Var} \begin{pmatrix} \mathbf{a} \\ \mathbf{u} \\ \mathbf{e} \end{pmatrix} = \begin{pmatrix} \sigma_A^2 \mathbf{A} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \sigma_u^2 \mathbf{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \sigma_e^2 \mathbf{I} \end{pmatrix} \quad (19.20b)$$

yielding a covariance matrix of \mathbf{y} as

$$\text{Var}(\mathbf{y}) = \mathbf{V} = \sigma_A^2 \mathbf{Z}\mathbf{A}\mathbf{Z}^T + \sigma_u^2 \mathbf{W}\mathbf{W}^T + \sigma_e^2 \mathbf{I} \quad (19.20c)$$

If we had assumed the validity of the model $\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{a} + \mathbf{e}$, the resulting covariance matrix for the residuals would be $\text{Var}(\mathbf{e}) = \sigma_e^2 \mathbf{W}\mathbf{W}^T + \sigma_e^2 \mathbf{I}$, which shows how the additional random effects alter the covariance structure, which is no longer of OLS form, $\sigma^2 \mathbf{I}$. Analysis of this model assuming an OLS covariance structure would thus be erroneous.

The resulting set of Henderson's mixed-model equations (Equation 19.4) for the model specified by Equations 19.20a and 19.20b becomes

$$\begin{pmatrix} \mathbf{X}^T \mathbf{X} & \mathbf{X}^T \mathbf{Z} & \mathbf{X}^T \mathbf{W} \\ \mathbf{Z}^T \mathbf{X} & \mathbf{Z}^T \mathbf{Z} + \lambda_A \mathbf{A}^{-1} & \mathbf{Z}^T \mathbf{W} \\ \mathbf{W}^T \mathbf{X} & \mathbf{W}^T \mathbf{Z} & \mathbf{W}^T \mathbf{W} + \lambda_u \mathbf{I} \end{pmatrix} \begin{pmatrix} \hat{\boldsymbol{\beta}} \\ \hat{\mathbf{a}} \\ \hat{\mathbf{u}} \end{pmatrix} = \begin{pmatrix} \mathbf{X}^T \mathbf{y} \\ \mathbf{Z}^T \mathbf{y} \\ \mathbf{W}^T \mathbf{y} \end{pmatrix} \quad (19.21a)$$

where

$$\lambda_A = \frac{\sigma_e^2}{\sigma_A^2} \quad \text{and} \quad \lambda_u = \frac{\sigma_e^2}{\sigma_u^2} \quad (19.21b)$$

Additional vectors of random effects can be incorporated in a similar manner; see LW Chapters 26 and 27 for details. The mixed-model equations again form the basis for iterative REML estimates of the unknown variance components (σ_A^2 , σ_u^2 , and σ_e^2), as discussed in detail in LW Chapter 27.

Example 19.6. Often the same trait is measured multiple times in the same individual, for example, the sizes of different litters from a single female. When multiple records are present for at least some individuals, a **repeatability model** is appropriate (Chapter 13; LW Chapter 26). Repeated measures from the same individual have three components: a breeding value, a_k , and a common (permanent) environmental value, p_k , which are the same in each measurement of individual k , and the residual environmental value, e , which varies between measurements, yielding the i th measurement of the k th individual as $a_k + p_k + e_{ki}$. The **repeatability** of the trait is $r = (\sigma_A^2 + \sigma_p^2)/\sigma_z^2$, making the variance of the residuals $\sigma_e^2 = (1 - r)\sigma_z^2$ and the variance of permanent environmental effects as $\sigma_p^2 = (r - h^2)\sigma_z^2$, where σ_z^2 is the trait variance after accounting for fixed effects. We remind the reader that permanent “environmental” effects can also include nonadditive genetic components, as these are not passed along to offspring under random mating.

The repeatability model was used by Estany et al. (1989) to examine the selection response for litter size in rabbits. Their model assumed that there are two groups of fixed effects: the year-season (environmental) effects, b_t which had 22 levels over the course of this experiment (with b_0 set to zero), and the reproductive state, l_i , of the doe (three levels; because only two of these factors are estimable, l_1 was assigned a value of zero). Their model had three random effects: a_k and p_k , for the additive genetic and permanent environmental effect of the k th doe, respectively, and the residual e , resulting in an overall model of

$$y_{tkli} = \mu + l_i + b_t + a_k + p_k + e_{tkli}$$

where y_{tkli} denotes the size of the ℓ th litter of doe k in reproductive state i in season-year t . In matrix form, the mixed model becomes

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{a} + \mathbf{Z}\mathbf{p} + \mathbf{e}$$

where \mathbf{a} and \mathbf{p} are $n \times 1$ vectors corresponding to the n does, $\text{Var}(\mathbf{a}) = \sigma_A^2 \mathbf{A}$, $\text{Var}(\mathbf{p}) = \sigma_p^2 \mathbf{I}$, and $\text{Var}(\mathbf{e}) = \sigma_e^2 \mathbf{I}$. \mathbf{X} and \mathbf{Z} are incidence matrices, and the vector of fixed effects is

$$\boldsymbol{\beta} = \begin{pmatrix} \mu \\ l_2 \\ l_3 \\ b_1 \\ \vdots \\ b_{22} \end{pmatrix}$$

The mixed-model equations are given by Equation 19.21a, with

$$\lambda_A = \frac{\sigma_e^2}{\sigma_A^2} = \frac{1 - r}{h^2} \quad \text{and} \quad \lambda_u = \frac{\sigma_e^2}{\sigma_p^2} = \frac{1 - r}{r - h^2}$$

The careful reader might notice that the two vectors of random effects, the breeding values, \mathbf{a} , and permanent environment effects, \mathbf{p} , enter the model as $\mathbf{Z}\mathbf{a}$ and $\mathbf{Z}\mathbf{p}$, respectively. Why, then, do we simply not combine these as, for example, $\mathbf{Z}\mathbf{u}$ where $\mathbf{u} = \mathbf{a} + \mathbf{p}$? The reason we do not do this (and indeed, the reason we can estimate \mathbf{a} and \mathbf{p} separately) is that \mathbf{a} and \mathbf{p} have different covariance structures, $\sigma_A^2 \mathbf{A}$ versus $\sigma_p^2 \mathbf{I}$. While estimates of \mathbf{a} borrow information from

relatives (correlated observations provide information to supplement a direct observation), estimates of \mathbf{p} depend only on the focal individual (as we assume these are uncorrelated between individuals).

Common Family and Maternal Effects

When sibs are present, any common-family environmental effects (if not included directly in the model) are subsumed into the residuals, creating a correlation between the residuals of sibs. For example, if two sibs (i and j) share a common environmental value, c , then $\sigma(e_i, e_j) = \sigma_c^2$. Hence, there are off-diagonal elements in the covariance matrix of residuals, and we no longer have the standard OLS assumption of $\text{Var}(\mathbf{e}) = \sigma_e^2 \mathbf{I}$. Such correlations can easily be accommodated by adding an additional vector of random effects.

Example 19.7. Meyer and Hill (1991) examined the response to selection on adjusted food intake (AFI) in mice (Example 19.2) and formulated a model incorporating shared family values, c , as random effects. In addition, their model accounts for fixed effects due to common environmental effects associated with generations (b , 22 levels), lines (L , 3 levels), sex (v , male/female), and litter size (l , 7 levels for litters of size 6 to 12 individuals). Under their model, the observed value for AFI from the i th individual from generation t , line ℓ and full-sib family k is given by

$$y_{\ell,tki} = \mu + b_t + L_\ell + v_j + l_m + a_{\ell,tki} + c_{\ell,tk} + e_{\ell,tki}$$

where this individual has sex j and was reared in a litter of size m . In matrix form, $\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{a} + \mathbf{W}\mathbf{c} + \mathbf{e}$. The vector of fixed effects, $\boldsymbol{\beta}$, contains the b , L , v , and l values, while the random effects are the vector of common family effects, \mathbf{c} , the vector of additive genetic values, \mathbf{a} , and the vector of residuals, \mathbf{e} .

The \mathbf{W} incidence matrix has 1 as its ik th element if individual i is from family k , or else the element is 0. Note that Meyer and Hill have two model variables to account for litter effects—a fixed effect, l , common to all litters of the same size, and a random effect, $c_{\ell,tk}$, that varies between families but is the same for all individuals within a particular family. The resulting REML estimate for heritability was 0.15, while the fraction of the total variation (after removal of the fixed effects) accounted for by random family effects was estimated to be $\gamma^2 = \sigma_c^2/\sigma_z^2 = 0.22$, where $\sigma_z^2 = \sigma_A^2 + \sigma_c^2 + \sigma_e^2$ is the fixed-effects adjusted trait variance. Because the intraclass correlation between sibs is $(h^2/2) + \gamma^2$ (Chapter 21), a larger fraction of the resemblance between sibs is due to shared family environments (potentially including maternal effects), rather than due to shared genes. One caveat is that the model assumes no dominance variance. If this is present, sibs also share dominance variance ($\sigma_D^2/4$), but under this model, it would be absorbed into σ_c^2 .

Sib correlations (beyond those accounted for by their correlations in breeding value for the focal trait) can arise for multiple reasons. The first is dominance, which we will address shortly. The second and third reasons are common family effects, which can arise from two different sources: shared *environmental* effects and shared maternal effects with a genetic component (i.e., maternal performance itself has a *genetic* component; see Chapters 15 and 22). The distinction between the genetic and the environmental components of maternal effects (both of which may be included in a model) was foreshadowed in Example 19.6, in that they result in different covariance structures. Environmental correlations are unique to a given family, while maternal-genetic effects are correlated over relatives, even those in different generations. In Example 19.7, the common environment, c , was assumed to be uncorrelated between sibships, implying that its covariance structure is $\text{Var}(\mathbf{c}) = \sigma_c^2 \mathbf{I}$, which is a diagonal matrix whose dimension is set by the number of families. There is no correlation across different sibships and thus no shared information.

When a mother has several litters (especially when each may contain a modest to large number of offspring), modifications beyond assigning a single (random) common-family environment value for all her litters may be considered. One approach is to assume that each particular litter has a unique common-family effect, that is uncorrelated across litters from the same mother. Here, the covariance structure remains $\text{Var}(\mathbf{c}) = \sigma_c^2 \mathbf{I}$, but now each litter (rather than each mother) has its own c value.

A second, and perhaps biologically more realistic, approach is to consider something akin to a repeatability model (Example 19.6), wherein the contribution from the mother to a particular litter has two components, one shared over all litters, and a second unique to each litter. Under this model, the common-family environmental effect for all sibs in the i th litter from mother k is given by $c_{ki} + p_k$, a permanent environmental effect for this mother, p_k (a common effect shared by all her litters, as in our initial model), plus a unique environment shared by all members of her i th litter, c_{ki} . For this model, we need to estimate the variances σ_p^2 and σ_c^2 , which correspond to the contributions from p_k and c_{ki} , respectively. We assume that at least one litter has two or more individuals, otherwise c_{ki} and p_k cannot be estimated separately. More generally, this model is not expected to be very efficient unless the expected number of offspring per litter is modest to large. If the common-litter effect under this model is environmental, namely, that a mother does not pass along any of her performance genetically to her daughters, then the covariance structure for these two vectors of random effects will be $\text{Var}(\mathbf{c}) = \sigma_c^2 \mathbf{I}$ and $\text{Var}(\mathbf{p}) = \sigma_p^2 \mathbf{I}$, square matrices whose dimensions are the total number of separate litters in the experiment and the number of mothers, respectively.

However, maternal performance could also have a *genetic* component, such that female relatives have correlated maternal performances. In this case, we would add a third random effect, a_m (the breeding value of this maternal effect), to the model. This vector of breeding values for maternal performance has a covariance matrix of $\text{Var}(\mathbf{a}_m) = \sigma_A^2(a_m)\mathbf{A}$. Distinguishing between maternal and direct effects requires that there are paternal, as well as maternal, links in the pedigree (Clément et al. 2001; Kruuk 2004; Chapter 22). A complication is that the breeding values for the focal trait and maternal performance can be correlated. This raises a multiple-trait problem (LW Chapter 27). We discuss maternal effects in greater detail in Chapter 22 in the context of more general models of associative effects.

In summary, from an operational standpoint, if maternal effects are suspected, at a minimum, a common-family effect should be included, and it should be in the form of a repeatability model if the female has multiple litters (provided each has several offspring). More generally, if there are many links between female relatives (with litters) in the data set, one should seriously consider a genetic maternal-effects model. Failure to do so may result in contributions from shared genetic maternal performance being regarded as breeding values for the direct trait, giving a biased picture of the nature of the selection response (Milner et al. 2000; Clément et al. 2001; Kruuk 2004). Chapter 22 will examine in more detail when to include, and when to exclude, random effects when constructing more complex models.

Treating Certain Breeding Values as Fixed Effects

How should one proceed if the base population has, itself, been under selection? Graser et al. (1987) suggested that if this is known, or suspected, to be the case, the base population breeding values should be treated as fixed, rather than random, effects. The motivation for this suggestion is that if the parents are selected, they are not a random sample from the base population. Because REML variance estimates are unbiased by fixed effects, any bias in the variance of the initial sample is ignored by treating the original parental breeding values as fixed. However, simulation studies show that even if initial bias is reduced by treating the parents as fixed, selection on the resulting offspring (or future generations) introduces additional bias (van der Werf 1990).

Despite this reservation, we briefly review the approach here, as parents (beyond the base population) whose records are missing are also often treated as fixed, which requires

some modifications of the mixed-model equations. Let \mathbf{a}_b be the vector of breeding values for the base population and \mathbf{a}_r be breeding values of the remaining individuals that descend from the base population. Following Graser et al. (1987), we can express the dependence of \mathbf{a}_r on the base population breeding values, \mathbf{a}_b , as follows

$$\begin{pmatrix} \mathbf{a}_b \\ \mathbf{a}_r \end{pmatrix} = \begin{pmatrix} \mathbf{I} & \mathbf{0} \\ \mathbf{P}_1 & \mathbf{P}_2 \end{pmatrix} \begin{pmatrix} \mathbf{a}_b \\ \mathbf{a}_r \end{pmatrix} + \begin{pmatrix} \mathbf{0} \\ \mathbf{s} \end{pmatrix} \quad (19.22)$$

where \mathbf{s} is the vector of segregational residuals (Equation 19.15a) and \mathbf{P}_1 and \mathbf{P}_2 are matrices with values of 1/2 in the parent's column in each row. Here, \mathbf{a}_r is treated as a random effect because it is a function of a fixed effect (\mathbf{a}_b) and a random effect (\mathbf{s}). The resulting mixed-model is

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}_1\mathbf{a}_b + \mathbf{Z}_2\mathbf{a}_r + \mathbf{e} \quad (19.23)$$

Graser et al. showed that the associated mixed-model equations are

$$\begin{pmatrix} \mathbf{X}^T \mathbf{X} & \mathbf{X}^T \mathbf{Z}_1 & \mathbf{X}^T \mathbf{Z}_2 \\ \mathbf{Z}_1^T \mathbf{X} & \mathbf{Z}_1^T \mathbf{Z}_1 + \lambda \mathbf{Q}^T \mathbf{G}^{-1} \mathbf{Q} & -\lambda \mathbf{Q}^T \mathbf{G}^{-1} \\ \mathbf{Z}_2^T \mathbf{X} & -\lambda \mathbf{G}^{-1} \mathbf{Q} & \mathbf{Z}_2^T \mathbf{Z}_2 + \lambda \mathbf{G}^{-1} \end{pmatrix} \begin{pmatrix} \hat{\boldsymbol{\beta}} \\ \hat{\mathbf{a}}_b \\ \hat{\mathbf{a}}_r \end{pmatrix} = \begin{pmatrix} \mathbf{X}^T \mathbf{y} \\ \mathbf{Z}_1^T \mathbf{y} \\ \mathbf{Z}_2^T \mathbf{y} \end{pmatrix} \quad (19.24a)$$

where $\lambda = (2\sigma_e^2/\sigma_A^2)$, and

$$\mathbf{Q} = (\mathbf{I} - \mathbf{P}_2)^{-1} \mathbf{P}_1 \quad \text{and} \quad \mathbf{G} = (\mathbf{I} - \mathbf{P}_2)^{-1} \mathbf{F} [(\mathbf{I} - \mathbf{P}_2)^{-1}]^T \quad (19.24b)$$

with the elements of the diagonal matrix, \mathbf{F} , given by Equation 19.16. Note that the information used to estimate the additive-genetic variance comes from the vector, \mathbf{s} , of segregation values, and thus estimates the additive genetic variance, σ_a^2 . If no linkage disequilibrium is present in the base population, this segregation-based estimate is also, then, an estimate of the additive genetic variance, σ_A^2 ; otherwise it is biased (as $\sigma_A^2 \neq \sigma_a^2$ when $d \neq 0$; Chapter 15).

Dominance

Up to this point, we have been assuming that all genetic variation is additive, requiring us to only consider the vector, \mathbf{a} , of breeding values and its numerator relationship matrix, \mathbf{A} . When nonadditive genetic variance is present, it creates additional genetic correlations between certain relatives beyond those accounted for by \mathbf{A} . The simplest setting is that in which dominance occurs, which inflates the covariance among (noninbred) full sibs by $\sigma_D^2/4$. As demonstrated previously, sibs can also have their covariance inflated by common-family effects, and separating the contribution of dominance from common-family environment is nontrivial, as it requires very specific types of links in the pedigree.

If the goal is simply to reduce the bias in predicted breeding values when dominance is present, an animal model with an additional random factor for common-family effects (e.g., Example 19.7) will often be satisfactory. This model simply estimates the common sib variance, σ_c^2 , which may include contributions from both dominance and shared-family environments.

The goal of estimating the dominance variance directly, and thus predicting dominance values, is considerably more difficult. Misztal (1997) found that roughly 20-fold more data are required for dominance estimates to match the precision of their additive counterparts. This is because information on dominance only arises from relatives with a nonzero coefficient of fraternity (Equations 11.13, 11.19a, and 11.19b; LW Equation 7.7), which requires that each parent from one individual be related to at least one parent of the other individual (see Equation 19.26a). Even in these cases, the coefficient of fraternity (which yields the corresponding weight on σ_D^2 in the covariance between relatives; LW Equation 7.7) is

small (e.g., 0.25 for full sibs, 0.0625 for double first-cousins, and much less for more distant relatives). If the only such links in a pedigree are between full sibs, then common-family environmental effects and dominance are fully confounded and cannot be separated (meaning that one must have a sufficient number of relatives with different, but nonzero, coefficients of fraternity).

Assuming no common-family environmental effects (which is a *major* assumption), we can attempt to estimate dominance as follows. Letting the vector \mathbf{d} denote the dominance effects, the mixed model becomes

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{a} + \mathbf{Z}\mathbf{d} + \mathbf{e} \quad (19.25a)$$

The overall genetic merit of an individual is estimated by $\hat{\mathbf{g}} = \hat{\mathbf{a}} + \hat{\mathbf{d}}$. Turning to the covariance structure of this model, as before, $\text{Var}(\mathbf{a}) = \sigma_A^2 \mathbf{A}$ and $\text{Var}(\mathbf{e}) = \sigma_e^2 \mathbf{I}$, while the covariance matrix for dominance effects is $\text{Var}(\mathbf{d}) = \sigma_D^2 \mathbf{D}$, yielding

$$\text{Var}(\mathbf{y}) = \mathbf{V} = \sigma_A^2 \mathbf{ZAZ}^T + \sigma_D^2 \mathbf{ZDZ}^T + \sigma_e^2 \mathbf{I} \quad (19.25b)$$

where \mathbf{D} is the **dominance genetic relationship matrix**, which will be detailed shortly. Equation 19.25b shows that if we assumed the validity of the model

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{a} + \mathbf{e}^* \quad (19.25c)$$

then the covariance structure is given by

$$\text{Var}(\mathbf{e}^*) = \sigma_D^2 \mathbf{ZDZ}^T + \sigma_e^2 \mathbf{I} \quad (19.25d)$$

If we assumed the validity of Equation 19.25c and the absence of dominance, we would (incorrectly) use $\sigma_e^2 \mathbf{I}$, instead of the correct error structure, which potentially would bias our estimates of \mathbf{a} .

The elements of \mathbf{D} are obtained as follows. The covariance between dominance effects for (noninbred) individuals i and j is the product of the dominance genetic variance and the coefficient of fraternity, $\sigma_D^2 \Delta_{ij}$. From LW Equation 7.7, this is given by

$$\Delta_{ij} = \Theta_{gk} \Theta_{hl} + \Theta_{gl} \Theta_{hk} \quad (19.26a)$$

where i 's parents are indexed by g and h and j 's parents are indexed by k and l , and where (as above), Θ is the coefficient of coancestry. Recalling that the elements of the numerator relationship matrix, \mathbf{A} , are $2\Theta_{ij}$, the off-diagonal elements of \mathbf{D} can be computed from the elements of \mathbf{A} by

$$D_{ij} = \frac{A_{gk} A_{hl} + A_{gl} A_{hk}}{4} \quad (19.26b)$$

whereas the diagonal elements are all $D_{ii} = 1$ (when i is not inbred). Note that \mathbf{D} is expected to be considerably more **sparse** (most of its off-diagonal elements are zero) than \mathbf{A} , and hence may not contribute information for most individuals. Ovaskainen et al. (2008) noted that Equation 19.26a is an approximation, requiring that the four probabilities (i.e., the Θ_{ij}) determining Δ_{ij} be independent. This is usually not a serious problem unless the pedigree is highly inbred. The resulting mixed-model equations for Equation 19.25a become

$$\begin{pmatrix} \mathbf{X}^T \mathbf{X} & \mathbf{X}^T \mathbf{Z} & \mathbf{X}^T \mathbf{Z} \\ \mathbf{Z}^T \mathbf{X} & \mathbf{Z}^T \mathbf{Z} + \lambda_A \mathbf{A}^{-1} & \mathbf{Z}^T \mathbf{Z} \\ \mathbf{Z}^T \mathbf{X} & \mathbf{Z}^T \mathbf{Z} & \mathbf{Z}^T \mathbf{Z} + \lambda_D \mathbf{D}^{-1} \end{pmatrix} \begin{pmatrix} \hat{\boldsymbol{\beta}} \\ \hat{\mathbf{a}} \\ \hat{\mathbf{d}} \end{pmatrix} = \begin{pmatrix} \mathbf{X}^T \mathbf{y} \\ \mathbf{Z}^T \mathbf{y} \\ \mathbf{Z}^T \mathbf{y} \end{pmatrix} \quad (19.27)$$

where $\lambda_A = \sigma_e^2 / \sigma_A^2$ and $\lambda_D = \sigma_e^2 / \sigma_D^2$. Hoeschele and Van Raden (1991) presented a rapid method for computing \mathbf{D}^{-1} for a noninbred population.

In addition to these concerns, inbreeding (which occurs in all selection experiments) introduces major complications. First, there may be inbreeding depression. In some situations, this can be dealt with by simply including the level of inbreeding (f) as a covariate, for example, by using a model such as

$$y_{ti} = \mu + (B \cdot f_{ti}) + a_{ti} + b_{ti} + e_{ti} \quad (19.28)$$

where f_{ti} is the inbreeding coefficient for the i th individual in generation t and B is the inbreeding depression under complete inbreeding, which is a fixed factor to be estimated. Because $A_{ii} = (1 + f_i)$, the value for f_{ti} immediately follows from the diagonal element of A corresponding to individual ti , namely $f_{ti} = A_{ti,ti} - 1$.

When the only nonadditive genetic interaction is dominance, inbreeding depression is a linear function of the inbreeding level, f , but this relationship is nonlinear when certain types of epistasis are present (LW Chapter 10). Thus, if there is significant epistasis, Equation 19.28 may not appropriately correct for inbreeding depression, especially at very high values of f (those approaching one). If the levels of inbreeding are very similar between a selected and a control population, the use of a control can account for nonlinear inbreeding depression. If f is expected to be small or modest (say $f \leq 0.3$), then f^2 will be 0.01 or less and the weighting on any epistatic term will be quite small. In such cases, a simple linear model for inbreeding should be sufficient.

A second, and more subtle, complication is that the covariance between inbred relatives with dominance is no longer a function of just σ_A^2 and σ_D^2 . As discussed in Chapter 11, these covariances now depend upon four other quadratic components (σ_{DI}^2 , σ_{ADI} , ι^* , ι^2); see Equation 11.13 and Table 11.2. While one could formulate a mixed model incorporating all six quadratic components (Equations 11.19a and 11.19b present the required covariance structures), the resulting model is extremely complex, numerically very demanding, and expected to yield very low precision estimates of nonadditive genetic effects. A start toward including these other variance components was developed by Smith and Mäki-Tanila (1990), who should be consulted for more details. A simpler, but only approximate, approach is to use Equation 19.27, with a D matrix that approximates the elements under inbreeding (Smith and Mäki-Tanila 1990). One could also combine the use of a modified D with a covariate for inbreeding depression (Equation 19.28), but this is still a largely ad hoc approach to a complex problem.

Some guidance on dealing with dominance is offered from simulations by de Boer and van Arendonk (1992), who examined the consequences of ignoring a cofactor for inbreeding depression and not using the full (i.e., correct) covariance structure under inbreeding. When a standard dominance model not accounting for inbreeding was used, estimates of both additive and dominance effects were biased. However, when a simple cofactor for inbreeding depression was included, but the full covariance structure under inbreeding was ignored, estimates of a were generally unbiased, at least up to the level of inbreeding used in the simulations ($f = 0.35$). Thus, simply including a fixed effect for inbreeding depression (Equation 19.28) and a random effect for common-family effects (Example 19.7) appears to be a relatively robust approach for handling dominance, at least for modest levels of inbreeding (those typically seen in most animal-breeding programs). With highly inbred populations (such as selfed lines), other approaches are required (Chapter 23).

The situation with epistasis is even more complex than that for dominance. The encouraging news is that the weighting of the nonadditive-variance component terms for the covariances between even modestly distant relatives is very small (e.g., LW Equation 7.12), so even if nonadditive components are significant, their *actual* contribution to the genetic covariance of most relatives, especially those separated by more than one generation, are very minor and can usually be ignored. In theory, epistatic terms can be included in the mixed-model equations in a similar fashion as with dominance; see LW Chapter 26 for details, and LW Chapter 27 for modifications of the REML equations to estimate nonadditive variances. In practice this is almost never done, as the effects are generally small and the precision of estimates is quite poor at best.

BAYESIAN MIXED-MODEL ANALYSIS

As mentioned throughout this chapter, a standard mixed-model analysis does not fully account for the uncertainty introduced into EBVs by using estimates of the model variance components (instead of their true values). While there are large-sample approximations for the sample variance of a REML variance estimator, it is never fully clear what constitutes “large.” Further, quantities of interest, such as the heritability, are often functions of the estimated quantities. The sample variances and distributions of such functions are very complicated, and they are typically obtained through either simulations or approximations (e.g., the delta method; LW Appendix 1). **Bayesian approaches** offer solutions to both of these problems. While Bayesian statistics (as opposed to more standard, or **frequentist**, statistics) are often touted for their ability to incorporate prior information, their key utility is in providing a more complete description of the uncertainty of an estimate.

Frequentists assume that the true value of a parameter is (typically) a constant and the samples are variable. Statistics (such as confidence intervals) are computed by conceptually drawing an infinite number of samples. For example, the frequentist’s expectation is that the true value of a parameter is contained within constructed 95% confidence intervals in all but 5% of such draws. In contrast, a Bayesian assumes that the sample is fixed while the parameter is random, the focus being on how the data changes our prior assumptions for the probability distribution for possible locations of the parameter. Thus, the term “Bayesian mixed model” is (formally) inappropriate, as *all* terms in a Bayesian analysis are assumed to be random, and hence never “mixed.” However, we use this term to emphasize that many of the basic foundations (such as the model formulation) of an MM analysis of selection experiments remain unchanged in a Bayesian framework. What does change is how we analyze the data.

Appendix 2 introduces some of the basic ideas in a Bayesian analysis (beyond our short introduction here). Computational issues are extremely important, and they are covered in Appendix 3. Indeed, the recent explosion in the application of Bayesian approaches largely follows from relatively recent computational approaches, such as Markov Chain Monte Carlo (MCMC) methods that allow complex distributions to be handled through straightforward (but computationally intensive) procedures (Appendix 3).

Introduction to Bayesian Statistics

While very deep (and subtle) differences in philosophy separate hard-core Bayesians from hard-core frequentists (Glymour 1981; Efron 1986), our treatment here of Bayesian methods is motivated simply by their use as a powerful statistical tool. Their introduction into quantitative genetics can be largely credited to the influential paper of Gianola and Fernando (1986), which reviewed Bayesian applications to animal breeding. Blasco (2001, 2017) provided nice overviews of Bayesian versus frequentist approaches in quantitative genetics and both are highly recommended, while a detailed treatment of applications to quantitative genetics was provided by Sorensen and Gianola (2002). Gianola and Rosa (2015) presented an excellent review of the history of statistical methods in animal breeding, culminating with the wide acceptance of Bayesian approaches.

The foundation of Bayesian statistics is **Bayes’ theorem** (Appendix 2), which provides the relationship between $\Pr(x | y)$ and $\Pr(y | x)$, namely, the flipped conditional probabilities. The continuous, vector-valued version of this theorem is

$$p(\boldsymbol{\Theta} | \mathbf{y}) = \frac{p(\mathbf{y} | \boldsymbol{\Theta}) p(\boldsymbol{\Theta})}{p(\mathbf{y})} = \frac{p(\mathbf{y} | \boldsymbol{\Theta}) p(\boldsymbol{\Theta})}{\int p(\mathbf{y}, \boldsymbol{\Theta}) d\boldsymbol{\Theta}} \quad (19.29a)$$

where $\boldsymbol{\Theta}^T = (\theta^{(1)}, \theta^{(2)}, \dots, \theta^{(k)})$ is a vector of k random variables. Here $p(\boldsymbol{\Theta})$ is our prior belief (**prior** for short) about the distribution of the unknown values, $\boldsymbol{\Theta}$, while $p(\mathbf{y} | \boldsymbol{\Theta})$ is simply a standard likelihood function for the probability density of the observed vector of data, \mathbf{y} , given that the unknown parameters have a specified value of $\boldsymbol{\Theta}$ (LW Appendix 4). The product of these two variables, normalized by $p(\mathbf{y})$ to form a proper probability

distribution (i.e., that integrates to 1), is our posterior belief (the **posterior**), $p(\boldsymbol{\Theta} | \mathbf{y})$, for the distribution of the unknown parameters, given both the data, \mathbf{y} , and the prior information, $p(\boldsymbol{\Theta})$. Because $p(\mathbf{y})$, the probability of the data vector \mathbf{y} , is a constant independent of $\boldsymbol{\Theta}$, it is typically ignored, and the posterior is often simply written as

$$p(\boldsymbol{\Theta} | \mathbf{y}) \propto p(\mathbf{y} | \boldsymbol{\Theta}) p(\boldsymbol{\Theta}) \quad (19.29b)$$

In words, the posterior is the product of the likelihood and the prior multiplied by a normalization constant to return a proper probability distribution.

Often, only a subset of the unknown variables is of concern, with the rest being regarded as **nuisance variables** (or **nuisance parameters**) that we wish to remove (or at least ignore). To see how this can be accomplished, partition the vector of unknown parameters as $\boldsymbol{\Theta}^T = (\boldsymbol{\Theta}_1^T, \boldsymbol{\Theta}_{nu}^T)$, where $\boldsymbol{\Theta}_{nu}$ is the column vector of nuisance variables. Integrating the full posterior over $\boldsymbol{\Theta}_{nu}$ yields the **marginal posterior distribution** for the variables of interest, $\boldsymbol{\Theta}_1$, as

$$\begin{aligned} p(\boldsymbol{\Theta}_1 | \mathbf{y}) &= \int p(\boldsymbol{\Theta}_1, \boldsymbol{\Theta}_{nu} | \mathbf{y}) d\boldsymbol{\Theta}_{nu} \\ &= \int p(\boldsymbol{\Theta}_1 | \boldsymbol{\Theta}_{nu}, \mathbf{y}) p(\boldsymbol{\Theta}_{nu} | \mathbf{y}) d\boldsymbol{\Theta}_{nu} \\ &= E_{\boldsymbol{\Theta}_{nu}} [p(\boldsymbol{\Theta}_1 | \boldsymbol{\Theta}_{nu}, \mathbf{y})] \end{aligned} \quad (19.30)$$

The last line highlights the fact that the marginal posterior is the conditional distribution of the parameters of interest, averaged over the distribution of nuisance parameters.

The marginal posterior is a very powerful tool, as it accounts for how uncertainty in the nuisance variables influences the level of uncertainty in the variable or variables of interest. This marginal probability calculation illustrates both the strength and the weakness of a Bayesian analysis before the advent of MCMC approaches. The strength is that obtaining such a marginal is very powerful for inference. The weakness is that the integration to obtain this marginal can be daunting (at best). Fortunately, MCMC techniques allow one to easily simulate draws from most marginal distributions (Appendix 3).

The dependence of the posterior on the prior (which can be partly assessed by examining the posterior's stability over different priors) provides an indication of how much information on one or more unknown variables is contained in the data. If the posterior is highly dependent on the prior, the data likely will have little signal, while if the posterior is largely unaffected by the shape of the assumed prior, the data will be highly informative. Such explorations of the effects of a prior under a careful Bayesian analysis offer some protection from incorrect conclusions based on weak likelihoods (a flat likelihood surface) or an overly strong prior. It is not uncommon to find, in the same analyses, that the marginal posterior for some variables is very robust to the choice of priors (with the data containing a strong signal generating a highly peaked likelihood surface for these variables), while for other variables, the marginal is highly dependent on the prior (with very little information contained in the data on these variables, generating a flat likelihood surface).

Example 19.8. As an example of a Bayesian analysis, consider the simple case of n observations from a normal distribution with an unknown mean, μ , but known variance, σ^2 . The details for this analysis (and more realistic cases, such as those in which both the mean and the variance are unknown) are developed in Appendix 2. Assuming the data $\mathbf{y} = (y_1, \dots, y_n)^T$ are n independent draws from this distribution, the resulting likelihood function, which corresponds to $p(\mathbf{y} | \mu)$, is

$$p(\mathbf{y} | \mu) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp \left(- \sum_{i=1}^n \frac{(y_i - \mu)^2}{2\sigma^2} \right)$$

Suppose we assume a Gaussian prior for the location of the mean, $\mu \sim N(\mu_0, \sigma_0^2)$, so that

$$p(\mu) = \frac{1}{\sqrt{2\pi\sigma_0^2}} \exp\left(-\frac{(\mu - \mu_0)^2}{2\sigma_0^2}\right)$$

While μ is treated as a fixed (but unknown) value in a standard (frequentist) analysis, it is treated as a *random variable* in a Bayesian analysis. There are no fixed effects in a Bayesian analysis, as everything is treated as a random variable.

The mean, μ_0 , and variance, σ_0^2 , are referred to as the prior **hyperparameters**, where μ_0 specifies a prior location for the mean and σ_0^2 specifies the uncertainty in this prior location. The larger is this variance, the greater is our uncertainty. In the limit (as $\sigma_0^2 \rightarrow \infty$), this corresponds to $p(\mu) = c$, a constant, which is a **uniform** or **flat** prior, where all values of μ between some upper and lower value are assumed to be equally likely. (Keynes 1921 called this the **principle of indifference**—all possible outcomes are equally probable.) A little algebra (Appendix 2) yields

$$p(\mu | \mathbf{y}) \propto p(\mathbf{y} | \mu) p(\mu) \propto \exp\left\{-\frac{(\mu - \mu_*)^2}{[2\sigma_*^2]}\right\}$$

where the expressions for μ_* and σ_*^2 are given in Appendix 2 (Equation A2.22b). Thus, the posterior density function for μ is a normal with a mean of μ_* and variance of σ_*^2 , which can be formally expressed as

$$\mu | (\mathbf{y}, \sigma^2, \mu_0, \sigma_0^2) \sim N(\mu_*, \sigma_*^2)$$

Notice that our Gaussian prior for μ **conjugated** with the likelihood function, with the product of the prior and likelihood returning a distribution in the same family as the prior (but whose distribution parameters, which here are the mean and the variance, have been changed from their values in the prior by the data). The use of such **conjugate priors** (for a given likelihood), which is a key tool in Bayesian analysis, is explored in detail in Appendix 2. For example, with normally distributed data and an unknown variance, using a **scaled inverse- χ^2** prior for the variance also conjugates the likelihood, with the posterior distribution for the variance also following a scaled inverse- χ^2 , but (as above) also with different distribution parameters (i.e., the shape and scale parameters are changed; Appendix 2).

A Bayesian analysis returns *distributions*, rather than *point estimates*. A number of summary statistics can be reported for the posterior, such as its mean, median (50% value), and mode (most frequent value, which is equivalent to the MLE in a likelihood analysis). More generally, when closed-form analytical expressions are not available, one can simply plot the posterior distribution via a histogram from values generated through MCMC methods (as discussed in Appendix 3).

What is the relative importance of the prior information, $p(\mu)$, compared to the actual data, \mathbf{y} ? Equation A2.22b gives the mean of the posterior distribution as

$$\mu_* = \mu_0 \frac{\sigma_*^2}{\sigma_0^2} + \bar{y} \frac{\sigma_*^2}{\sigma^2/n}$$

With a very diffuse prior on μ (i.e., $\sigma_0^2 \gg \sigma^2$), Equation A2.22b shows that $\sigma_*^2 \rightarrow \sigma^2/n$ and thus $\mu_* \rightarrow \bar{y}$, so with very weak prior information, the mean of the posterior distribution is close to the usual estimate of μ , which is the sample mean, \bar{y} . Conversely, as we collect enough data (i.e., large n), $\sigma_*^2 \rightarrow \sigma^2/n$ and again $\mu_* \rightarrow \bar{y}$. Thus, even with a very strong prior belief about the location of the mean (σ_0^2 is small), as our sample size becomes sufficiently large, the mean of the posterior approaches the sample mean. With a modest prior and data (meaning that σ_0^2 and n are modest), this expression shows how these two contributions are weighted.

Example 19.9. A simulation study by Sorensen et al. (1994) examined the effects on the posterior estimate of heritability by using different priors on the variance components. To study the impact of sample size, the data were analyzed in two sets: the entire data set (Large) and a partial subset (Small). The simulated heritability was 0.5. Both uniform and scaled inverse- χ^2 priors for the additive and residual variance were used. The uniform spreads belief

evenly over all possible values within a defined range, while the inverse- χ^2 places more weight on specific values (Appendix 2). The mean and variance of the marginal posterior distribution for h^2 (denoted by $E[h^2 | \mathbf{y}]$, and $\sigma^2[h^2 | \mathbf{y}]$, respectively) in these four cases were as follows

Data Set	Prior	$E[h^2 \mathbf{y}]$	$\sigma^2[h^2 \mathbf{y}]$
Small	Uniform	0.737	0.0226
Small	Inverse- χ^2	0.501	0.0029
Large	Uniform	0.550	0.0163
Large	Inverse- χ^2	0.529	0.0024

Note the disparity of the estimates under the two priors in the partial data case (Small) and their agreement in the full data case (Large). In the partial data case, the effect of the prior had a strong influence, indicating a weak signal (likelihood) for h^2 in this particular data set. With the full data set, the signal greatly increased, mitigating the effects of the prior. As expected, the posterior variance, $\sigma^2[h^2 | \mathbf{y}]$, decreased under the larger sample size (Small versus Large) for both priors. Also note that the posterior variance was smaller under the assumed inverse- χ^2 priors. Thus, the choice of a prior influences not only the mean of the estimate, but also its variance. In this case, while the different priors yielded essentially the same mean heritability in the full data set, their variances differed by an order of magnitude.

This is an example of a **sensitivity analysis** using different priors to probe the stability of the posterior. With complex posteriors, one can observe broad stability for many of the variables (insensitivity to changes in the priors), but extreme dependence in the others. The use of different priors provides one means to explore the amount of signal along the different directions (variables) of the likelihood surface.

Example 19.10. In the context of analyzing a selection response experiment, the vector of breeding values, \mathbf{a} , is of interest, while the q fixed effects ($\boldsymbol{\beta}$) and variances (σ_A^2, σ_e^2) are often regarded as nuisance parameters. In this case, Equation 19.30 gives the marginal distribution of the breeding values \mathbf{a} , given the data \mathbf{y} , as

$$p(\mathbf{a} | \mathbf{y}) = \int p(\mathbf{a}, \boldsymbol{\beta}, \sigma_A^2, \sigma_e^2 | \mathbf{y}) d\boldsymbol{\beta} d\sigma_A^2 d\sigma_e^2$$

The integration is over the $q + 2$ dimensional space given by the q elements in $\boldsymbol{\beta}$ and the two variances. This conditioning removes any dependencies of estimates of the response on estimates of the variance components and fixed effects. Uncertainties introduced by estimating these nuisance parameters are automatically accommodated when considering the marginal distribution. While solving this multidimensional integral is extremely challenging, a Gibbs sampler (below) can often be constructed to obtain draws from this marginal distribution.

With the marginal density, $p(\mathbf{a} | \mathbf{y})$, in hand, and recalling Equation 19.8b, one can obtain estimates of the response to selection, $\mathbf{K}^T \mathbf{a}$, that are *independent* of the assumed (or estimated) additive-genetic variance, σ_A^2 . The error due to estimation of the additive variance from the data is directly incorporated when the marginal is computed, as we integrate over possible values of σ_A^2 and their support, given the data. This independence of the estimated selection response from the estimate of additive variance and the subsequent incorporation of the error in estimating σ_A^2 in the estimate of the response are two very compelling reasons for performing a Bayesian analysis of response.

This example hints at a key feature noted by Gianola and Fernando (1986). If all the data on which selection was based are included in the analysis, then (by integrating over all nuisance parameters) the Bayesian approach accounts for any potential bias introduced by selection (provided that the model assumptions, such as multivariate normality, hold).

Computing Posteriors and Marginals: MCMC and the Gibbs Sampler

Historically, the widespread implementation of Bayesian approaches was limited by the difficulty in obtaining marginal posterior distributions, which typically requires the integration

of complex, high-dimensional functions (e.g., Equations 19.29a and 19.30). **Markov Chain Monte Carlo (MCMC)** approaches (Appendix 3) provide a solution by offering straightforward (although computationally demanding) procedures for generating random draws from very complex distributions. One such distribution is the posterior (given the data and the prior) in a Bayesian analysis, and it often turns out to be fairly easy to implement a **sampler** that allows draws from this distribution.

Simulating random vectors directly drawn from some complex **target distribution** (such as the posterior for a given model and particular data set) can be a very difficult task. The idea behind MCMC approaches is to successively draw samples from far simpler distributions in such a way that the distribution of the samples converges to the target distribution. These approaches are so named because one uses the previous sample value to randomly generate the next sample value, thus generating a **Markov chain** (Appendix 3). While there are a wide range of MCMC methods, two of the most commonly encountered in the quantitative-genetics literature are the **Metropolis-Hastings algorithm** (Metropolis and Ulam 1949; Metropolis et al. 1953; Hastings 1970), and the **Gibbs sampler** (Geman and Geman 1984).

Under Metropolis-Hastings, one simulates draws from a complex target distribution by first drawing a random variable from a specified (and simpler) distribution and then using a probability-based decision rule to decide whether to keep that realization or reject it (details are in Appendix 3). The strength of Metropolis-Hastings is that it can be applied to a very wide range of problems, such as priors that do not conjugate with the likelihood (and hence do not have a simple form). Its weakness is that candidate values can end up being rejected with a very high probability, making the sampler very inefficient (requiring very long runs to produce a reasonably sized trimmed sequence with low correlation between elements), especially in a multivariate setting, where each simulated draw is a vector of random variables.

The Gibbs sampler is a special case of Metropolis-Hastings sampling wherein the random value is always accepted. The key to this sampler is that one only considers univariate conditional distributions—the distribution that results when all of the random variables but one are assigned fixed values. Typically, one uses conjugate priors to form a Gibbs sampler (see below). More generally, one can also use a **block implementation** of the sampler, generating draws using conditional multivariate distributions.

To introduce the Gibbs sampler, consider a bivariate random vector (x, y) , and suppose we wish to compute one or both marginals, $p(x)$ and $p(y)$. The idea behind the sampler is that it is far easier to consider a sequence of conditional distributions, $p(x | y)$ and $p(y | x)$, than it is to obtain the marginal by integration of the joint density $p(x, y)$, e.g., $p(x) = \int p(x, y) dy$. The sampler starts with some initial value y_0 for y and obtains x_0 by generating a random variable from the conditional distribution, $p(x | y = y_0)$. The sampler then uses x_0 to generate a new value, y_1 , drawing from the conditional distribution based on the value x_0 , $p(y | x = x_0)$. The sampler proceeds as follows:

$$x_i \sim p(x | y = y_{i-1}) \quad (19.31a)$$

$$y_i \sim p(y | x = x_i) \quad (19.31b)$$

Repeating this process k times generates a **Gibbs sequence** of length k , where a subset of points (x_j, y_j) is taken to represent our simulated draws from the full joint distribution. To obtain the desired total of m sample points, we first sample the chain after a sufficient **burn-in** period to remove the effects of the initial starting values and then at set time points (say, every n samples) following the burn-in (**trimming** or **thinning** the sequence). For example, Wang et al. (1994b) created a Gibbs sampler for an animal model that generated a total of 1,205,000 sample vectors. The first 5000 were discarded (corresponding to the burn-in), and then every tenth subsequent iteration was saved (to reduce correlations between sample vectors), to yield a total sample of 120,000 vectors. The burn-in period, and sampling interval following the burn-in can be delicate, and careful analysis of the resulting Gibbs sequence using convergence diagnostic tools is critical (Appendix 3).

When more than two variables are involved, the sampler is extended in the obvious fashion. For example, if there are four variables, (w, x, y, z) , the sampler becomes

$$\begin{aligned} w_i &\sim p(w \mid x = x_{i-1}, y = y_{i-1}, z = z_{i-1}) \\ x_i &\sim p(x \mid w = w_i, y = y_{i-1}, z = z_{i-1}) \\ y_i &\sim p(y \mid w = w_i, x = x_i, z = z_{i-1}) \\ z_i &\sim p(z \mid w = w_i, x = x_i, y = y_i) \end{aligned}$$

Any feature of interest for the marginals can be computed from the m realizations of the Gibbs sequence. For example, the expectation of any function, f , of the random variable, x , is approximated by

$$E[f(x)]_m = \frac{1}{m} \sum_{i=1}^m f(x_i) \quad (19.32a)$$

which is simply the average of the function evaluated over the points in the sampler. This is the **Monte Carlo (MC) estimate** of $f(x)$, as $E[f(x)]_m \rightarrow E[f(x)]$ as $m \rightarrow \infty$. Likewise, the MC estimate for any function of n variables $(\theta^{(1)}, \dots, \theta^{(n)})$ is given by

$$E[f(\theta^{(1)}, \dots, \theta^{(n)})]_m = \frac{1}{m} \sum_{i=1}^m f(\theta_i^{(1)}, \dots, \theta_i^{(n)}) \quad (19.32b)$$

Example 19.11. As a toy example of how to use the output of a Gibbs sampler, suppose we are interested in the distribution of breeding values in a particular generation (measured by four individuals in the analysis), as well as in the base population heritability. A Gibbs sampler has been implemented and the realizations at three different iterations (say 100, 200, and 300) after a sufficient burn-in period are as follows:

Factor	Sample 100	Sample 200	Sample 300
$a(1)$	1.5	1.8	2.2
$a(2)$	2.1	3.4	1.4
$a(3)$	3.1	2.9	4.4
$a(4)$	3.3	4.3	3.6
σ_A^2	0.55	0.64	0.46
σ_e^2	1.10	0.98	1.20

Here $a(1)$ through $a(4)$ correspond to the values (realizations of the posterior distribution) of the four breeding values in that particular iteration of the sampler, and σ_A^2 and σ_e^2 are, similarly, the realizations for the variances in that iteration. The mean and variance for the breeding value of these four individuals, in sample i , are

$$\bar{a}_i = \frac{1}{4} \sum_{j=1}^4 a_i(j) \quad \text{and} \quad \text{Var}(a)_i = \frac{1}{4-1} \sum_{j=1}^4 [a_i(j) - \bar{a}_i]^2$$

and the base population heritability

$$h_i^2 = \sigma_{A,i}^2 / (\sigma_{A,i}^2 + \sigma_{e,i}^2)$$

Using these three realizations

	Sample 100	Sample 200	Sample 300
\bar{a}	2.5	3.1	2.9
$\text{Var}(a)$	0.72	1.09	1.83
h^2	0.33	0.40	0.28

Thus, the sampler has returned three values for each of the quantities of interest. Of course, a full sampler consists of thousands to hundreds of thousands of such realization, allowing us to empirically generate the full distribution of any for these functions. For example, the mean of the marginal posterior for the mean breeding value over these four individuals is simply the mean of \bar{a} over the entire sample from the Gibbs sequence. Likewise, the empirical histogram of h_i^2 values is the marginal posterior for the heritability, and thus accounts for any source of variation in estimating h^2 (given that the assumed model is correct).

Bayesian Analysis of the Animal Model

The use of Bayesian approaches for the analysis of selection experiments was first suggested by Sorensen and Johansson (1992). Starting with the standard animal model

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{a} + \mathbf{e}, \quad \text{where } \mathbf{y} \sim \text{MVN}(\mathbf{X}\boldsymbol{\beta}, \sigma_A^2 \mathbf{Z}\mathbf{A}\mathbf{Z}^T + \sigma_e^2 \mathbf{I})$$

The (unconditional) mean and variance for this model follow from $E[\mathbf{y}] = \mathbf{X}\boldsymbol{\beta}$, and $\text{Var}(\mathbf{y}) = \text{Var}(\mathbf{Z}\mathbf{a} + \mathbf{e}) = \sigma_A^2 \mathbf{Z}\mathbf{A}\mathbf{Z}^T + \sigma_e^2 \mathbf{I}$. Wang et al. (1993, 1994a, 1994b), Sorensen et al. (1994), and Jensen et al. (1994) developed Gibbs samplers for this model and its extensions. As before, the conditional distribution of the data, given the vectors of fixed effects, $\boldsymbol{\beta}$, breeding values, \mathbf{a} , and the environmental variance, σ_e^2 , is multivariate normal

$$\mathbf{y} | \boldsymbol{\beta}, \mathbf{a}, \sigma_e^2 \sim \text{MVN}(\mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{a}, \sigma_e^2 \mathbf{I}) \quad (19.33a)$$

The infinitesimal model is assumed, with the distribution of breeding values, given the relationship matrix, \mathbf{A} , and additive genetic variance, σ_A^2 , being multivariate normal

$$\mathbf{a} | \mathbf{A}, \sigma_A^2 \sim \text{MVN}(\mathbf{0}, \sigma_A^2 \mathbf{A}) \quad (19.33b)$$

Sorensen et al. (1994) assumed a uniform prior for $\boldsymbol{\beta}$, a normal prior for \mathbf{a} , and both uniform and inverse- χ^2 priors for the variances. For example, the joint prior for \mathbf{a} and σ_A^2 is the product of $p(\mathbf{a} | \sigma_A^2, \mathbf{A}) \cdot p(\sigma_A^2)$, where the first distribution is a multivariate normal (Equation 19.33b) and the second is either a uniform or an inverse- χ^2 (Appendix 2). These distributions are chosen because they are conjugate priors (Appendix 2) for the multivariate normal, resulting in analytical expressions for the $p + q + 2$ univariate conditional distributions for each factor in the model (p breeding values, a_k , q fixed effects, β_j , and the variances, σ_A^2 and σ_e^2). Using these univariate conditionals, a Gibbs sampler can be constructed. The outline for the sampler is as follows:

1. Set initial values for \mathbf{a} , $\boldsymbol{\beta}$, σ_A^2 , and σ_e^2 .
2. Using the current values of \mathbf{a} , $\boldsymbol{\beta}$, σ_A^2 , and σ_e^2 and the conditional distributions (see Sorensen et al. 1994 for exact expressions):
 - (i) Update the fixed effects by sequentially drawing (for $j = 1, \dots, q$) from the conditionals (which are univariate normals)

$$\beta_{j,i} \sim p(\beta_j | \beta_{1,i}, \dots, \beta_{j-1,i}, \beta_{j+1,i-1}, \dots, \beta_{q,i-1}, \mathbf{a}_{i-1}, \sigma_{A,i-1}^2, \sigma_{e,i-1}^2)$$

where $\beta_{j,i}$ is the value of β_j during the i th iteration of the sample. The current values of these parameters define the mean and variance for a normal, from which a random value is drawn. For factor j , we take the values for \mathbf{a} and the variances from the last iteration ($i - 1$), the values of β_1 to β_{j-1} from the current iteration (i), and the values of β_{j+1} to β_q from the last iteration ($i - 1$). These values are inserted to give the parameters (here, the conditional mean and variance) for the univariate normal that corresponds to the conditional distribution for β_j and a random variable is drawn from this distribution to yield $\beta_{j,i}$.

- (ii) Update the breeding values by sequentially drawing (for $i = 1, \dots, p$) from the conditionals (again univariate normals), where the vector, β , of fixed effects is taken as the updated version

$$a_{j,i} \sim p(a_j | \beta_i, a_{1,i}, \dots, a_{j-1,i}, a_{j+1,i-1}, \dots, a_{p,i-1}, \sigma_{A,i-1}^2, \sigma_{e,i-1}^2)$$

- (iii) Update the additive variance by drawing from the conditional (a scaled inverse- χ^2 distribution)

$$\sigma_{A,i}^2 \sim p(\sigma_A^2 | \beta_i, \mathbf{a}_i, \sigma_{e,i-1}^2)$$

- (iv) Update the error variance by drawing from the conditional (again, a scaled inverse- χ^2 distribution)

$$\sigma_{e,i}^2 \sim p(\sigma_e^2 | \beta_i, \mathbf{a}_i, \sigma_{A,i}^2)$$

3. Using the updated values, repeat (2) until k samples have been obtained, from which m are extracted (following the burn-in and trimming) for the Gibbs-sampler chain.

This Bayesian analysis makes most of the standard animal-model assumptions, in particular that the infinitesimal model and multivariate normality, hold (as with an MM analysis, a Bayesian approach is potentially biased by selection-induced changes in allele frequencies). A Bayesian analysis has all the advantages of an MM analysis (over an LS analysis) and, in addition, the posterior marginals correctly give the distribution of any parameter of interest, independent of the values assumed for other parameters. Any uncertainty introduced by estimating these additional parameters is fully captured by the marginal posteriors. The Bayesian approach yields the correct distribution (assuming that the model assumptions hold and the prior is reasonable) for the estimated selection response, independent of the additive genetic variance. By contrast, an MM analysis is highly dependent on the assumed (or estimated) additive variance, and the standard error of a REML/BLUP estimate for the response (Equation 19.8c) does not account for the additional uncertainty introduced by using a REML estimate of σ_A^2 . One standard package for Bayesian analysis is Winbugs, and Damgaard (2007) outlined how to apply this software to animal models.

Application: Estimating Selection Response in Pig Litter-size Components

Blasco et al. (1998) used the method of Sorensen et al. (1994) to estimate the response to selection on ovulation rate and prenatal survival in French Large White pigs. Three lines were followed, with single lines selected separately on each trait (ovulation rate and survival) and a control line. The relevant selection and control lines were jointly analyzed to estimate the selection response. Ovulation rate was examined using the standard animal model

$$\mathbf{y} | \beta, \mathbf{a}, \sigma_e^2 \sim \text{MVN}(\mathbf{X}\beta + \mathbf{Z}\mathbf{a}, \mathbf{I}\sigma_e^2) \quad \text{and} \quad \mathbf{a} | \mathbf{A}, \sigma_A^2 \sim \text{MVN}(\mathbf{0}, \mathbf{A}\sigma_A^2)$$

Prenatal survival (as a function of the mother) was examined using the repeatability model, where c is the permanent environmental effect of a mother over multiple litters

$$\mathbf{y} | \beta, \mathbf{a}, \mathbf{c}, \sigma_e^2 \sim \text{MVN}(\mathbf{X}\beta + \mathbf{Z}\mathbf{a} + \mathbf{W}\mathbf{c}, \mathbf{I}\sigma_e^2)$$

$$\mathbf{a} | \mathbf{A}, \sigma_A^2 \sim \text{MVN}(\mathbf{0}, \mathbf{A}\sigma_A^2) \quad \text{and} \quad \mathbf{c} | \sigma_c^2 \sim \text{MVN}(\mathbf{0}, \mathbf{I}\sigma_c^2)$$

Among the fixed effects in β are terms for the **parity** of the mother (first litter, second litter, and so on). The marginal posterior distribution for breeding values (and hence, recalling Equation 19.8b, for the response via $\mathbf{K}^T \mathbf{a}$) was obtained by using the Gibbs-sampler approach of Sorensen et al. (1994) outlined previously. For each trait, two independent chains

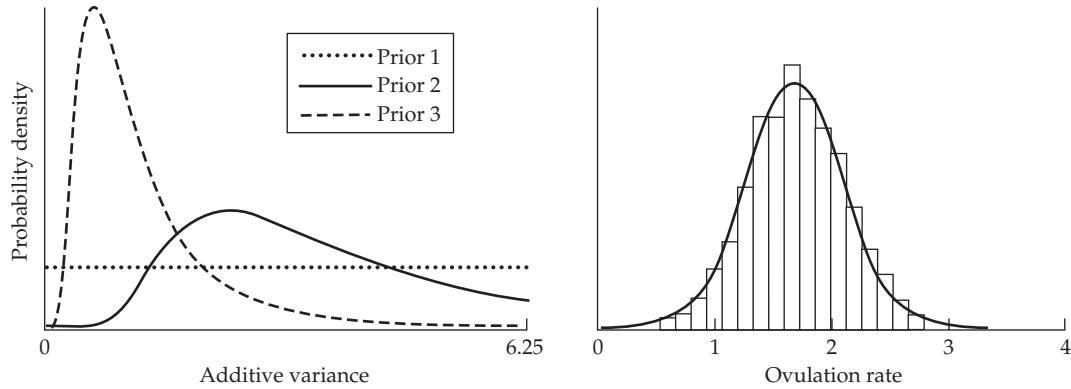

Figure 19.3 Analysis of ovulation rate at puberty in French Large White pigs. **Left:** Assumed priors for σ_A^2 (see text for details). **Right:** The Bayesian estimate of selection response is shown by presenting the marginal posterior density for the mean breeding value in ovulation rate in the last generation of selection as a histogram (all three priors gave very similar results). This distribution is approximately normal (the solid curve). (After Blasco et al. 1998.)

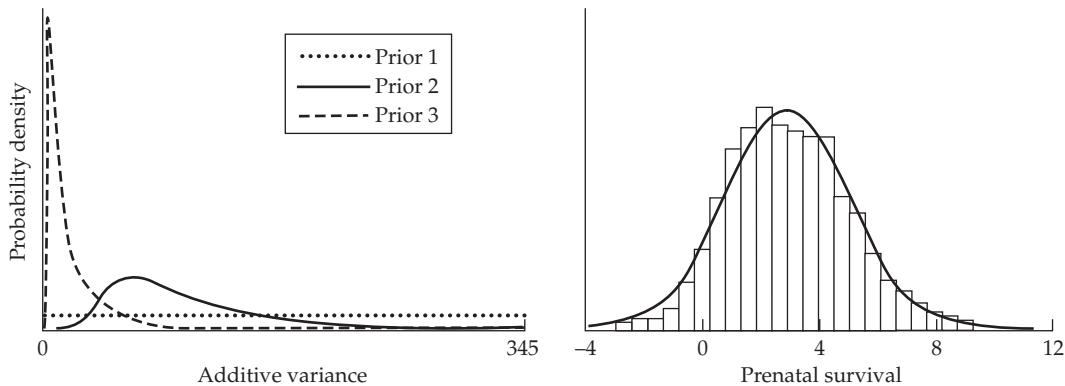

Figure 19.4 Analysis of French Large pig prenatal survival. **Left:** Priors for the additive variance (see text for details). **Right:** Posterior distribution of mean breeding values (at generation 4) in prenatal survival (based on prior 1), which deviates from the best-fitting normal. (After Blasco et al. 1998.)

of length 100,000 were computed, with the first 10,000 samples discarded (to remove burn-in effects) and sampling at every 30 iterations thereafter, which generated a trimmed sampler of length 3000. The authors obtained these burn-in and resampling values after several initial runs, using the diagnostics suggested by Raftery and Lewis (1992a) for level of precision and Geyer (1992) for autocorrelation between samples. A uniform prior was taken for the fixed effects, while different priors were used for the variances (discussed below).

We will consider the results for ovulation rate at puberty first. Figure 19.3 shows the three priors assumed for the additive variance in this trait. The phenotypic variance of this trait is 6.25, which sets an upper limit on σ_A^2 . Prior 1 is a uniform distribution that weights all values in the parameter space equally. Priors 2 and 3 (which are scaled inverse- χ^2

Table 19.1 Estimated response to selection for ovulation rate at puberty and prenatal survival in French Large White pigs. Bayesian analysis with three different priors (Figure 19.3 for ovulation and Figure 19.4 for prenatal survival) were used to obtain Monte-Carlo estimates of the mean response and their associated standard deviations (the latter incorporating the additional error from estimating the additive variance and other parameters). For comparison, least-squares (LS) estimates ($\bar{z}_{i+1} - \bar{z}_i$) and mixed-model (REML/BLUP) estimates are also included. (After Blasco et al. 1998.)

Total Response in Ovulation Rate at Puberty				
Method	Gen. 1	Gen. 2	Gen. 3	Gen. 4
Bayesian, Prior 1	0.30 ± 0.31	0.51 ± 0.35	1.03 ± 0.39	1.58 ± 0.43
Bayesian, Prior 2	0.31 ± 0.30	0.51 ± 0.34	1.05 ± 0.38	1.55 ± 0.42
Bayesian, Prior 3	0.31 ± 0.31	0.51 ± 0.35	1.01 ± 0.35	1.53 ± 0.38
LS	-0.09	0.35	1.98	1.87
REML/BLUP	0.27	0.45	1.00	1.54

Total Response in Prenatal Survival				
Method	Gen. 1	Gen. 2	Gen. 3	Gen. 4
Bayesian, Prior 1	-0.53 ± 1.44	1.23 ± 1.61	2.83 ± 1.94	2.89 ± 2.12
Bayesian, Prior 2	-0.64 ± 1.70	1.50 ± 1.87	3.46 ± 2.05	3.49 ± 2.30
Bayesian, Prior 3	-0.46 ± 1.45	1.22 ± 1.60	2.84 ± 1.82	2.90 ± 2.01
LS	-5.71	2.11	4.13	-2.82
REML/BLUP	-0.54	1.49	3.26	3.42

distributions) reflect additional information. Published heritabilities for this trait in pigs and rabbits range from 0.1 to 0.6, and prior 2 assumes a broad distribution around the approximate median value ($\sigma_A^2 = 0.4 \cdot 6.25 = 2.5$). A study specifically in French Large Whites gave an estimate of $h^2 = 0.11 \pm 0.02$, and the tight distribution around this value is reflected in prior 3. Blasco et al. obtained Monte Carlo estimates of the (base population) heritability under these three priors of $h^2 = 0.39 \pm 0.07$, 0.39 ± 0.06 , and 0.32 ± 0.06 . Table 19.1 shows the estimated cumulative response after each of the four generations of selection, in comparison with the least-squares (differences between generation means) and mixed-model (REML/BLUP) estimates. Note that the three different priors give very consistent estimates of response, implying that the data contained sufficient information to overpower most of the signal coming from the assumed prior. The Bayesian and MM analyses yielded very similar results, while LS analysis yields a substantially different estimates of response.

While the results for ovulation rate were consistent across the three priors and with the MM analysis, those for prenatal survival were more problematic (Table 19.1). Figure 19.4 shows the assumed different priors. In this case, as with ovulation rate, prior 1 is uninformative, weighting all potential additive variances equally. Prior 2 (as with prior 2 for ovulation rate) assumed a broad distribution around the mean heritability ($h^2 \simeq 0.2$) of this trait in a number of studies, while prior 3 used the estimate of $h^2 = 0.03 \pm 0.03$ found using French Large Whites. The three priors returned Monte Carlo estimates of heritability (and its standard deviation) of $h^2 = 0.12 \pm 0.06$, 0.16 ± 0.04 , and 0.11 ± 0.04 . Likewise, these priors give Monte Carlo estimates of the repeatability (r) of 0.23 ± 0.05 , 0.23 ± 0.04 , and 0.19 ± 0.04 . As Table 19.1 shows, the standard deviations for the Monte Carlo estimates of mean response were very large, but the three priors and the MM analysis gave consistent results, while the LS results were quite different. Clearly, the information on prenatal survival in the experiment was modest, as the posterior is significantly influenced by the prior. Additional early examples of Bayesian analysis of selection experiments involved lean growth in pigs (Rodriguez et al. 1996) and body weight in chickens (Su et al. 1997).

LS, MM, OR BAYES?

Just what analysis should an investigator use for a selection experiment? Obviously, in the

absence of any pedigree information, a least-squares analysis is the only option, although this could also be placed in a Bayesian framework. With the pedigree in hand (either observed or inferred; see Chapter 20), a mixed-model analysis is much more powerful and is strongly preferred over LS, unless there is strong evidence that model assumptions have been violated. If a mixed-model approach is appropriate and chosen, should the analysis be frequentist or Bayesian? As mentioned, the Bayesian approach does a much better job of treating uncertainty, but this comes at a higher computational cost, especially when one does a proper analysis using several different priors to assess sensitivity. Perhaps the best advice is that offered by Blasco (2001):

“The choice of one school or the other should be related to whether there are solutions in one school that the other does not offer, to how easily the problems are solved, and to how comfortable scientists feel with the way they convey their results.”

Blasco’s last point is especially important: it is much more important for investigators to use a method with which they are comfortable, in the sense of knowing its limitations and having some intuition into the approach, than to simply use a method because it is new and trendy.

Generally speaking, simpler methods (such as LS) tend to be more robust to model fragility than more complex approaches (e.g., mixed-models). While the latter can be considerably more powerful when the model assumptions *do hold*, they can also be significantly more biased when they fail. Ideally, one should use several different approaches in the analysis of any dataset. If the results are consistent, one can have additional confidence that the model assumptions may be holding or that the methods are immune to violations. If the results are rather different, this provides a critical indicator to the investigator that a much more careful examination of model assumptions is in order.

20

Selection Response in Natural Populations

Associations between phenotype and fitness, however appealing, will give a misleading impression of the potential for evolution in a trait if the true target of selection is unmeasured or immeasurable. Kruuk et al. (2002)

Under artificial selection (animal and plant breeding and laboratory selection experiments), the breeder's equation machinery developed in Chapters 13 through 19 for the prediction and analysis of response generally works well. However, there is considerable angst as to whether this is also true for natural populations (e.g., Merilä et al. 2001c; Morrissey et al. 2010, 2012; Pemberton 2010; Timothée et al. 2017). There are two principal reasons for this. First, under artificial selection, individuals are strictly chosen by the phenotypic value of their focal trait or traits. By contrast, in natural populations, one *infers* the target of selection, typically by looking for changes in the mean and/or variance of certain candidate traits within and/or across generations. The problem is that the phenotypic moments of an unselected trait can change if it is correlated with another trait under selection. A within-generation change (a nonzero selection differential) occurs if an unselected trait is phenotypically correlated with a selected one (Equation 13.25c), while a between-generation change (a response) occurs if the traits are genetically correlated (Equation 13.26c).

The second complication is lack of control over the environment. With artificial selection, there is generally considerable environmental control, in part due to husbandry and cultivation methods designed to standardize rearing and growing conditions and to mitigate extreme environmental events. This is certainly not the case when attempting to track selection in natural populations. Indeed, we are largely unable to determine which environmental factors may be important, let alone be able to control them. Further, artificial selection experiments generally impose considerable control over the *biotic* (in addition to the physical) environment in which an organism finds itself (e.g., the collection of species interacting with the focal population). In natural populations, the biotic environment is both absolutely critical and largely uncontrollable. One potential consequence of lack of environmental control arises when unmeasured environmental factors jointly influence the trait and fitness. Changes in the environment can also mask underlying genetic changes and can lead to significant changes in the nature of selection from one generation to the next (such as favoring larger trait values in wet years and smaller values in dry years). Finally, changes in the environment can modify genetic and environmental variances, thus altering the heritability.

This chapter addresses these concerns in two parts. The first is largely theoretical, centering on the bias caused by selection on unmeasured features. We initially frame this concern within the context of correlated characters, and then focus on the special case where an unmeasured variable is entirely environmental, which can generate a nonzero selection differential but no response. Next, we extend the univariate breeder's equation to account for all of the possible biases that arise from any unmeasured traits influencing the focal trait. We conclude by recasting the selection response under both versions of Robertson's secondary theorem, $R = \sigma(A_z, A_w)$ and $R = \sigma(A_z, w)$ (Chapter 6), as opposed to the breeder's equation ($R = h^2 S$) framework. Here, w is relative fitness, and A_z and A_w are, respectively, the breeding values for the trait and relative fitness. Contrasts between these two predictions suggest tests for assessing whether a focal trait is the sole target of selection.

The second part of our treatment is largely empirical, examining the advantages and pitfalls of applying mixed models (Chapter 19) in natural populations. During the first decade of the 2000s, there was much excitement that BLUP predictions of breeding values

would offer powerful insight into the nature of selection response in natural populations. A rash of results, many initially viewed as classic, quickly appeared from the analysis of pedigrees from several vertebrate populations under long-term observation (reviewed in Kruuk et al. 2008). However, problems with BLUP estimates of breeding values in natural settings, initially noticed by Postma (2006), were shown by Hadfield (2008) and Hadfield et al. (2010) to be extremely serious. Hence, many of these initial results need to be seriously reconsidered.

Nonetheless, certain aspects of the animal model, in particular REML estimates of specific covariances (such as that between the breeding values of a trait and fitness), remain powerful approaches. We first review how a BLUP analysis in a natural population proceeds (with a specific focus on estimating the relationship matrix, \mathbf{A}), then show where flaws can appear, and finally examine how certain features of the animal model can still prove useful. The rapid rise, even quicker demise, and then phoenix-like resurrection (and reorientation) of animal-model applications in natural populations can be quite confusing to the novice reading the historical literature, so we try to carefully navigate through the shoals of confusion. We conclude by reviewing a number of examples of selection response (or lack thereof) in natural populations, using the developed theoretical and statistical machinery to highlight problems that can arise when attempting to predict response in a natural population.

EVOLUTION IN NATURAL POPULATIONS: WHAT IS THE TARGET OF SELECTION?

While there are many assumptions underlying the breeder's equation (Chapter 6; Table 13.2), the one that is most likely to fail in natural populations, and the one that is most challenging to test, involves *causality*—our assumption that the phenotype of the focal trait is the sole target of selection (in the sense that it is genetically and phenotypically uncorrelated with any other traits under selection). Under the breeder's equation, the trait value (z) entirely governs fitness, and transmission of the resultant change in the mean of z to the next generation is entirely described by h^2 . The conceptual beauty of the breeder's equation is that it partitions evolution into separate, and distinct, ecological (S) and genetical (h^2) processes, allowing ecologists to focus on the former (the nature of selection) and geneticists on the latter (the inheritance of the trait). If we incorrectly assign the target of selection, the breeder's equation will give misleading results.

Direct and Correlated Responses

Bias from correlated traits can be removed by using the multivariate breeder's equation, *provided* all relevant traits are included. This equation expresses the vector, \mathbf{R} , of responses (changes in means) as a function of the genetic (breeding value), \mathbf{G} , and phenotypic, \mathbf{P} , covariance matrices for the traits of interest, and the vector, \mathbf{S} , of their selection differentials. From Equations 13.23b and 13.26a,

$$\mathbf{R} = \mathbf{GP}^{-1}\mathbf{S} = \mathbf{G}\beta$$

where the selection gradient, $\beta = \mathbf{P}^{-1}\mathbf{S}$, controls for any phenotypic correlations among the measured traits, returning the amount of direct selection acting on each particular character (LW Chapter 8; Chapter 30).

Focusing on the bivariate version of this equation provides insight into some of the complications that can arise by ignoring selection on correlated traits. Suppose we are following trait 1, which is influenced by a second (and unmeasured) feature, which we denote as trait 2. Noting that $\mathbf{S} = \mathbf{P}\beta$, the selection differential on trait 1 becomes

$$S_1 = P_{11}\beta_1 + P_{12}\beta_2 = \sigma^2(z_1)\beta_1 + \sigma(z_1, z_2)\beta_2 \quad (20.1a)$$

A within-generation change ($S_1 \neq 0$) in trait 1 occurs from: (i) direct selection on trait 1 ($\beta_1 \neq 0$), and/or (ii) indirect selection from a *phenotypically* correlated one (trait 2) under

directional selection ($\beta_2 \neq 0$ and $\sigma(z_1, z_2) \neq 0$). As a result, the signs of S_1 and β_1 can differ, and even strong direct selection ($\beta_1 \neq 0$) on a trait can still be associated with a net selection differential of nearly zero (or worse, of opposite sign). Turning to the expected response in trait 1,

$$R_1 = G_{11}\beta_1 + G_{12}\beta_2 = \sigma^2(A_1)\beta_1 + \sigma(A_1, A_2)\beta_2 \quad (20.1b)$$

Trait 1 can evolve as a consequence of direct selection (if it has additive variation) or as a correlated response from direct selection on another *genetically* correlated trait (with the breeding values of the two traits being correlated within individuals, $\sigma(A_1, A_2) \neq 0$).

As the following example highlights, some of the best studies of the response to selection in natural populations come from birds (reviewed by Merilä et al. 2001b; Merilä and Sheldon 2001; Gienapp et al. 2008; Kruuk et al. 2008; Clutton-Brock and Sheldon 2010; Charnantier et al. 2014). In certain settings (such as isolated islands), the entire population can be banded and all nests located (often through the use of nest boxes), allowing for accurate measurement of individual fitness (Chapter 29).

Example 20.1. Alatalo et al. (1990) examined tarsus length in a population of collared flycatchers (*Ficedula albicollis*) residing in the southern part of the island of Gotland in the Baltic Sea. Measurements of lifetime fitnesses in this isolated bird population were possible because most surviving offspring (which are tagged before fledging, i.e., before leaving the nest) return to breed in the area where they were reared as offspring. In addition to tarsus length, fledgling weight was also measured (with both traits scaled in standard-deviation units) and Pearson-Lande-Arnold regressions (Chapter 30; LW Chapter 8) were performed to compute the amounts of direct selection (the estimated selection gradients) on both characters, yielding

Year	Observed \bar{t} on tarsus length	Estimated selection gradients, $\hat{\beta}$	
		Tarsus length	Fledgling weight
1981	0.19**	0.01	0.25*
1983	0.08	-0.01	0.21*
1984	0.20**	0.12	0.33***
1985	0.02	-0.06	0.27***
pooled	0.12**	0.03	0.27***

^{*} $p < 0.05$, ^{**} $p < 0.01$, ^{***} $p < 0.001$

Although there was a significant selection differential (which is presented as the selection intensity, \bar{t} , because the trait was scaled in standard deviations; Equation 13.6a) on tarsus length in two of the years (and in the pooled data), there was no significant *direct* selection on tarsus length itself (none of the estimated selection gradients for this trait were significant). Rather, direct selection was on fledgling weight. While there is a significant phenotypic correlation between tarsus length and fledgling weight ($r = 0.32$; $p < 0.001$), it appears to be entirely due to within-individual correlations of environmental effects, as there is no correlation between the fledgling weight of an offspring and the tarsus length of its parent ($r = -0.01$; $p > 0.1$). The latter observation implies an absence of a genetic correlation between tarsus length and fledgling weight, and hence (from Equation 20.1b) no response in tarsus length is expected.

Example 20.2. As reviewed in Grant and Grant (1995, 2002; and references therein), one of the best documented cases of natural selection is on body size and bill morphology in Darwin's finches (*Geospiza fortis*) on the Galápagos island of Daphne Major. Two strong episodes of selection were observed during their long-term study, due to serious droughts in 1976–1977 (when the population crashed from 634 birds down to 95, a 15% survival rate), and in 1984–1986 (556 birds reduced to 180, a 32% survival rate). Six (log-transformed) morphological traits were followed through both episodes, and (after rescaling all traits to have unit variances) the selection differentials, $S = \bar{t}$ (as traits are scaled to unit variance), and gradients, β , for the two episodes were as follows (where * denotes $p < 0.05$):

Trait	1976–1977		1984–1986	
	\bar{t}	β	\bar{t}	β
Weight	0.74*	0.477*	-0.11	-0.040
Wing length	0.72*	0.436*	-0.08	-0.015
Tarsus length	0.43*	0.005	-0.09	-0.047
Bill length	0.54*	-0.144	-0.03	0.245*
Bill depth	0.63*	0.528*	-0.16*	-0.135
Bill width	0.53*	-0.450*	-0.17*	-0.152

Two striking features are apparent. First, the observed (within-generation) change in the mean, \bar{t} , was not a good predictor of the actual amount of direct selection, β , on a trait, and can even have a different sign (e.g., bill length). Second, the nature of selection changed over the two drought periods. During the 1976–1977 drought, larger individuals were favored, and there was selection on bill shape (increased bill depth, decreased bill width). A change in the dominant food supply during a subsequent drought in 1984–1986 resulted in selection favoring smaller birds. Hence, the two episodes of selection were in opposite directions (at least in terms of body size).

Grant and Grant had an estimate of the genetic variance matrix, \mathbf{G} , for these traits in hand, allowing them to substitute these estimated β s into the multivariate breeder's equation (13.26a) to examine how well responses were predicted. Response was well predicted in 1976, but overpredicted in three of the six traits in the 1984 episode. They suggested that the main reason for these discrepancies was a change in the biotic environment. Higher population densities for offspring in 1984 retarded growth, resulting in an overprediction of size-related traits.

Character	1976–1977		1984–1986	
	Predicted	Observed	Predicted	Observed
Weight	17.39 ± 0.22	17.52 ± 0.25	16.82 ± 0.13	15.48 ± 0.08*
Wing length	69.98 ± 0.39	69.65 ± 0.35	67.93 ± 0.17	67.21 ± 0.11***
Tarsus length	19.45 ± 0.09	19.32 ± 0.14	19.02 ± 0.04	19.02 ± 0.04
Bill length	11.14 ± 0.10	11.06 ± 0.11	10.86 ± 0.05	10.96 ± 0.03
Bill depth	9.83 ± 0.12	9.94 ± 0.09	9.51 ± 0.06	9.32 ± 0.03**
Bill width	8.96 ± 0.08	8.97 ± 0.08	8.77 ± 0.04	8.70 ± 0.03

* $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$

Environmentally Generated Correlations Between Fitness and Traits

In natural populations, one or more environmental factors can influence both an individual's trait value and its fitness. This generates a correlation between the trait and fitness, and hence (from the Robertson-Price identity; Equation 6.10) a selection differential, $S = \sigma(z, w)$, on the trait, even if there is no direct selection on the trait itself. Consider the following example, which was suggested by Rausher (1992).

Suppose, for example, that soil nitrate concentration influences both fitness (seed production) and the amount of alkaloids (secondary plant chemicals) in the foliage of a plant. As Figure 20.1 shows, if we were able to partition individuals from a population into high- and low-nitrate environments, within each group we might find no association between alkaloid concentration and fitness. However, if we ignored this partition and simply lumped all individuals into a single group, we would find a positive covariance between alkaloid concentration and fitness. An investigator unaware of this difference in soil nitrates might conclude that there was a fitness effect from the presence of alkaloids (for example, as an insect deterrent), when in fact the correlation between trait and fitness arises solely because both are influenced by a third, and unmeasured, variable. In this setting, the breeder's equation would lead to an erroneous prediction of a selection response in alkaloid levels because it assumes that alkaloids are the causative agent of fitness differences. (As an aside, this particular observation is an example of Simpson's paradox, introduced in Chapter 10, wherein individual association tables give a different picture from their amalgamated table.)

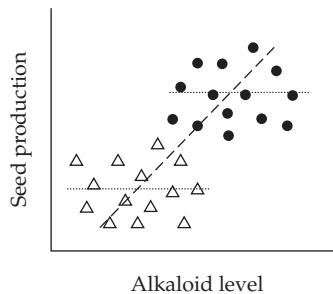

Figure 20.1 An environmental variable (soil nitrate) influences both fitness and trait value (alkaloid levels), creating a covariance between the trait and fitness (measured by seed production), when in fact the trait value is not a causal determinant of fitness. In low-nitrate soils (open triangles), plants have low fitness and low levels of alkaloids. In high-nitrate soils (filled circles), plants have high fitness and high levels of alkaloids. Within each of the two environments, there is no association between the trait and fitness (dotted regressions). If one ignores the environmental effects and simply lumps all the individuals together, there is a strong association between fitness and the trait value (dashed regression). (Based on Rausher 1992 and Mauricio and Mojonniere 1997.)

Rausher's example (in the previous paragraph) introduces the concept of selection on a nonheritable feature that also influences the focal trait. While the feature, soil nitrate, is a primary determinant of plant fitness, it is an environmental factor that also influences alkaloid levels. From Equations 20.1a and 20.1b, the selection differential and response are

$$S_{\text{alkaloid level}} = \sigma(\text{alkaloid level}, \text{soil nitrate})\beta_{\text{soil nitrate}} \neq 0$$

$$R_{\text{alkaloid level}} = \sigma(A_{\text{alkaloid level}}, A_{\text{soil nitrate}})\beta_{\text{soil nitrate}} = 0 \cdot \beta_{\text{soil nitrate}} = 0$$

While plants with high alkaloid levels (which are heritable) appear to have higher fitness ($S > 0$), alkaloid levels do not increase in the next generation ($R = 0$). This is because plants with high *environmental* values for alkaloids (due to high soil nitrate values) were selected, not plants with high *genetic* values, and hence there is no selection response. Put another way, there is selection on a component of the *environmental* value of alkaloid level (that due to soil nitrate value), but *not* on its *breeding* value, and hence no response (Chapter 13).

Example 20.3. Considering the evolution of **clutch size** (z_1) in birds (number of eggs laid in a particular episode), Price and Liou (1989) suggested that fitness is largely determined by the nutritional state, z_2 , of a mother, which also influences her own clutch size, $\sigma(z_1, z_2) \neq 0$. They assumed that nutritional state is entirely environmental, $\sigma^2(A_2) = 0$. Equation 20.1a implies that, even if there is no direct selection on clutch size per se ($\beta_1 = 0$), we would still observe a selection differential on clutch size if it is phenotypically correlated with nutritional state and the latter is itself under selection ($\beta_2 \neq 0$), as $S_1 = \beta_2 \sigma(z_1, z_2) \neq 0$. The resulting selection response in clutch size, R_1 , is $\beta_2 \sigma(A_1, A_2) = 0$, because nutritional state is assumed to have no heritable variance, which implies $\sigma(A_1, A_2) = 0$. As a result, there is apparent directional selection on clutch size ($S_1 \neq 0$), but no response ($R_1 = 0$).

The notion of nutritional status, or some other measure of well-being, of an organism is often referred to as **condition** by ecologists (Le Cren 1951). Although this term is often used fairly loosely, without any formal definition, one common operational measure is the residual from a regression of weight on some measure of body size (i.e., size-adjusted weight). The motivation for this metric is that individuals in good condition will be heavier than expected given their size, while individuals in poor condition will be underweight. Jakob et al. (1996), Green (2001), and Schulte-Hostedde et al. (2005) discussed the merits of this metric. While condition is often treated entirely as a product of the environment, as with any standard quantitative trait, it is reasonable to assume that it may have some genetic component as well (e.g., Gosler and Harper 2000; Merilä et al. 2001a).

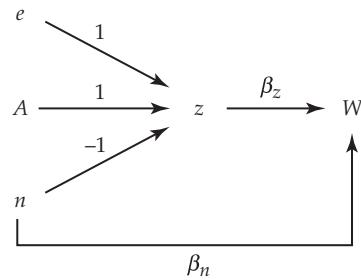

Figure 20.2 A path diagram (LW Appendix 2) of the components in the Fisher-Price-Kirkpatrick-Arnold model, showing the connections between breeding date, z , nutritional state, n , and fitness, W . The breeding value, A , general environmental value, e , and nutritional state, n , all influence the breeding date, z , which itself influences fitness (path coefficient β_z). Further, there is a second path to fitness directly from the nutritional state (β_n), which represents the direct contribution to W of n after its indirect contribution through breeding date is removed. We assume that A , e , and n are all uncorrelated, and hence not connected by any paths. (After Price et al. 1988.)

THE FISHER-PRICE-KIRKPATRICK-ARNOLD MODEL FOR EVOLUTION OF BREEDING DATE

The idea of an environmental feature being the target of selection dates back to Darwin and Fisher. Fisher (1958), based on observations by Darwin (1871), suggested that the condition of a bird influences both her clutch size and the date at which she breeds, with healthier females breeding earlier and having larger clutch sizes. Price, Kirkpatrick, and Arnold (1988) used Fisher's idea as an explanation for the apparent lack of selection response for breeding date in many birds in the temperate zone. Birds that reproduce early have higher fitness than those that breed later in the season, and hence S for breeding date is negative (selection to move the breeding date earlier). Further, when examined, the breeding date typically has moderate to high heritability. Because both h^2 and S are nonzero, the breeder's equation predicts a response to selection resulting in a decrease in breeding date, but this is not seen.

The model of Price et al. (1988) to explain this lack of response is shown in Figure 20.2. For brevity, we refer to the **Fisher-Price-Kirkpatrick-Arnold model** as simply **Fisher's model** (we will resist the temptation of referring to this as the Fisher-Price toy model). The model is as follows: assume that the breeding date, z , of a female has three components

$$z = A - n + e \quad (20.2)$$

A is the breeding value for breeding date, e is the environmental value, and n is the nutritional state (or condition) of the female. Equation 20.2 shows that females with a higher value of n (higher nutritional status) breed earlier (i.e., z declines with increasing values of n). Price et al. (following Fisher) treated n as a nonheritable environmental factor, but one could also model n as a heritable trait, thus changing this to a multivariate selection problem (Chapter 13; Volume 3). The three components of Equation 20.2 are assumed to be uncorrelated and normally distributed, with variances of σ_A^2 , σ_n^2 , and σ_e^2 . Let μ be the current mean breeding value and assume that the means of n and e are zero.

Price et al. (1988) modeled the process of selection by considering two separate components of fitness. First, they assumed there is an optimum breeding date, θ , so that z is under stabilizing selection. Recall from Equation 16.17 that a standard model for stabilizing selection in natural populations is nor-optimal (or normalizing) selection (Weldon 1895; Haldane 1954), where

$$W(z) = \exp\left(-\frac{(z - \theta)^2}{2\omega^2}\right) \quad (20.3a)$$

This function, giving the expected fitness, $W(z)$, of an individual with a phenotypic value of z , has the same form as a normal distribution, with the highest fitness at the optimal phenotypic value ($z = \theta$) and declining as one moves away from θ . The strength of selection is described by ω^2 , the “width” of the fitness function. The larger the value of ω^2 , the more slowly fitness declines as one moves away from the optimum. If $\omega^2 \gg \sigma_z^2$, selection is weak (most of the population has roughly the same fitness), while selection is strong when $\omega^2 \ll \sigma_z^2$. One advantage of this fitness function is that if z is normally distributed before selection, it remains normally distributed following selection, and expressions for the new mean and variance are easily obtained (Equation 16.18a).

Second, Price et al. assumed that fitness increases with the nutritional status, n . One way to express this is to assume that

$$W(n) = \exp(\alpha n) \quad \text{for } \alpha > 0 \quad (20.3b)$$

Note that if $|\alpha n| \ll 1$, then $W(n)$ is approximately $1 + \alpha n$. As was the case with non-optimal fitness, under the fitness function given by Equation 20.3b, traits that were normally distributed before selection remain normal following selection.

Conditioned on breeding date, z , and nutritional value, n , the resulting fitness is

$$W(n, z) = W(z) \cdot W(n) = \exp\left(\alpha n - \frac{(z - \theta)^2}{2\omega^2}\right) \quad (20.4a)$$

Recalling Equation 20.2, fitness can be expressed in terms of the components of the model

$$W(n, e, A) = \exp\left(\alpha n - \frac{(A - n + e - \theta)^2}{2\omega^2}\right) \quad (20.4b)$$

Under the assumption that A is normally distributed with a mean of μ , while n and e are normally distributed with a mean of zero, Heywood (2005) found the change in mean to be

$$R = \sigma_A^2 \left(\frac{\theta - \mu + \alpha \sigma_n^2}{\omega^2 + \sigma_z^2} \right) \quad (20.5)$$

where σ_n^2 is the variance in nutritional value. From Equation 20.5, at equilibrium ($R = 0$), the mean breeding date is

$$\hat{\mu} = \theta + \alpha \sigma_n^2 \quad (20.6)$$

which is later than the optimal breeding date, θ . Price et al. (1988) commented that this displacement of the equilibrium mean above θ occurs because females that are in good nutritional condition ($n > 0$) breed *earlier* than the mean breeding value at equilibrium, as $z = A - n + e$ (Equation 20.2), and hence

$$E[z|n > 0] = E[A - n + e|n > 0] = E[A] + E[e] - E[n|n > 0] = \hat{\mu} + 0 - E[n|n > 0] < \hat{\mu}$$

Because $\hat{\mu} > \theta$, females that are in good nutritional condition ($n > 0$) have a mean breeding date below $\hat{\mu}$, and therefore closer to the optimal value, θ . Price et al. noted that this model may also apply to clutch size in birds and might be a reasonable model for seed germination time (especially for the latter if there is a significant nonheritable nutritional contribution from the maternal endosperm).

MODIFYING THE BREEDER'S EQUATION FOR NATURAL POPULATIONS

As these examples show, one of the most serious limitations in applying the breeder's equation to natural populations is that fitness can be influenced by unmeasured traits and environmental features. Additionally, genotype-environment correlations can be a concern,

(A) Assumptions under the standard breeder's equation

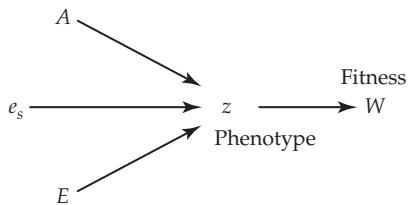

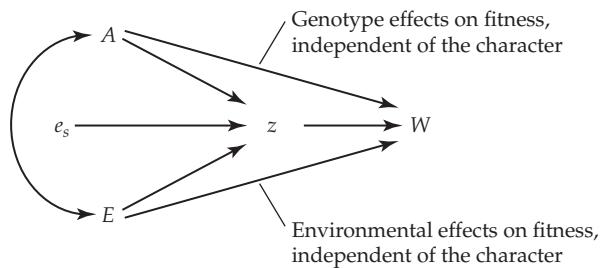

(B) All possible relationships between component values (A, E, z) and fitness

Figure 20.3 The pathways by which the components of a character (phenotype, z , additive genetic value, A , common environmental effect, E , and special environmental effect, e_s) influence fitness, W . **A:** The breeder's equation assumes that only the phenotype (z) of a character causally influences fitness. This is not an unreasonable starting assumption for artificial selection, wherein the breeder directly chooses individuals on the basis of phenotypes and randomizes environments with respect to phenotypes. **B:** Other pathways by which the components of a character can influence fitness. Either (or both) of the additive genetic and environmental values can influence fitness *independently* of their influence on phenotype. For example, an environmental value can both influence the character of interest and independently influence fitness. The influence of other traits that are also under selection, whose breeding values are correlated with our focal trait, appears through A and not through z . Similarly, the effect of shared environmental factors on phenotypic correlations appears through E . Finally, genotypic and environmental values may be correlated ($\sigma(A, E) \neq 0$), which is indicated by the double-headed arrows connecting A and E .

as (for example) larger individuals may be able to occupy better environments. In artificial selection and breeding situations, such a correlation is less of a concern because there is usually some attempt to randomize individuals over environments. Here we develop a general expression for the selection response of a single trait when all of these factors are in play. We do so by first assuming that there is a static environment (no environmental change), namely, that the distribution of environmental effects within the population remains constant over the generations of response being predicted.

Complications in the Absence of Environmental Change

How these complications bias the breeder's equation was examined by van Tienderen and de Jong (1994), with similar analysis (under a multivariate breeder's equation framework) by Hadfield (2008). van Tienderen and de Jong assumed complete additivity (no dominance or epistasis), multivariate normality, and linear parent-offspring regressions. As shown in Figure 20.3, they used a path analysis argument (LW Appendix 2) to explore the relationship between the selection response (R) and the selection differential (S) when complications such as selection on correlated characters and genotype-environment correlations exist.

To proceed, we decompose the phenotype, z , as

$$z = A + E + e_s$$

where A is the additive genetic value, E is the general environmental effect (for example, the average impact of a particular macrohabitat), and e_s is the special (or residual) environmental effect unique to each individual (LW Chapter 6). By construction, e_s is independent of the other variables (meaning that the total environmental variance is $\sigma_E^2 + \sigma_{e_s}^2$), but A and E may be correlated. Consider Figure 20.3, which shows possible paths of how the environmental value, E , the genotypic value, A , and the phenotypic value, z , can influence fitness. Figure 20.3A shows the breeder's equation assumption that E and A influence fitness only through the phenotypic value, z .

Figure 20.3B shows the general situation where E and A can influence fitness independent of (or, in addition to) their effects on z , as can occur if the focal trait is phenotypically and/or genetically correlated with other characters that are under selection. If fitness is entirely determined by the phenotypic value of the focal trait, there should be no expected differences in the fitness of individuals with the same phenotypic value, z , but different underlying genetic (A) or environmental values (E). Suppose two individuals both have $z = 100$ and $e_s = 0$, but individual 1 has $A = 80$ and $E = 20$, while individual 2 arrives at this phenotypic value by $A = 10$ and $E = 90$. If selection is entirely on the phenotype, both individuals have the same expected fitness, but their expected fitnesses may differ if there is additional selection on A and/or E beyond that based on direct selection on z . For example, if correlated characters are under selection, then individuals with the same z value can have different fitnesses due to correlations between their A and/or E values with the genetic and/or environmental values at other traits that influence fitness.

To quantify the effects from these different paths influencing fitness, van Tienderen and de Jong considered the multiple regression of relative fitness, w , as a function of z , A , and E ,

$$w = \alpha + \beta_z z + \beta_A A + \beta_E E + \epsilon \quad (20.7a)$$

The partial regression coefficients (β) represent the expected change in fitness when holding the other variables constant (LW Chapter 8). For example, β_z is the expected change in fitness from a unit change in the phenotype, z , holding the other variables (A and E) constant. In particular, if selection is *entirely* based on phenotypic value, then $\beta_A = \beta_E = 0$, because once we have controlled for z , A and E will have no effect on fitness. As shown by Queller (1992a), the condition for this to occur is that the partial covariances (given z) of breeding value and fitness, and of environmental value and fitness, are both zero,

$$\sigma(A, w \mid z) = \sigma(E, w \mid z) = 0 \quad (20.7b)$$

We return to this observation in the next section. The notation $\sigma(x, y \mid z)$ is used to remind the reader that the partial covariance of x and y (given z) can be *different* from $\sigma(x, y \mid z)$, which is the covariance of x and y conditional on z (see Example 6.8).

A notational aside is that we use β for the *partial* regression coefficients with respect to fitness (a special case of which is β_i , the selection gradient on trait i in the multivariate breeder's equation, e.g., Equation 20.1a), and we use b in the next section for the slopes of the *univariate* fitness regressions based on either A , E , or z separately. For example, for the univariate regression $w = 1 + b_z z + \epsilon$, the regression slope is $b_z = \sigma(z, w)/\sigma_z^2$, while β_z denotes the partial regression slope on fitness when A and E are also included (Equation 20.7a). As developed in the next section, comparing the appropriate univariate (b) and partial (β) regression slopes provides information on whether unmeasured variables are potentially influencing response.

From multiple regression theory (LW Chapter 8), the partial regression coefficients in Equation 20.7a satisfy the matrix equation

$$\begin{pmatrix} \sigma(w, z) \\ \sigma(w, A) \\ \sigma(w, E) \end{pmatrix} = \begin{pmatrix} S \\ R \\ \sigma(w, E) \end{pmatrix} = \begin{pmatrix} \sigma_z^2 & \sigma(z, A) & \sigma(z, E) \\ \sigma(z, A) & \sigma_A^2 & \sigma(E, A) \\ \sigma(z, E) & \sigma(E, A) & \sigma_E^2 \end{pmatrix} \begin{pmatrix} \beta_z \\ \beta_A \\ \beta_E \end{pmatrix} \quad (20.8a)$$

The left-most vector contains the covariances between relative fitness, w , and the predictor variables (z , A , and E), with $S = \sigma(w, z)$ following from the Robertson-Price identity

(Equation 6.10) and $R = \sigma(w, A)$ from Robertson's secondary theorem (his 1966 version; Equation 6.25a). The 3×3 matrix on the right-hand side of Equation 20.8a is the variance-covariance matrix for the three predictor variables, where the covariance

$$\sigma(z, A) = \sigma(A + E + e_s, A) = \sigma_A^2 + \sigma(E, A) \quad (20.8b)$$

In a similar fashion, one can show that $\sigma(z, E) = \sigma_E^2 + \sigma(E, A)$. Using these identities, and considering the first two rows of Equation 20.8a after multiplying out the matrix product, returns the within-generation change as

$$\begin{aligned} S &= \sigma_z^2 \beta_z + \sigma(z, A) \beta_A + \sigma(z, E) \beta_E \\ &= \sigma_z^2 \beta_z + [\sigma_A^2 + \sigma(E, A)] \beta_A + [\sigma_E^2 + \sigma(E, A)] \beta_E \\ &= \sigma_z^2 \beta_z + \sigma_A^2 \beta_A + \sigma_E^2 \beta_E + \sigma(E, A) (\beta_A + \beta_E) \end{aligned} \quad (20.9a)$$

and the response as

$$\begin{aligned} R &= \sigma(A, z) \beta_z + \sigma_A^2 \beta_A + \sigma(E, A) \beta_E \\ &= [\sigma_A^2 + \sigma(E, A)] \beta_z + \sigma_A^2 \beta_A + \sigma(E, A) \beta_E \\ &= \sigma_A^2 \beta_z + \sigma_A^2 \beta_A + \sigma(E, A) (\beta_z + \beta_E) \end{aligned} \quad (20.9b)$$

If there are no genotype-environment correlations [$\sigma(E, A) = 0$], then

$$S = \sigma_z^2 \beta_z + \sigma_A^2 \beta_A + \sigma_E^2 \beta_E \quad (20.10a)$$

and

$$R = \sigma_A^2 (\beta_z + \beta_A) \quad (20.10b)$$

It is worth noting the connection between the expression for S from Equation 20.10a (based on following a single focal trait) and Equation 20.1a, where the selection differential on a focal trait is expressed in terms of direct selection on that trait (β_1) plus indirect selection from a correlated trait under selection ($\beta_2 \neq 0$). If we equating the two equations, we obtain

$$S = \sigma^2(z_1)\beta_1 + \sigma(z_1, z_2)\beta_2 = \sigma_z^2 \beta_z + \sigma_A^2 \beta_A + \sigma_E^2 \beta_E \quad (20.11a)$$

where trait 2 (with a value of z_2) is the unmeasured correlated trait and trait 1 (with a value of $z_1 = z$) is the focal trait. In the notation of Equation 20.1a, $\sigma^2(z_1)\beta_1 = \sigma_z^2 \beta_z$, giving

$$\sigma(z_1, z_2)\beta_2 = \sigma_A^2 \beta_A + \sigma_E^2 \beta_E \quad (20.11b)$$

Writing $z_1 = A + E$, we have

$$\sigma(z_1, z_2)\beta_2 = \sigma(A + E, z_2)\beta_2 = \sigma(A, z_2)\beta_2 + \sigma(E, z_2)\beta_2 \quad (20.12a)$$

If we match the terms in Equations 20.11b and 20.12a,

$$\sigma(A, z_2)\beta_2 = \sigma_A^2 \beta_A \quad \text{and} \quad \sigma(E, z_2)\beta_2 = \sigma_E^2 \beta_E \quad (20.12b)$$

Under the formulation for S given by Equation 20.9a, selection on any phenotypically correlated traits appears as a nonzero value of β_A (if the phenotypic correlations are, at least in part, due to correlated breeding values) and/or β_E (if the correlations are due, at least in part, to shared environmental values). Turning to the response, Equation 20.9b is much more general than the single correlated-trait expression given by Equation 20.1b, as β_A and β_E encompass all of the effects of any genetically and/or phenotypically correlated traits.

Further insight into the generalized response when no genotype-environment correlations are present follows if we first rearrange Equation 20.10a to isolate $\sigma_z^2 \beta_z$ and then multiply both sides of Equation 20.10a by h^2 , which yields

$$h^2 \sigma_z^2 \beta_z = \sigma_A^2 \beta_z = h^2 [S - (\sigma_A^2 \beta_A + \sigma_E^2 \beta_E)] \quad (20.13a)$$

Substituting this expression for $\sigma_A^2 \beta_z$ into Equation 20.10b yields

$$R = h^2 S + \sigma_A^2 (1 - h^2) \beta_A - h^2 \sigma_E^2 \beta_E \quad (20.13b)$$

Any extra (positive) selection on additive genetic values, $\beta_A > 0$ (due to selection on genetically correlated traits), inflates the selection response over the value predicted by the breeder's equation, while extra (positive) selection on environmental values ($\beta_E > 0$) decreases the response. The response is similarly decreased when $\beta_A < 0$.

Finally, following this same approach, Equations 20.9a and 20.9b yield a more general response (when $\sigma(E, A) \neq 0$) of

$$R = h^2 S + \sigma_A^2 (1 - h^2) \beta_A - h^2 \sigma_E^2 \beta_E + \sigma(E, A) [\beta_z - h^2 \beta_A + (1 - h^2) \beta_E] \quad (20.14)$$

These expressions can be further simplified if selection acts only on the phenotype of the character being considered. In this case, $\beta_A = \beta_E = 0$, and Equation 20.9a reduces to $S = \sigma_z^2 \beta_z$, implying that $\beta_z = S/\sigma_z^2$. Substituting these values into Equation 20.9b gives the response as

$$R = \beta_z [\sigma_z^2 + \sigma(E, A)] = \left(h^2 + \frac{\sigma(E, A)}{\sigma_z^2} \right) S \quad (20.15a)$$

which (as expected) reduces to the breeder's equation when there is no genotype-environment correlation. As discussed in Chapter 15, unless the correlation between E and A is perfect, the component of response from $\sigma(E, A)$ is transient, decaying to zero once selection stops.

Finally, these expressions provide insight into a key difference between artificial and natural selection. Under artificial selection, it is generally assumed that individual fitness is entirely based on the phenotype of the character of interest, specifically those phenotypes chosen by the breeder. In this case, the partial regression coefficients of fitness on genotype and environmental values are zero, as the phenotype entirely determines fitness. In natural populations, however, we do not have this luxury, and another possibility is that there is no natural selection on the character of interest (i.e., its phenotype, by itself, has no effect on fitness, meaning that $\beta_z = 0$), but rather that selection occurs on characters correlated with the one we are following. If these traits under selection are only connected to the focal trait through its breeding value (i.e., there is no environmental correlation between characters), then $\beta_A \neq 0$ while $\beta_z = \beta_E = 0$. In this case, using Equation 20.9a to express β_A in terms of S returns the response as

$$R = \beta_A \sigma_A^2 = S \left(\frac{\sigma_A^2}{\sigma_A^2 + \sigma(E, A)} \right) \quad (20.15b)$$

which reduces to $R = S$ in the absence of a genotype-environment correlation for the focal trait. The reason for this strong response is that (in this extreme setting) all of the selection is on the breeding value of the trait. With selection on phenotypes (the breeder's equation), only a fraction (h^2) translates into selection on breeding values.

A final possibility is that the only correlation between features influencing fitness and our focal character is through shared environmental effects, giving $\beta_E \neq 0$, while $\beta_A = \beta_z = 0$. In this case, using Equation 20.9b, the response becomes

$$R = \beta_E \sigma(E, A) = S \left(\frac{\sigma(E, A)}{\sigma_E^2 + \sigma(E, A)} \right) \quad (20.15c)$$

which equals zero unless a genotype-environment correlation exists. Again, in the absence of a perfect correlation between E and A , this response is transient (Chapter 15).

Additional Complications From Environmental Change

The above analysis considered the complications from uncontrolled, but static, environmental effects. A further layer of complexity arises when the environment (more formally, the distribution of possible environments) changes from year to year. First, the target of selection may radically change from one year to the next (e.g., Example 20.2). The significance of such temporal variation in selection remains an unresolved question. Siepielski et al. (2009) claimed that it is rather common and that changes in sign can be expected. Conversely, a reanalysis of the Siepielski et al. dataset by Morrissey and Hadfield (2012) concluded that the strength of directional selection in these studies is actually remarkably consistent after accounting for sampling variation. A related question is whether evolution is largely shaped by relatively rare, but major, events, (e.g., Example 20.2; Marrot et al. 2017), or rather by more gradual, but constant, pressures with less temporal variation.

A second complication is that a major shift in the environment can result in a shift in the trait mean even in the absence of any genetic change. As we will see later, a deterioration in the environment can mask significant underlying genetic change, leading to the appearance of stasis if the response and environmental change are in opposite directions. Finally, changes in the environment can result in changes in components of genetic (and environmental) variance and hence in h^2 .

IS A FOCAL TRAIT THE DIRECT TARGET OF SELECTION?

Causality—wherein the phenotypic value of a focal trait is the sole target of selection—is a critical assumption when applying the breeder’s equation to natural populations. With multiple traits, causality means that the covariance of the focal traits with fitness is entirely due to the phenotypic values of that set of focal traits. As we have seen, however, an observed selection differential can be generated by direct selection on a trait, direct selection on phenotypically correlated traits, an environmental covariance between the focal trait and fitness, or a combination of all of these (Equations 20.1a and 20.9a). One approach to control for phenotypically correlated traits is to include them in the analysis and then compute the vector, $\beta = \mathbf{P}^{-1}\mathbf{S}$, of selection gradients (Equation 13.25a; Chapter 30). However, how does one ascertain if all relevant traits are included in the analysis? Many missing factors that are assumed to be traits could in fact be environmental features that influence both the focal trait and fitness, some (or all) of which could easily be overlooked in even the most careful analysis. One approach to assess causality (initially suggested by Rausher and Simms 1989; Queller 1992a; and Rausher 1992) is intimately connected with Robertson’s secondary theorem of natural selection (Chapter 6). If the predicted selection response using Robertson’s theorem is consistent with that from the breeder’s equation, meaning that $\sigma(A_z, w) \simeq h^2 S$, one can have significantly increased confidence that the phenotypic value of the focal trait is indeed the target of selection. We refer to this basic strategy, and its variants, as **Robertson consistency tests**. This strategy can also involve a comparison of the fraction of the selection differential that is associated with a trait’s breeding versus environmental values (more formally, the latter is the residual trait value following the removal of its breeding value) and whether either of these differentials is inconsistent with selection based solely on the phenotypic value, z , of the focal trait.

What is the advantage of a consistency test versus simply comparing the realized response in a natural population with its prediction from the breeder’s equation? A lack of fit between observed and predicted response, by itself, is not informative as to which assumptions underlying the breeder’s equation failed. By contrast, if a consistency test fails, this strongly suggests that selection is acting on more than just the phenotype of the focal trait or traits.

Robertson’s Theorem: Response Prediction Without Regard to the Target of Selection

Recall from Chapter 6 that the breeder’s equation is not the only expression for predicting the selection response (Table 6.1). Exact (but largely unusable) expressions follow from Price’s

theorem (Equations 6.8, 6.39, and 6.40). Under the assumption that parental breeding values are good predictors of the mean trait value of their offspring, Robertson's (two) secondary theorems of natural selection (Equations 6.24a and 6.25a) provide alternative expressions for the selection response.

As discussed in Chapter 6, there is some confusion in the literature on the secondary theorem, as Robertson actually suggested two slightly different versions. Robertson (1966a) suggested that $R = \sigma(A_z, w)$, namely, that response in a specific trait is equal to the covariance between the breeding value of that trait (A_z) and relative fitness (w), while later (Robertson 1968) he suggested that $R = \sigma(A_z, A_w)$, where relative fitness, w , is replaced by its breeding value, A_w . The relationship between the 1966 and 1968 versions follows (Equation 6.25c) by noting

$$\sigma(A_z, w) = \sigma(A_z, A_w + e_w) = \sigma(A_z, A_w) + \sigma(A_z, e_w)$$

showing that while the 1966 version is more general, the two are equal when $\sigma(A_z, e_w) = 0$. There is no reason to suggest that this covariance should generally be zero, as it simply states that there is a covariance between the residual component of fitness (once the effect of the breeding value of fitness has been removed) and the breeding value of the trait itself.

Example 20.4. One of the earliest applications of Robertson's theorem to natural populations examined mean nestling weight and offspring survival in great tits (*Parus major*) (van Noordwijk 1988). The key idea exploited by van Noordwijk was to consider two different covariances involving an individual's nestling weight, z . The first, $\sigma(z, w)$, was with its own survival (standardized by mean survival of the population to obtain a relative fitness, w). From the Robertson-Price identity (Equation 6.10), this is simply the selection differential, S , on nestling weight. With an estimate of h^2 for nestling weight, the expected responses of $R = h^2 S$ under the breeder's equation are given in the table below.

In the same study van Noordwijk also considered the covariance of parental nestling weight with the survival of its offspring. In the absence of any shared environmental effects, the covariance between one trait in a parent (nestling weight) and a second trait in its offspring (offspring survival) is through the breeding value of the parental trait. He examined the difference between the mean weight of all parents and the mean weight of parents who had surviving offspring. While not stated as such by van Noordwijk, this selection differential (on the parents) conditioned on the survival of their offspring is an estimator of $\sigma(A_z, w)$, and hence this is the predicted response under Robertson's theorem. The results for 1975 to 1978 are in the final column in the following table.

Year	S	h^2	$R = h^2 S$	$R = \sigma(A_z, w)$
1975	0.24	0.38	0.07	0.00
1976	0.68	0.47	0.32	0.03
1977	0.16	0.26	0.04	0.06
1978	0.53	0.29	0.15	0.05
mean	0.40	0.35	0.14	0.035

The breeder's equation significantly overpredicts the selection response relative to Robertson's theorem, suggesting that factors correlated with nestling weight also influence fitness.

Robertson Consistency Tests

Queller (1992a), Rausher (1992), and Morrissey et al. (2010, 2012) all suggested that an analysis that estimates the required parameters for both the breeder's equation and Robertson's theorem can provide insight on whether the breeder's equation applies to a focal trait in a natural population (Example 20.4). If the two estimates of response agree, this suggests that the phenotypic value, z , of the focal trait is largely causative as the target of selection.

If the predictions are significantly different, other forces beside direct selection on z are involved. Note that this analysis checks the prediction under the *static environment assumption*. Generational changes in E (e.g., shifting selection targets, shifts in trait mean from entirely environmental factors, or changes in variance components due to $G \times E$) can all cause Robertson's theorem (as well as the breeder's equation) to fail. Likewise, if the standard breeding-value model is not a good approximation of the genetics of transmission, both Robertson's theorem and the breeder's equation can fail (Chapter 6).

Under what conditions should the breeder's equation and Robertson's theorem agree? If we use the more general, 1966, version of Robertson's theorem, the two predicted responses are equal when

$$R = h^2 S = \frac{\sigma^2(A_z)}{\sigma^2(z)} \sigma(z, w) = \sigma(A_z, w) \quad (20.16a)$$

Rearranging the last equality yields the result of Queller (1992a; also Hadfield 2008)

$$\frac{\sigma(z, w)}{\sigma^2(z)} = \frac{\sigma(A_z, w)}{\sigma^2(A_z)} \quad (20.16b)$$

The left-hand side of Equation 20.16b is the slope (b_z) of the univariate linear regression of w on trait phenotypic value (z), while the right-hand side is the slope (b_A) of the univariate regression of w on the breeding value (A_z) of the trait. If $b_z \simeq b_A$, then the breeder's equation is likely to hold (subject to the assumptions of a static environment and the infinitesimal model for inheritance). However, if b_z and b_A are significantly different, additional targets of selection besides the phenotypic value of the focal trait influence the selection response of the focal trait. This test hinges on the ability to obtain an unbiased estimate of $\sigma(A_z, w)$, a subject discussed in detail below. Finally, note that when Equation 20.16b is satisfied, this expression can be rearranged to yield

$$h^2 \sigma(z, w) = \sigma(A_z, w) \quad (20.16c)$$

Rausher's Consistency Criteria

Rausher (1992) obtained a multivariate version of Equation 20.16b by equating the vector of responses, \mathbf{R} , under Robertson's theorem with that predicted from the multivariate breeder's equation (Equation 13.23b)

$$\mathbf{R} = \sigma(\mathbf{A}_\mathbf{Z}, w) = \mathbf{G}\mathbf{P}^{-1}\mathbf{S} \quad (20.17a)$$

where the i th component of the vector $\sigma(\mathbf{A}_\mathbf{Z}, w)$ is $\sigma(A_i, w)$, the covariance between the breeding value of trait i and relative fitness (Equation 6.25a; the 1966 version of Robertson's theorem). If we multiply both sides by \mathbf{G}^{-1} and recall the multivariate version of the Robertson-Price identity ($\mathbf{S} = \sigma(\mathbf{z}, w)$; Equation 6.10), Equation 20.17a can be restated as

$$\mathbf{G}^{-1}\sigma(\mathbf{A}_\mathbf{Z}, w) = \mathbf{P}^{-1}\sigma(\mathbf{z}, w) \quad (20.17b)$$

which is **Rausher's consistency condition** and the multivariate version of Equation 20.16b. This is a slight generalization of Rausher's (1992) original result, which assumed the 1968 version of Robertson's theorem, with $\sigma(\mathbf{A}_\mathbf{Z}, A_w)$ replacing $\sigma(\mathbf{A}_\mathbf{Z}, w)$. Notice in Equation 20.17b that $\mathbf{G}^{-1}\sigma(\mathbf{A}_\mathbf{Z}, w)$ is the vector of coefficients for the regression of relative fitness on the vector of trait breeding values, while $\mathbf{P}^{-1}\sigma(\mathbf{z}, w)$ is the vector of coefficients for the phenotype-fitness regression. Rausher's consistency condition is that the coefficients for the regression of fitness are the same (for a given trait) when one uses breeding values in place of phenotypic values.

For a univariate trait, Equation 20.17b reduces to Equation 20.16b, in which case Equation 20.16c immediately yields

$$h^2 S_z = S_A \quad (20.18)$$

namely, the selection differential, $S_A = \sigma(A, w)$, based on the breeding value of a trait is simply h^2 times the phenotypic selection differential, $S_z = \sigma(z, w)$. Although Rausher's

condition (Equation 20.17b) directly leads to Equation 20.18, the formal regression test he proposed (Rausher and Simms 1989; Rausher 1992) is slightly different (Equation 20.20), and thus Equation 20.18 is referred to as **Postma's test** (Postma 2006).

Rausher framed his consistency test in terms of the relative strengths of selection on the components of the focal trait's phenotypic value, namely, its breeding (A) and environmental (E) values (more formally, the latter is the residual value in z after A is removed, meaning that E can also include nonadditive genetic terms). Consider the slopes, b_z and b_A , of the univariate regressions of relative fitness on phenotype, z , and breeding value, A . When Equation 20.16b holds, then

$$b_A = b_z \quad (20.19a)$$

which is simply the univariate version of the condition given by Equation 20.17b. Similarly, for the univariate regression of fitness on E , $b_E = \sigma(E, w)/\sigma_E^2$. If we note that $\sigma^2(A)/h^2 = \sigma^2(z)$ and $\sigma_E^2/(1 - h^2) = \sigma^2(z)$, we can relate the slope, b_z , of the univariate regression of fitness on z with the corresponding univariate regression slopes b_A and b_E (based on A and E , respectively) as follows:

$$\begin{aligned} b_z &= \frac{\sigma(w, z)}{\sigma^2(z)} = \frac{\sigma(w, A) + \sigma(w, E)}{\sigma^2(z)} \\ &= \frac{\sigma(w, A)}{\sigma^2(A)} h^2 + \frac{\sigma(w, E)}{\sigma^2(E)} (1 - h^2) \\ &= b_A h^2 + b_E (1 - h^2) \end{aligned} \quad (20.19b)$$

When the identity given by Equation 20.16b is satisfied, then $b_z = b_A$ (Equation 20.19a), and Equation 20.19b becomes

$$b_z = b_A = b_A h^2 + b_E (1 - h^2), \quad \text{or} \quad b_A (1 - h^2) = b_E (1 - h^2)$$

and hence $b_z = b_E = b_A$ (provided $\sigma[A, E] = 0$).

This observation suggests the **Rausher-Simms equality test** (Rausher and Simms 1989; Rausher 1992). Here, one computes the multiple regression of fitness on both the trait breeding value, A , and the residual deviation, E , namely,

$$w = 1 + \beta_A A + \beta_E E + e \quad (20.20)$$

If z is the sole target of selection, then $\beta_A = \beta_E$, which can be tested in a straightforward fashion using standard results from regression theory (LW Chapter 8), assuming that A and E are known. A closely related test queries whether β_A is significantly different from zero, as this indicates that at least *some* of the selection is translated onto the breeding value of the focal trait. The equality test is more stringent, asking whether selection is *strictly* a function of the phenotypic value of the focal trait, no matter how that phenotype is obtained (e.g., individuals with high breeding value versus high environmental deviation, but the same phenotype, experience the same amount of selection).

The reader might be inclined to assume that when $\beta_A \neq \beta_E$, the component with the larger partial regression coefficient experienced stronger selection. To see that this reasoning can be misleading, suppose that phenotypic selection influences both β_A and β_E by 0.4 (a unit change in z changes w by 0.4). Assume also that additional selection on A (over and above that through selection on z , such as on a genetically correlated, but unmeasured, trait) adds -0.35 , and additional selection on E (for example, a specific environmental factor improving fitness beyond that achieved through direct selection on trait value z) adds 0.05, resulting in $\beta_A = 0.05$ and $\beta_E = 0.45$. While this superficially suggests that there is more selection on E , the additional direct component of selection (beyond that due to z) is actually much stronger on A .

The $\beta_A = \beta_E$ and $\beta_A \neq 0$ tests were suggested before the application of mixed models to natural populations, leaving the critical issue of how to estimate breeding values

unresolved. Focusing on plants, Rausher and Simms (1989) and Stinchcombe et al. (2002) replicated genotypes (when clones were available) or sibs (half, full, or selfed) over environments, estimating the genotypic value of a clone by its average over the sampled environments, and likewise assigning all sibs the same breeding value, namely, their family mean. Because sib (or clone) means replicated over environments are used as estimates of the breeding or genotypic values, there are different sample sizes associated with β_A (number of families) and β_E (number of individuals). Stinchcombe et al. (2002) discussed how to deal with this issue. Using the regression approach given by Equation 20.20, Stinchcombe et al. and Scheiner et al. (2002) compared estimates of selection for six plant species grown on experimental plots (and hence under stricter environmental control than expected for populations in nature). Even in these settings, these authors found that a significant fraction (around 25%) of the traits they measured appeared to show selection on factors other than z (β_A was significantly different from β_E). While this bias rarely resulted in a change in sign, it often significantly impacted the estimated strength of selection directly on z .

While tests based on sibs or replicated genotypes were an important conceptual advance, their actual utility was rather limited. In addition to the logistical issues involved in implementing such a design, this approach *critically* depends upon the randomization of genotypes over environments. The estimated breeding value assigned to all members of a sibship is their family effect, which is a function of the mean breeding value of their parents but also of maternal effects, dominance (for full sibs), and common-family environmental values. If environments are not randomized, a common-family environment could influence both the trait and fitness, and this would appear in the family effect. In this case, β_A could be significantly different from zero, but as a reflection of selection on common-family environmental values rather than on breeding values. A further complication with full sibs is that they potentially share an additional covariance of $\sigma_D^2/4$, which could be loaded into β_A even when environments are randomized.

The realization in the early 2000s that mixed models (Chapter 19; LW Chapters 26 and 27) could return estimates of trait breeding values for *individuals* led to a brief period (with a flurry of publications) during which BLUP-estimated breeding values were used to test for associations between trait breeding value and fitness (e.g., Kruuk 2004). While potentially much more powerful than clone or family studies (using individual, rather than group, breeding values), as we detail below, given the structure of most natural pedigrees, BLUP-estimated breeding values have a strong environmental bias, and were eventually realized to be highly unreliable for these sort of studies (Postma 2006; Postma and Charmantier 2007; Hadfield 2008; Hadfield et al. 2010; Wilson et al. 2010). However, while estimates of *individual* breeding values may be suspect, the power of a mixed-model analysis can still be used through direct REML estimates of *population*-level parameters, such as either $\sigma(A_z, A_w)$ or $\sigma(A_z, w)$. By directly estimating such covariances under a bivariate animal model, the pitfalls of using predicted breeding values of individuals can be avoided (Hadfield et al. 2010). We will examine all of these issues in detail shortly.

Morrissey et al.'s Consistency Criteria

An alternative expression for consistency can be obtained as follows. Writing

$$\sigma(z, w) = \sigma(A_z + E_z, A_w + e_w) = \sigma(A_z, A_w) + \sigma(E_z, e_w) + \sigma(A_z, e_w) + \sigma(E_z, A_w)$$

where $E_z = z - A_z$ is the residual trait value after the removal of the breeding value, with $e_w = w - A_w$ similarly defined. Likewise noting that $\sigma(A_z, w) = \sigma(A_z, A_w) + \sigma(A_z, e_w)$, the consistency condition given by Equation 20.16b becomes

$$\frac{\sigma(A_z, A_w) + \sigma(E_z, e_w) + \sigma(A_z, e_w) + \sigma(E_z, A_w)}{\sigma^2(A_z) + \sigma^2(E_z)} = \frac{\sigma(A_z, A_w) + \sigma(A_z, e_w)}{\sigma^2(A_z)} \quad (20.21a)$$

which can be rearranged to

$$1 + \frac{\sigma(E_z, e_w) + \sigma(E_z, A_w)}{\sigma(A_z, A_w) + \sigma(A_z, e_w)} = 1 + \frac{\sigma^2(E_z)}{\sigma^2(A_z)}$$

implying

$$\frac{\sigma(E_z, e_w) + \sigma(E_z, A_w)}{\sigma(A_z, A_w) + \sigma(A_z, e_w)} = \frac{\sigma^2(E_z)}{\sigma^2(A_z)}$$

Finally, this rearranges to yield an alternative consistency condition

$$\frac{\sigma(E_z, e_w) + \sigma(E_z, A_w)}{\sigma^2(E_z)} = \frac{\sigma(A_z, A_w) + \sigma(A_z, e_w)}{\sigma^2(A_z)} \quad (20.21b)$$

By assuming Robertson's 1968 version, with $\sigma(A_z, e_w) = 0$, and also that $\sigma(E_z, A_w) = 0$, this reduces to

$$\frac{\sigma(E_z, e_w)}{\sigma^2(E_z)} = \frac{\sigma(A_z, A_w)}{\sigma^2(A_z)} \quad (20.21c)$$

which is the **Morrissey consistency condition** (Morrissey et al. 2010, 2012).

Example 20.5. As detailed shortly, mixed models can be used to estimate the variance components required for Equation 20.21c. This was done by Morrissey et al. (2012), who used a bivariate animal model (the focal trait plus fitness as the second trait). They examined four morphological traits in Soay sheep (*Ovis aries*) on the island of St. Kilda. Body size was of special interest, because estimates of S and h^2 suggested a positive response using the breeder's equation, yet the sheep were, if anything, getting smaller. By contrast, the expected response under the secondary theorem (1968 version), $R = \sigma(A_z, A_w)$, was slightly negative (but not significantly different from zero). Using estimates of the components of Equation 20.21c showed that the two sides of this consistency condition were significantly different ($p = 0.048$). Thus, the failure of the selection response to match that predicted by the breeder's equation is likely a result of unmeasured factors that do not influence selection on the breeding value, but upwardly bias estimates of the amount of selection on the phenotype.

The Breeder's Equation Versus the Secondary Theorem

The elegance of the breeder's equation is that it fully separates ecology (S) from genetics (h^2). Queller (1992a) noted that when Equation 20.16b is satisfied, this separation occurs. More formally, **Queller's separation condition** is that the partial covariance (Example 6.8) of A and w given z is zero, $\sigma(A, w | z) = 0$ (Equation 20.7b; which also implies $\sigma(E, w | z) = 0$; see Queller 1992a). This is simply an alternative way of interpreting Equation 20.16b: that the residual values of A and w (following their separate regression on z) are uncorrelated (e.g., Equation 6.31a). Thus, after accounting for the phenotypic value, there is no residual correlation between breeding value and fitness. (As a technical aside, note that when the separation condition holds, Heywood's spurious response term, Equation 6.31a, is zero.)

In contrast, the secondary theorem fully *confounds* (rather than separates) selection and genetics, as the covariance of A (genetics) with w (ecology) is a combined, rather than a separable, function of these two features. Further, the secondary theorem says absolutely nothing about the nature of selection on the *phenotype*. Rather, it simply does the accounting and asks what fraction of selection translates into direct selection on the breeding value. The secondary theorem is thus largely about genetics (van Tienderen and de Jong 1994; Morrissey et al. 2012) and rather devoid of ecology. As such, it is generally expected to be more predictive than the breeder's equation, as it ignores the actual target of selection (but, as mentioned, can still fail). When the two predicted responses (from the breeder's equation and Robertson's theorem) agree, we can have some confidence that we have found a causal target of selection (z), implying that the breeder's equation is not significantly compromised by selection on unmeasured variables.

Which approach, the breeder's equation, $R = h^2 S = \sigma^2(A)\beta$, or the secondary theorem, $R = \sigma(A_z, w)$, should be used by an investigator? In large part, this depends on the question

being asked. In a conservation biology setting, such as when trying to predict if a species has sufficient genetic variation to withstand a major environmental change, selection response is the major issue of concern, as opposed to the actual targets of selection. An example of this was provided by Etterson and Shaw (2001), who used Robertson's theorem to show that there were significant constraints in response to selection from climate change in a native annual legume from the Great Plains region. Antagonistic genetic correlations among the traits under selection reduced the amount of usable additive variation in the direction favored by selection. While knowing the targets of selection (i.e., those particular traits favored by selection) is always of interest, the more pressing concern for Etterson and Shaw was whether the population could mount a successful selection response to the pressures generated by climate change. Robertson's theorem can address this question without any bias from unmeasured characters influencing the focal traits by examining if there is a sufficiently high covariance between the trait breeding value and relative fitness to generate some required amount of response. Conversely, the targets of selection are generally of great interest to ecologists and evolutionary biologists, and the joint use of the breeder's equation and Robertson's theorem can help clarify the importance of candidate traits.

APPLYING MIXED MODELS TO NATURAL POPULATIONS: BASICS

Recall from Chapter 19 that mixed models offer a very flexible platform for genetic analysis in the presence of multiple fixed effects and multigenerational relatives. In particular, the general **animal model**, so called because of its initial focus on estimating the breeding values of a single trait in a collection of individual animals (originally in dairy cattle),

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}_a\mathbf{a} + \sum_{i=1}^k \mathbf{Z}_i \mathbf{u}_i + \mathbf{e} \quad (20.22a)$$

has been widely used in animal breeding since the 1970s. As detailed in Chapter 19, $\boldsymbol{\beta}$ is the vector of unknown fixed effects, \mathbf{a} is the random vector of breeding values, \mathbf{e} is the random vector of residuals, and the \mathbf{u}_i denote k other possible vectors of random effects. These additional random effects can accommodate permanent environmental effects under a repeated-records design, common family or maternal effects, and other factors that can complicate the residual error structure (Chapters 19 and 22).

In Equation 20.22a, \mathbf{y} is an observed vector of trait values, \mathbf{X} is the design matrix for the fixed effects, and \mathbf{Z}_a and the \mathbf{Z}_i are incidence matrices for the random effects. The power of a mixed model is its ability to borrow information on random effects from correlated observations. This is done through their covariance structure, which determines the strength of additional information provided by correlated observations. The vector, \mathbf{a} , of breeding values has a covariance structure determined by the (assumed known) relationship matrix, \mathbf{A} , and it is assumed that \mathbf{a} and \mathbf{e} are uncorrelated, so

$$\begin{pmatrix} \mathbf{a} \\ \mathbf{e} \end{pmatrix} \sim \begin{pmatrix} \mathbf{0} \\ \mathbf{0} \end{pmatrix}, \begin{pmatrix} \sigma^2(\mathbf{A}) \mathbf{A} & \mathbf{0} \\ \mathbf{0} & \sigma_e^2 \mathbf{I} \end{pmatrix} \quad (20.22b)$$

where $\sigma^2(\mathbf{A})$ denotes the additive-genetic variance of the trait. Similar assumptions are made about the covariance structures for any additional random effects (Chapters 19 and 22), and the assumed covariance structure in combination with Equation 20.22a fully specify the model.

Variance components are estimated by REML (Chapter 19; LW Chapter 27), which are then used to estimate the vector, $\hat{\mathbf{a}}$, of **predicted breeding values (PBVs)** using BLUP (Chapter 19). These are also called **estimated breeding values (EBVs)** in the literature, but our preference is to use *predicted* for random effects and *estimated* for fixed effects. As we will show, while REML estimates of variances and covariances are appropriate when using animal models in wild populations, using individual PBVs is generally not

appropriate unless performed within an appropriate Bayesian framework. Indeed, Hadfield et al. (2010) said they would “discourage future use of BLUP as an inferential tool in the fields of ecology and evolutionary biology.” The reasoning here, and solutions to some of the issues, are examined in the next major section. First, however, we consider the limitations of constructing an animal model for a wild population, with analysis issues examined later.

Animal-model Analysis in Natural Populations: Overview

Given sufficiently large, complete, and accurate pedigrees, animal models can help separate genetic from environmental trends (Chapter 19), and their ability to estimate *individual* breeding values seemed to offer the possibility of conducting more accurate Robertson consistency tests. Given these features, it is surprising that the application of mixed models to natural populations was rather recent, starting with suggestions by Shaw (1987) and then by Konigsberg and Cheverud (1992) and Cheverud and Dittus (1992), who applied them to free-living primate populations. These papers went somewhat unnoticed, and a second wave of applications to ungulate mammals and nesting birds started in 1999 (Réale et al. 1999), and has been a rapid growth industry ever since (Kruuk 2004; Kruuk and Hadfield 2007; Postma and Charmantier 2007; Kruuk and Hill 2008; Clutton-Brock and Sheldon 2010; Hadfield et al. 2010; Wilson et al. 2010; Postma 2014).

The animal model has generally been quite successful in the analysis of artificial selection experiments and breeding programs (Chapter 19). However, natural populations differ in fundamental ways from these more controlled settings, leading to a number of design issues (Table 20.1). First, in natural populations, the relationship matrix must be ascertained indirectly, and this is usually done with a bias toward finding mother-offspring (maternal) links, while missing (or misspecifying) father-offspring (paternal) connections.

Second, artificial selection experiments, and many breeding programs, involve **closed populations**, with little to no immigration from outside sources once selection has started. Further, most (if not all) organisms in the population are included in the analysis. When immigration occurs, it is usually controlled, and hence immigrants can be identified in the pedigree. However, in most natural populations, immigration from outside the study area is generally the norm, which causes serious ascertainment problems. Immigrants potentially bring in a different distribution of breeding values, and sufficiently high immigration rates can remove any signal of local genetic change or falsely create such a signal when none is present. Further, analysis in natural populations is usually based on a somewhat haphazard sample of individuals, rather than information from the entire population (which is often available in artificial selection experiments or commercial-breeding populations).

Finally, an important consequence of the more open structure of natural populations is that the connectedness (number of relatives) is lower, often substantially so, than for breeding programs. The relationship matrices, **A**, from breeding programs tend to be denser than those for natural populations (the former having more nonzero and larger off-diagonal elements than the latter), as most individuals in a breeding-program sample have measured relatives in previous generations. The presence of such measured relatives is *not* ensured for a sample of individuals from a natural population.

To see the significance of a sparse relationship structure, consider an individual that is unconnected to any others in the pedigree. In this setting, that individual’s PBV is simply the estimated heritability times its phenotypic value (adjusted for fixed effects). In the simplest case of a single fixed effect (the mean μ), its PBV is simply $\hat{a} = h^2(z - \mu)$. When an individual has links (via **A**) to other members in the sample, BLUP uses this covariance information to obtain an improved estimate of its PBV, making the latter less dependent on just the individual’s own phenotypic value (which has some environmental influence). In large pedigrees with many links (such as in most breeding programs), this substantial additional information can significantly improve the accuracy of PBVs. In natural populations, the number of links may be far smaller, in which case an individual’s predicted breeding value may be largely determined by its own phenotype alone. In such cases, PBVs can

Table 20.1 Design limitations when applying animal models to natural populations.

The relationship matrix, \mathbf{A} , must be estimated. Pedigree errors result in bias and lower power.
Open population structure. Immigration from outside of the study area complicates the interpretation of model results.
Lack of sufficient size or depth of the sampled pedigree (low connectedness). Low variation in sample relatedness results in low power, potentially confounding parameters of interest.
Lack of power complicates model selection. Low power to detect variance components can complicate results. Interpretations of the key parameters can substantially change over alternative models incorporating different sets of random effects. Such additional effects are often only included when their associated variance components are significant.

be strongly influenced by the environment, a point to which we will return to below. Because of this fragility of individual PBV estimates when pedigree links are sparse, their use is now strongly discouraged in such settings (Postma 2006; Hadfield 2008; Hadfield et al. 2010).

One important observation is that, to date, most estimates of heritability based on mixed-model analyses of wild populations are *lower* than more traditional h^2 estimates based on parent-offspring regressions (Kruuk 2004; Postma 2014). As mentioned in Chapter 19, the *opposite* pattern is expected. This is because heritability under a mixed model is defined as the ratio of the additive variance to the sum of all variance components, with the latter being computed *after* fixed effects (and thus a significant source of variation) have been removed (Wilson 2008). Phrased another way, once the fixed effects have been removed, the sum of all variance components is less than the trait variance, $\sigma^2(z)$, when individuals differ in their fixed effects. Thus, parent-offspring regressions and mixed-model h^2 estimates are looking at slightly different quantities, with the latter estimate expected to be larger. Why does this not seem to be the case?

Åkesson et al. (2008) and de Villemereuil et al. (2013) suggested that one reason for this apparent discrepancy might involve subtle differences in the datasets, with parent-offspring regressions (PO) often using the average values of offspring, while mixed-models (MM) use individual measures, and hence have a higher intrinsic variance. These authors found that when mixed models were run using the offspring mean, parent-offspring and animal-model estimates of heritabilities were very similar, while when they were run using a repeated-measures mixed model (i.e., keeping the individual measures; Chapter 19), heritability estimates were lower.

Biological factors could also be involved. Given that the vast majority of mixed-model estimates are for species with extensive parental care (birds and mammals), part of the difference between MM and PO estimates may arise from a lack of control over maternal effects. Most parent-offspring regressions in the wild involve mother-offspring relationships, confounding direct and maternal effects, which in turn can inflate regression-based estimates of h^2 . Mixed models that include maternal effects remove this bias.

An extension of this general idea is that parents and offspring often share similar environments in natural populations, inflating their phenotypic similarity (Magnussen 1993). Indeed, Stopher et al. (2012) noted that when home-range overlap is included in mixed models, the heritability estimates for several traits in red deer decreased, consistent with the notion that relatives in natural populations share environmental effects. While the potential presence of shared environmental effects is poorly controlled in parent-offspring regressions, they may still not be fully accounted for in mixed models, as the chain of relatives used to estimate the breeding value of a focal individual may still (albeit more weakly) share environmental features due to living in relatively close proximity to each other.

Obtaining the Relationship Matrix: Direct Observation of the Pedigree

The central difficulty in applying the animal model to free-living populations is obtaining the relationship matrix, A , for the measured sample of individuals. One source of information is the **social pedigree** based on field observations, especially for birds and mammals (which to date comprise the majority of BLUP applications to wild populations). If we observe a mother nursing an offspring, we have fairly high confidence that the offspring is from that mother. Assessing paternity is more difficult, however. Again, field observations may be useful, for example, observations of which male visits the nest or appears to be the dominant male in other social settings.

Of course, none of these social observations is foolproof. For example, **intraspecific brood parasitism** occurs when a female lays an egg in the nest of another female. Likewise, even with (apparently) pair-bonded couples, **extra-pair paternities** can occur. The frequency of such extra-pair events is ~15% in the collared flycatcher (*Ficedula albicollis*) population discussed in Example 20.1 (Sheldon and Ellegren 1999), similar to the values for other socially monogamous birds (Firth et al. 2015). Hence, the simple observation of a male helping at the nest does not imply that he is the father. Similarly, it is not guaranteed that the dominant male in a harem sired all of the offspring.

Pedigree errors can be high even in systems with apparently strong control over matings. Visscher et al. (2002) estimated a sire error rate of ~10% for UK dairy cattle, despite the very widespread use of artificial insemination, while Leroy et al. (2011) found rates of 1–9% for dogs, 1–10% for sheep, and 4% for a French cattle population. Recording errors, as well as the ingenuity of organisms searching for mates, should never be underestimated! Because of this intrinsic bias toward determining the mother, pedigrees from wild populations often show an excess of **maternal linkages**. This has implications when maternal effects are present, as the pedigree must contain a sufficient number of **paternal linkages** to disentangle direct effects from maternal effects (Clément et al. 2001; Kruuk 2004).

Obtaining the Relationship Matrix: Marker Data

A second source of information on relatedness is provided by polymorphic molecular markers. Methods estimating ancestry from marker data can be grouped into two categories: those that are hypothesis-driven (e.g., tests for paternity from a pool of candidate males, or for individuals being half- or full-sibs) and those that make no prior assumptions about relatedness. These two approaches can be restated as a focus on categorical **relationships** (assigning pairs of individuals into discrete classes such as parent-offspring, or full- or half-sibs) versus continuous measures of **relatedness** (estimates of the coefficient of coancestry; LW Chapter 7). A number of methods to estimate pairwise relatedness have been proposed (reviewed by Ritland 2000; van de Casteele et al. 2001; Blouin 2003; Garant and Kruuk 2005; Thomas 2005; Csilléry et al. 2006; Oliehoek et al. 2006; Weir et al. 2006; Frentiu et al. 2008; Pemberton 2008; Powell et al. 2010; Sillanpää 2011; Gay et al. 2013; Bérénos et al. 2014; Jensen et al. 2014; Speed and Balding 2015; Conomos et al. 2016; Ackerman et al. 2017; Wang et al. 2017).

At first blush, one might think to simply use one of these methods to estimate the pairwise relatedness between all sampled individuals, substituting these as the elements of A . However, there are numerous problems with this approach. First, there are high sampling variances for these estimates (see the reviews mentioned above). Second, such procedures often result in the molecular-based relationship matrix used to estimate A not being positive-definite (not having all positive eigenvalues; see Appendix 5) and hence it is not a proper covariance matrix (Frentiu et al. 2008). There is also the issue that some pairwise methods may return negative estimates of relatedness for nonrelatives. Although such estimates are often set to zero, doing so introduces a bias akin to that introduced by setting negative variance estimates to zero (Ackerman et al. 2017).

One approach for constructing a marker-based relationship matrix is to ignore more distant relationships that must be inferred solely from molecular markers and instead use markers to confirm (or find) sets of close relatives, such as parent-offspring (Blouin 2003;

Jones and Ardren 2003; Jones et al. 2010; Walling et al. 2010) and sibs (Thomas and Hill 2000; Wang 2004; Wang and Santure 2009; Huisman 2017). Much of the power in a mixed model comes from data on the closest relatives, which justifies an initial focus on detecting and confirming close pedigree linkages. Further, for distant relatives, the sampling (and segregation) variances for relatedness measures can be considerable (Speed and Balding 2015). Early studies using markers to infer paternity or to assign individuals to sibships typically used no more than one or two dozen microsatellite loci. Although these are highly polymorphic markers, and hence have significant power for verifying very recent ancestry (such as first-degree relatives, which share half their alleles IBD), the expected fraction of alleles shared between two relatives with a common ancestor k generations in the past is $(1/2)^{2k-1}$. Relatives with a common ancestor two generations in the past thus share (on average, but with considerable variance) only 1/8 of their alleles IBD, which greatly reduces the power for a relatively small number of markers to detect this degree of ancestry, yet alone more distant relationships.

In cases where there are a modest number of markers, the most powerful approach for reconstructing a natural pedigree is to combine marker data with additional information, such as ranges of specific individuals and their behavior (e.g., apparent position in a dominance hierarchy, and hence the likelihood of being a sire). Hadfield et al. (2006) presented such an analysis, which they set within a Bayesian framework, so that uncertainty in relationship estimates is fully captured in the posterior uncertainty of parameter estimates. In a full Bayesian analysis, information at different levels can inform each other (O'Hara et al. 2008). For example, consider a setting where, based on marker information, individual A is ever so slightly more likely than B to be the father of C. Phenotypic data provide additional information on whether C is closer to A or B, but is ignored in a sequential likelihood analysis (which estimates relationships first and then uses these to estimate genetic parameters), which would use A in this case. Under a Bayesian analysis, this additional phenotypic information will influence the posterior paternity estimates.

In the few cases where (for a natural population) the estimates of a relationship matrix from an explicit pedigree plus marker-information study have been compared to an entirely marker-inferred relatedness matrix, erratic behavior in the estimated variance components has been seen (e.g., Thomas et al. 2002; Coltman 2005; Frentiu et al. 2008; Pemberton 2008). In part, this is likely due to the very low resolution offered by the limited number of markers used in these early studies to estimate relationships. Indeed, using a much larger set of markers (~800 SNPs), Santure et al. (2010) obtained much better behavior over a 20-generation pedigree of a captive zebra finch population. They still, however, recommended using markers to estimate one- or two-generation pedigree links (i.e., sibs, father-offspring), which are then assembled into a pedigree matrix (e.g., connecting grandsons to grandfathers through separately estimated grandfather-to-father and father-to-son linkages), as opposed to simply using the marker relationship matrix directly. As Example 20.6 suggests, this may be less of a limitation when one scores thousands of markers. Lopes et al. (2013) found that roughly 2,000 SNPs worked well when comparing marker- and pedigree-based estimates in pigs, while Rolf et al. (2010) suggested that 2,000 to 10,000 markers would be required to construct reasonable molecularly based pedigrees in cattle. Indeed, Bérénos et al. (2014) obtained very similar heritability estimates using pedigrees that estimated only parent-offspring relationships compared to those based on whole-genome relatedness at ~40,000 SNPs in a wild population of Soay sheep.

Given the potential of very dense marker information to more accurately infer relationships, it has been suggested that most wild populations will soon have the potential to permit an animal-model style analysis, with \mathbf{A} directly estimated from marker information alone (Moore and Kukuk 2002; Gienapp et al. 2017). Does this mean that, in the near future, animal-model analyses will be practical for many, or even most, natural populations? The answer is likely no, as even if \mathbf{A} is estimated with complete accuracy, any analysis is still limited by the *variance among relationships* in the sample (Visscher and Goddard 2015). If the sample lacks sufficient diversity in links between relatives (**low variance in relatedness**), it

will contain little information for an animal-model analysis (Thomas and Hill 2000; Thomas et al. 2002; Csilléry et al. 2006). For example, if one randomly samples a very large population over multiple generations, there is a reasonable expectation that very few, if any, relatives will be found. Although a very large sample might suggest significant power, if the true relationship matrix for the population sample is of the form $\mathbf{A} = \sigma^2(A)(\mathbf{I} + \epsilon \mathbf{B})$, where \mathbf{B} is a matrix of off-diagonal elements (indicating sets of relatives in the sample) and $\epsilon \ll 1$ (meaning that any off-diagonal elements are very small), then practically speaking, the sample consists of unrelated individuals (\mathbf{A} is essentially a diagonal matrix). With little information from relatives, the power of a mixed-model analysis vanishes, as most breeding values are estimated solely from an individual's own phenotype. Balancing this pessimistic view are two studies on free-living fish that spend part of their time in the open ocean, which found sampled individuals to be enriched for close relatives (Thériault et al. 2007; DiBattista et al. 2009).

Example 20.6. We now possess the ability—either through dense SNP chips or by whole-genome sequencing—to score thousands to millions of SNPs, which offers a very simple approach for obtaining the relationship matrix, \mathbf{A} . Given their very low mutation rates, two SNP alleles that are **alike in state (AIS)**, or, equivalently, show **identity by state (IBS)**, can be viewed as also being identical by descent (IBD) with respect to some ancient base population (Speed and Balding 2015), allowing us to compute the coefficient of coancestry, θ_{ij} (LW Chapter 7), directly from the SNP data, and hence the entry $A_{ij} = 2\theta_{ij}$ in the relationship matrix.

The use of dense marker data highlights the important distinction between **pedigree kinship** and **realized kinship** (Wang et al. 2017). The value of θ calculated using a known pedigree (e.g., LW Chapter 7) is the *expected* value of the kinship, given the relationship between two individuals. However, with the exception of clones and parent-offspring pairs (which always shared *exactly* one allele IBD), all other relationships have some *variation* in the fraction of alleles shared about their expected kinship value due to Mendelian sampling (Risch and Lange 1979; Suarez et al. 1979; Stam 1980; Guo 1996; Visscher et al. 2006; VanRaden 2007, 2008; Hill and Weir 2011). Consider outbred full sibs. At any given locus, the probability that a pair shares 0, 1, or 2 IBD alleles is 1/4, 1/2, and 1/4, respectively. In a pedigree approach, all pairwise A_{ij} values among full sibs would be the same (1/2), which is the expectation of 2θ for noninbred full sibs (LW Chapter 7). This is the pedigree kinship. However, there is variation in the actual fraction of shared IBD alleles, so that (for example) sibs 1 and 2 may have a realized value of $2\theta_{12} = 0.55$, while 1 and 3 have a realized value of $2\theta_{13} = 0.42$. Dense SNP data capture this variation in relatedness, giving more accurate weights when using information from relatives (replacing expected values by their actual realizations). This is the basis of the genomic selection method known as **G-BLUP** (genomic-BLUP), wherein a marker-estimated (**genomic relationship**) matrix is used in place of a pedigree relationship matrix for \mathbf{A} to improve the BLUP estimates (e.g., VanRaden 2007, 2008; Hayes et al. 2009; Volume 3 examines this method in detail).

There are a large number of proposed methods that translate SNP data into estimates of θ . The basic approach is as follows. Consider two individuals, x and y . We denote the two alleles in x by a and b (which may be alike in state), and similarly in y by c and d . The **molecular similarity** at locus ℓ between x and y is defined by

$$S_{xy,\ell} = \frac{I_{ac} + I_{ad} + I_{bc} + I_{bd}}{4} \quad (20.23a)$$

where I_{ad} is an indicator function that equals one if a and d are AIS, and otherwise is zero. For diallelic loci (such as most SNPs), $S_{xy,\ell}$ takes on values of 0, 1/2, or 1. A value of 1/4 requires at least three distinct alleles, and values of 3/4 do not occur as, if the first three combinations are one, so is the last (Oliehoek et al. 2006). Toro et al. (2002) referred to Equation 20.23a as **molecular coancestry**, as when AIS equals IBD, then $E[S_{xy,\ell}] = \theta_{xy}$, with the average over all loci giving an estimate of the elements of the relationship matrix

$$\widehat{A}_{xy} = 2\widehat{\theta}_{xy} = \frac{2}{L} \sum_{\ell=1}^L S_{xy,\ell} \quad (20.23b)$$

While simple, the issue with this estimator is the equating of AIS with IBD. In order to adjust for AIS status, one needs to assign a base (or reference) population and use the expected genotype frequencies in this base population as the correction for AIS.

Specifically, suppose we let s_ℓ denote the probability that two randomly drawn alleles in the base population are AIS. Obviously, s_ℓ is (at a minimum) a function of the allele frequencies at ℓ . As shown by Lynch (1988c), the expected value for $S_{xy,\ell}$ is given by

$$E[S_{xy,\ell}] = \theta_{xy} + (1 - \theta_{xy})s_\ell \quad (20.23c)$$

For a diallelic locus in Hardy-Weinberg,

$$s_\ell = p_\ell^2 + (1 - p_\ell)^2 = 1 - 2p_\ell(1 - p_\ell)$$

Rearranging Equation 20.23c suggests a more general estimator

$$\hat{\theta}_{xy} = \frac{1}{L} \sum_{\ell=1}^L \frac{S_{xy,\ell} - s_\ell}{1 - s_\ell} \quad (20.23d)$$

where L is the number of SNPs for which x and y contain no missing data. Negative estimates of θ can arise when $S_{xy,\ell} < s_\ell$ over a large number of loci, implying that these individuals are less related than expected by chance. Assuming $s_\ell = 0$ eliminates this problem (the assumption behind Equation 20.23b), but also introduces bias (Speed and Balding 2015; Ackerman et al. 2017). Oliehoek et al. (2006) obtained an adjusted value for s_ℓ to ensure that all the $\hat{\theta}_{xy}$ are nonnegative, but again this likely introduces some slight bias.

Alternatively, one can base a kinship estimator on the total number of shared AIS alleles over L loci (Day-Williams et al. 2011). First, we define

$$S_{xy} = \sum_{\ell=1}^L S_{xy,\ell} \quad (20.23e)$$

Summing Equation 20.23c over all loci yields

$$E[S_{xy}] = \sum_{\ell=1}^L E[S_{xy,\ell}] = \sum_{\ell=1}^L [\theta_{xy} + (1 - \theta_{xy})s_\ell] = L\theta_{xy} + (1 - \theta_{xy}) \sum_{\ell=1}^L s_\ell \quad (20.23f)$$

Rearranging yields the **Day-Williams** estimator

$$\hat{\theta}_{xy,DW} = \frac{S_{xy} - \sum_{\ell=1}^L s_\ell}{L - \sum_{\ell=1}^L s_\ell} \quad (20.23g)$$

Wang et al. (2017) showed that Equations 20.23d and 20.23g are special cases of a general weighting scheme of per-locus information, which ignore any linkage disequilibrium among SNPs. They also examined estimators that included information from SNP LD patterns.

Closely related to these approaches are estimators of θ based upon the average correlation among alleles (Cotterman 1940; Malécot 1948). This equivalence of θ with a correlation immediately suggests why some estimates can be negative, as, unlike a probability, a correlation can be negative, and $\theta < 0$ simply suggests that the two individuals are more *dissimilar* than expected by chance. To proceed, code the two alleles at a given SNP locus (ℓ) as **0/1** and let the random variable b_ℓ denote the value of a randomly drawn allele from this SNP, where $E[b_\ell] = p_\ell$ is the frequency of allele **1**, and $\sigma^2(b_\ell) = p_\ell(1 - p_\ell)$. Analogous to Equation 20.23c, the probability that a randomly drawn allele from x and y are both **1** is

$$\Pr(b_{x,\ell} = b_{y,\ell} = 1) = \theta_{xy}p_\ell + (1 - \theta_{xy})p_\ell^2 \quad (20.23h)$$

which rearranges to

$$\theta_{xy} = \frac{\Pr(b_{x,\ell} = b_{y,\ell} = 1) - p_\ell^2}{p_\ell(1 - p_\ell)} = \frac{E[b_{x,\ell} b_{y,\ell}] - (E[b_\ell])^2}{p_\ell(1 - p_\ell)} = \frac{\sigma(b_{x,\ell}, b_{y,\ell})}{\sigma(b_{x,\ell})\sigma(b_{y,\ell})} = \text{corr}(b_{x,\ell}, b_{y,\ell}) \quad (20.23i)$$

namely, the correlation between a random allele in x and a random allele in y .

Similarly, we can consider the correlation in allelic copy number between x and y . Let $T_{x,\ell}$ denote the number of copies of allele **1** (from SNP ℓ) that x carries, where $T_{x,\ell} = 0, 1$, or 2. Hence, $E[T_\ell] = 2p_\ell$, yielding a contribution to the covariance in T_ℓ between two relatives of

$$(T_{x,\ell} - 2p_\ell)(T_{y,\ell} - 2p_\ell)$$

The variance in T_ℓ is $\sigma^2(T_\ell) = E[T_\ell^2] - (E[T_\ell])^2$, which under Hardy-Weinberg, becomes

$$[0^2 \cdot (1 - p_\ell)^2 + 1^2 \cdot 2 \cdot p_\ell(1 - p_\ell) + 2^2 \cdot p_\ell^2] - (2p_\ell)^2 = 2p_\ell(1 - p_\ell)$$

yielding a correlation in T between x and y at SNP ℓ of

$$\text{corr}(T_{x,\ell}, T_{y,\ell}) = \frac{\sigma(T_{x,\ell}, T_{y,\ell})}{\sigma(T_{x,\ell}) \cdot \sigma(T_{y,\ell})} = \frac{(T_{x,\ell} - 2p_\ell)(T_{y,\ell} - 2p_\ell)}{2p_\ell(1 - p_\ell)} \quad (20.23j)$$

To relate $\text{corr}(T_{x,\ell}, T_{y,\ell})$ with θ_{xy} , we write $T_{x,\ell} = b_{x,\ell} + b'_{x,\ell}$, where b and b' represent the two SNP alleles in x , to yield that

$$\sigma(T_{x,\ell}, T_{y,\ell}) = \sigma(b_{x,\ell} + b'_{x,\ell}, b_{y,\ell} + b'_{y,\ell}) = 4\sigma(b_{x,\ell}, b_{y,\ell})$$

Substituting this result into Equation 20.23j and recalling Equation 20.23i yields

$$\text{corr}(T_{x,\ell}, T_{y,\ell}) = \frac{4\sigma(b_{x,\ell}, b_{y,\ell})}{2p_\ell(1 - p_\ell)} = 2 \left[\frac{\sigma(b_{x,\ell}, b_{y,\ell})}{p_\ell(1 - p_\ell)} \right] = 2\text{corr}(b_{x,\ell}, b_{y,\ell}) = 2\theta_{xy} \quad (20.23k)$$

Summing over uncorrelated SNPs returns

$$\hat{A}_{xy} = 2\hat{\theta}_{xy} = \frac{1}{L} \sum_{\ell=1}^L \frac{(T_{x,\ell} - 2p_\ell)(T_{y,\ell} - 2p_\ell)}{2p_\ell(1 - p_\ell)} \quad \text{for } x \neq y \quad (20.23l)$$

Yang et al (2010) showed that a slight modification is required when considering the coancestry of x with itself,

$$\hat{A}_{xx} = 1 + \frac{1}{L} \sum_{\ell=1}^L \frac{T_{x,\ell}^2 - (1 + 2p_\ell)T_{x,\ell} + 2p_\ell^2}{2p_\ell(1 - p_\ell)} \quad (20.23m)$$

where the term following the one is the estimate of inbreeding. Note that this term could be negative, implying that the individual shows less homozygosity than expected (Ackerman et al. 2017). Two technical comments are in order concerning these estimators. First, formally speaking, the correlations are between deviations of allelic counts with their expected values under the *assumed base population*, for example, $\text{corr}(b_{x,\ell} - p_\ell, b_{y,\ell} - p_\ell)$ and $\text{corr}(T_{x,\ell} - 2p_\ell, T_{y,\ell} - 2p_\ell)$, as p_ℓ may differ from the average allele frequency, \hat{p}_ℓ , in the sample. Second, Yang et al. (2010) showed that Equations 20.23l and 20.23m are slightly biased due to sampling error and suggested a regression-based correction (Yang et al. 2011a).

There are a number of subtleties in connecting AIS/IBS with IBD, largely dealing with how one defines a base population, whose descendants have alleles that are IBD. As detailed in Powell et al. (2010), IBD estimators that adjust AIS data for marker-allele frequencies assume a particular base population (set by the assumed allele frequencies, p_ℓ) as the point of reference for IBD estimates. Using the currently observed allele frequencies sets the current population as the base. Powell et al. noted that the objective of most IBD estimators is to predict the AIS status at unobserved loci. In our case, these unobserved loci are the QTL underlying the traits of interest. If these causative alleles have a different allele-frequency spectrum than the marker alleles being used to estimate IBD (for example, the trait has been under selection, with most sites having rare alleles), this introduces some error. IBD estimates from pedigree data (which estimates IBD independent of the underlying genetic structure) are robust to this effect.

Consequences of Pedigree Errors

Because the strength of a mixed-model analysis arises from accurately borrowing information from relatives, pedigree errors result in both bias and a loss of power. Generally speaking, there are two types of errors: (i) missing a link (setting relatives to unrelated); and (ii) incorrectly linking unrelated individuals together. In natural populations, there is a strong bias toward maternal connections, in that (depending on the biology of the focal species) many mother-offspring connections will be found and the incorrect assignment of maternity is unlikely (but certainly possible). In contrast, assigning fathers is much more problematic, with many offspring potentially having unassigned fathers, even when their true fathers are in the sample. Missed or incorrect paternal assignments have the effect of making what the model assumes to be unrelated individuals more similar (when the father is in the sample but not assigned to its offspring) and related individuals less similar (an incorrect father is assigned). This generally reduces heritability estimates. More importantly, there are significant implications for the detection of maternal effects. If most pedigree errors are paternal, then offspring will tend to resemble their mothers more than their fathers, resulting in a false signal of maternal effects (Postma and Charmantier 2007). Proper estimation of maternal effects requires a significant number of correct paternal links, as these allow direct and maternal effects to be disentangled (Chapter 22).

The consequences of misassigned paternities are a function of the pedigree structure and the trait heritability. In animal-breeding designs, where there is a great excess of mothers (dams) over fathers (sires), the effects can be substantial. In beef cattle, simulations by Lee and Pollak (1997) revealed a significant reduction in the estimated heritability (0.1 versus the true value of 0.3) when 20% of the sires were misidentified. Their pedigree structure had roughly 2% sires and 22% dams, and the rest were nonparents. In contrast, simulations by Charmantier and Réale (2005), assuming roughly equal percentages of sires and dams, found that if the rate of misassigned paternity was under 20%, then the bias in h^2 was modest (a relative error of less than 15%). Similar findings were reported by Firth et al. (2015). For Soay sheep (*Ovis aries*), Milner et al. (2000) found that estimates of h^2 were higher when using a pedigree with 95% confidence on a paternity than when based on a pedigree with 80% paternity confidence. Working with morphological traits in Darwin's finches (*Geospiza fortis*), Keller et al. (2001) found that not accounting for maternal effects introduced a much greater bias than did extra-pair matings (i.e., misassigned paternities).

Estimates of individual predicted breeding values (PBVs) are more impacted by incorrect pedigree links than are estimates of h^2 , which is critical as PBVs are the key in assessing direct selection on breeding values. As seen with the prediction of a breeding value from a single phenotype, $\hat{a} = h^2(z - \mu)$, the effect of the heritability is to shrink an estimate back toward the mean breeding value (zero). If h^2 is large, most of the phenotypic deviation is retained by the estimate, while if h^2 is close to zero, all estimates are shrunk back to very near zero. Because pedigree errors typically result in underestimated heritabilities, this results in excessive shrinkage of PBVs (Geldermann et al. 1986; Israel and Weller 2000). As a result, the magnitudes of true extreme breeding values are underestimated (see Figure 20.4).

How does an investigator deal with all of this pedigree uncertainty? Henderson (1988) suggested that if a father is not known with certainty, it may be more efficient to include all possible sires (weighted by their paternal probabilities, e.g., weighting all possible sires equally) than to simply not include any sire-offspring linkages in the pedigree. He introduced the idea of an **average numerator relationship matrix** to accomplish this. Konigsberg and Cheverud (1992) applied this approach to estimate heritabilities of several craniometric traits in a macaque (*Macaca sinica*) colony on Cayo Santiago. Here, mothers were known with certainty but sires were unknown, although field and social data could be used to exclude many possible sires for each offspring. If there were k possible sires, Konigsberg and Cheverud simply weighted them all with equal probability ($1/k$) and applied Henderson's method. The natural (and more sophisticated) extension of this idea is a fully Bayesian approach, wherein uncertainty in the pedigree estimates is directly built into the model, with the resulting marginal posteriors fully incorporating all of this uncertainty (e.g., Hadfield

et al. 2006).

With all these potential uncertainties in the pedigree, performing a sensitivity analysis given its basic structure in a study is critical before applying an animal model. Following Morrissey et al. (2007), the investigator first assumes a rough pedigree framework for the study population and then randomly incorporates the types of pedigree errors suspected, given the biological system in question. Simulation studies can then be used to examine the power (the ability to estimate parameters) and sensitivity (how robust these estimates are in the face of pedigree errors). Software for such an analysis was developed by Morrissey and Wilson (2010). Using a framework pedigree for Soay sheep (*Ovis aries*), Morrissey et al. (2007) found that the simple animal model (where breeding values are the only random effect) was relatively robust to pedigree errors, but that when maternal effects were present, the results were more fragile (i.e., much more sensitive to pedigree errors). This finding is not surprising, as separating maternal and direct effects is fairly sensitive to the types of links in the pedigree. Quinn et al. (2006), using the pedigrees for two bird species, suggested a rough rule of thumb that at least three years and 100 individuals per year are required to estimate heritability with confidence. These numbers should be treated as lower bounds, as other sampled natural populations may contain fewer relatives than do the samples for Quinn et al.'s species, significantly reducing the power.

In summary, although there appears to be a wealth of tools for using molecular markers to assign relationships, using them as the sole means to reconstruct A is suspect unless the marker density is high. Rather, using field observations to first suggest potential relationships and then molecular markers to confirm them should provide fairly reliable A matrices (albeit culled for more distant relatives). In a multigenerational study, this approach can provide links across generations, and connecting these links over several generations can largely fill out the important entries in A. A further caveat is that, as mentioned in Chapter 19, BLUP and REML methods can be compromised by previous selection, which is exactly what is expected in natural populations. Given the generally smaller size and shallower depth (connectiveness) of wild pedigrees relative to those from much larger, designed breeding programs, a full and formal accounting of all uncertainty is critical, and our recommendation is that Bayesian approaches be used whenever possible.

Model Selection

A final concern when using wild pedigrees is the delicate issue of model selection—determining which additional random effects among a set of candidates should be incorporated (e.g., whether a common family effect should be added to the model). Typically one incorporates additional random effects when their associated variance component is significant or when the model fit is improved by some criterion (e.g., the likelihood ratio test or model selection statistics such as AIC or BIC; see Example 12.5). One interesting consequence of a Bayesian analysis is that unless a variance prior has some point mass at zero, the resulting posterior confidence interval will always exclude zero, resulting in all variance components (for which the MCMC converges) being significant in the sense of a value of zero being excluded. In such settings, goodness-of-fit measures such as BIC should be the criteria used for model selection.

The incorporation of additional random effects into a model may significantly change the interpretation of a key feature (such as the additive variance). The problem faced by an investigator is determining when to include such additional random effects, given that the power to declare a variance component significant is likely small. Further, it is not uncommon for some variance components in natural populations to be almost fully confounded (e.g., Kruuk and Hadfield 2007; Ovaskainen et al. 2008). Given the expected low power for a mixed model using a pedigree sampled from a wild population, the sensibilities of the investigator come into play. If the a priori feeling is that the biology of the trait dictates the inclusion of a specific random effect (such as a maternal effect), this is best left in the model. Its inclusion will not result in bias estimates of the breeding values, but it may result in a

Table 20.2 Summary of best practices for examining common evolutionary questions on response to selection within the animal-model framework. BV is the true breeding value (A) of the focal trait, PBV is the predicted BV from an animal model (\hat{a}), and w denotes relative fitness. Full details are included in the text.

Task: Conducting Robertson consistency tests based on BV-fitness associations

Problem: The variance of PBVs is less than the additive variance of the trait (Postma 2006).

This biases Rausher's test (Equation 20.20) for direct selection on the focal trait, as the slope, $b_{\hat{a}}$, of a fitness-PBV regression overestimates the slope, b_A , of the fitness-BV regressions (Equation 20.25b).

Solution: Use a bivariate (trait, relative fitness) animal model and frame tests in terms of REML variance components, for example, Morrissey's test (Equation 20.21c).

Problem: If trait BVs are estimated with a univariate animal model, $\sigma(\hat{a}, w)$ is a biased estimate of $\sigma(A, w)$, as when A and w are correlated, these must be estimated *jointly*, which is not the case when using a univariate model (Hadfield 2008). This biases Postma's test for direct selection on the focal trait (Equation 20.18).

Solution: Use a bivariate animal model (focal trait, fitness) to estimate S_z and S_A directly from REML variance components (Equations 20.28a, 20.28b, 20.29c, and 20.29d).

Task: Detecting genetic trends using temporal regressions based on PBVs

Problem: The error structure associated with PBVs is of GLS, not OLS, form, with heteroscedastic and correlated residuals. This results in strongly anticonservative tests, with p values highly biased toward smaller values (Hadfield et al. 2010).

Solution: Use a Bayesian posterior for the regression slopes (Figure 20.6; Example 20.7).

reduction of power. At a minimum, one strategy is to present analyses under a series of models (even if the resulting variance components may not be significant) if they result in substantially different interpretations of key results.

APPLYING MIXED MODELS TO NATURAL POPULATIONS

Animal models have been used to address two important questions regarding the nature of the response to selection on a focal trait. First, is there evidence of selection on the breeding values of that trait, and if so, is it consistent with selection largely on the phenotype of the focal trait (as opposed to some other target)? Second, is there any genetic trend (change in mean breeding values) in the data? Historically (during the first decade of the 2000s), these tasks were accomplished by regressing relative fitness on individual PBVs to address selection on the breeding value of a trait and by regressing population mean PBVs on year (or generation number) to detect any genetic trend. As detailed below, both of these approaches are flawed when simply using the PBVs directly, but both questions can be safely addressed within an animal-model framework with the appropriate adjustments (Table 20.2).

Consistency Tests: Accuracy, Reliability, and Caveats when Using PBVs

Many of the initial applications of animal models in natural populations used individual PBVs in tests of selection on breeding, versus environmental, values (Equations 20.18 and 20.20), for example, fitting the Rausher-Simms regression using PBVs, $w = 1 + \beta_A \hat{a} + \beta_E \hat{e} + \epsilon$. However, Postma (2006) noted that there are significant problems with using an estimated value, \hat{a} , in place of the true breeding value, A (to conform with the literature, we use an italicized A for the true breeding value, \hat{a} for the PBV, and a bold roman A for the relationship matrix). His central point was that when the pedigree adds little additional information, the PBV for an individual is almost entirely determined by its phenotype. The resulting

PBVs are biased by environmental values influencing the phenotypes of individuals, which confounds their ability to separate A from E . Further, as shown by Hadfield (2008, Hadfield et al. 2010), PBVs are correlated with each other, and this correlation structure must be taken into account for proper inference.

To quantify these concerns, we first need to consider several related measures of the uncertainty of predicted breeding values. Their **accuracy**, ρ , is the correlation between the predicted, \hat{a} , and actual, A , breeding values (Chapter 13), while the **reliability**, ρ^2 , is the fraction of variation in A accounted for by the PBVs. When using only the phenotype of an individual to obtain its PBV, $\rho = h$ (Chapter 13). The difference, $\rho^2 - h^2$, between the reliability of a particular PBV and the heritability is a measure of how much additional information is provided from relatives (i.e., from the pedigree). Expressing a PBV as its expected value (the true breeding value) plus an uncorrelated residual, $\hat{a} = A + \epsilon$, then $\sigma^2(\hat{a} - A) = \sigma^2(\epsilon)$ is the **prediction-error variance** (PEV; Chapter 19). When the PEVs are small, the PBVs will be very close to the true breeding values.

These measures of uncertainty (ρ and PEV) in the PBVs are connected as follows. By construction, A and the residual ϵ are uncorrelated, implying $\sigma(\hat{a}, A) = \sigma(\hat{a}, \hat{a} + \epsilon) = \sigma^2(\hat{a})$. This allows us to express the PEV as

$$\sigma^2(\epsilon) = \sigma^2(\hat{a} - A) = \sigma^2(\hat{a}) - 2\sigma(\hat{a}, A) + \sigma^2(A) = \sigma^2(A) - \sigma^2(\hat{a}) \quad (20.24a)$$

Second, the definition of a correlation yields the accuracy as

$$\rho = \frac{\sigma(\hat{a}, A)}{\sqrt{\sigma^2(\hat{a}) \sigma^2(A)}} = \sqrt{\frac{\sigma^2(\hat{a})}{\sigma^2(A)}} \quad (20.24b)$$

Hence,

$$\sigma^2(\hat{a}) = \rho^2 \sigma^2(A) \quad (20.24c)$$

Because $\rho^2 \leq 1$, it immediately follows that $\sigma^2(\hat{a}) \leq \sigma^2(A)$.

We have already seen a hint of this result, in that individual PBVs are shrunk back toward their expected values, A , reducing their variance relative to the variance of their true values (Figure 20.4). These results imply that the correlation between the PBV and the phenotypic value of the trait, z , is greater than the correlation between A and z , as $\sigma(\hat{a}, z) = \sigma(A - \epsilon, z) = \sigma(A, z)$, hence

$$\begin{aligned} |\text{corr}(\hat{a}, z)| &= \frac{|\sigma(\hat{a}, z)|}{\sqrt{\sigma^2(\hat{a}) \sigma^2(z)}} = \frac{|\sigma(A, z)|}{\sqrt{\sigma^2(\hat{a}) \sigma^2(z)}} \\ &= \frac{|\sigma(A, z)|}{\rho \sqrt{\sigma^2(A) \sigma^2(z)}} = \frac{|\text{corr}(A, z)|}{\rho} \geq |\text{corr}(A, z)| \end{aligned} \quad (20.24d)$$

where we use corr to denote a correlation, as ρ here is restricted to a very specific correlation, namely, that between \hat{a} and A (the accuracy). Equations 20.24a and 20.24c show the connection between ρ and the PEV, with

$$\sigma^2(\epsilon) = \sigma^2(\hat{a} - A) = (1 - \rho^2) \sigma^2(A) \quad (20.24e)$$

Finally, for $z = A + E$, Postma (2006) showed that the prediction-error variance equals the covariance between the PBV and the environmental (or more generally, residual) deviation, E , so that we can also write

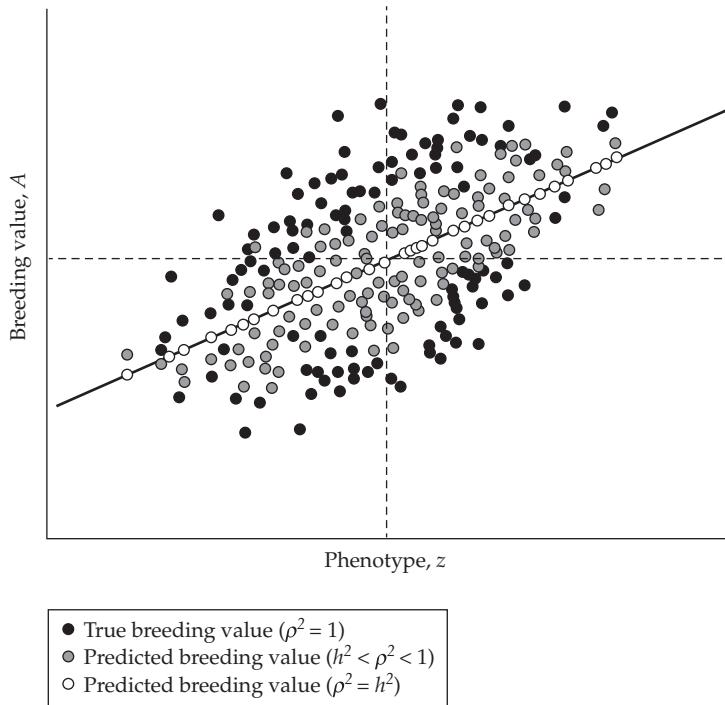

Figure 20.4 Comparison of predicted breeding values (PBVs) as a function of phenotypic value, z , based on different amounts of information from relatives. With only a single observation (i.e., no relatives), PBVs (open circles) show no variation about their predicted value of $\hat{a} = h^2(z - \mu)$, and $\rho^2 = h^2$. As more information from relatives accrues, $\rho^2 > h^2$, and the PBVs (gray-filled circles) become less dependent on an individual's phenotype, showing greater spread about the regression. Now, for a given phenotypic value, z , the residual variance of a PBV around its mean predicted value of $h^2(z - \mu)$ is $(\rho^2 - h^2)\sigma^2(A)$. When $\rho = 1$ (PBV = true BV, shown in the figure as black circles) this spread around z is $(1 - h^2)\sigma^2(A)$, which can be substantial when heritability is low, as z is a poor predictor of A . (After Postma and Charmantier 2007.)

$$\sigma^2(\epsilon) = \sigma(\hat{a}, E) = (1 - \rho^2) \sigma^2(A) \quad (20.24f)$$

When $\rho^2 < 1/2$, the implication is that PBVs resemble individual *phenotypes* more than they do the *true breeding values* (Figure 20.4), and hence PBVs are *biased by environmental influences on the phenotype*. In particular, Equation 20.24f shows that the prediction error is the covariance of an individual's environmental value and its PBV. When $\rho^2 \sim 1$, the environmental value has no impact on the estimate, \hat{a} , but when ρ^2 is modest to small, the PBV is a mixture of the true breeding value, A , plus an error reflecting environmental effects.

Figure 20.4 illustrates this phenomenon in a plot of predicted breeding values versus phenotypic values. When the predicted breeding value is based solely on the phenotypic value, z , of a single individual (open circles), there is no variation about its predicted value of $h^2(z - \mu)$, as all individuals with the same z value have the same predicted breeding value. In this case, while there is no variance in the PBVs for a given z (as all PBVs are the same), the residual variance between z and the *true* breeding value can be considerable, namely $\sigma^2(\epsilon) = (1 - h^2) \sigma^2(A)$. This follows from Equation 20.24e and the fact that $\rho^2 = h^2$ when only z is used to predict A . With a standard heritability of around 0.3, this amounts to 70% of the additive variance remaining unaccounted for by the PBVs. When PBVs are based on information from the phenotypes of relatives (in addition to an individual's phenotype), the reliability ρ^2 exceeds h^2 , and influenced by this information from relatives, the predicted values start to vary about their mean value of $h^2(z - \mu)$ for a given z , giving a more accurate picture of the true values. The influence of relatives is to make an individual's

predicted breeding value less dependent on its own phenotypic (and hence, environmental) value. The residual variance for the true breeding value for a given phenotypic value, z , is $(\rho^2 - h^2)\sigma^2(A)$, which is maximized at $(1 - h^2)\sigma^2(A)$, when the reliability is complete ($\rho = 1$). Postma and Charmantier (2007) noted that ρ^2 is often around 0.5 for wild pedigrees, so that roughly half of the estimate of a typical PBV is influenced by the environment (Equation 20.24f).

The prediction-error variance for any specific PBV can be obtained from Equation 19.5c, which returns the covariance matrix of the PEVs for each of the estimated breeding values (also see Meyer 1989; Tosh and Wilton 1994). The i th diagonal element of this covariance matrix yields a prediction-error variance for individual i of

$$PEV_{ii} = (1 - \rho_i^2)\sigma^2(A) \quad (20.24g)$$

and hence a prediction reliability of

$$\rho_i^2 = 1 - \left(\frac{PEV_{ii}}{\sigma^2(A)} \right) \quad (20.24h)$$

The degree to which ρ_i^2 exceeds h^2 is a measure of the amount of additional information on that individual's breeding value provided by the pedigree (i.e., the additional information beyond that provided by the phenotype of the focal individual). A more subtle, but equally important, point is that the PEV matrix is not a diagonal, but rather contains numerous nonzero off-diagonal elements, as the PBVs for relatives are correlated (because they are based on shared information). Hence, the residual-error structure for the Rausher-Simms regression (Equation 20.20) is complex, requiring GLS, not OLS, regression (Chapter 18; LW Chapter 8). We return to this point below, as it has consequences for tests of genetic trends.

These results also have important implications for populations under selection. If an individual is lost before it leaves offspring (i.e., its fitness is zero), it will have fewer links in the pedigree than higher-fitness individuals who survive to leave offspring. The breeding-value predictions for individuals of low fitness are thus expected to have lower reliabilities than for individuals with higher fitness, and are thus more influenced by environmental values than those for higher-fitness individuals (Postma 2006). This can bias estimates of the amount of selection on breeding value.

Postma (2006) noted that besides the prospect of differential bias in PBVs for individuals with different fitnesses, a critical component of Rausher's consistency condition (Equation 20.17b) fails to hold when this regression is based on \hat{a} . Recall that when selection is entirely on phenotypic values (i.e., when Equation 20.16b is satisfied), then

$$b_A = \frac{\sigma(w, A)}{\sigma^2(A)} = \frac{h^2\sigma(w, z)}{h^2\sigma^2(z)} = b_z \quad (20.25a)$$

namely, the univariate regression slope is the same when relative fitness is regressed on either breeding (A) or phenotypic (z) value. However, when using predicted breeding values (\hat{a}) in place of A , recalling Equation 20.24c yields

$$b_{\hat{a}} = \frac{\sigma(w, \hat{a})}{\sigma^2(\hat{a})} = \frac{h^2\sigma(w, z)}{\rho^2h^2\sigma^2(z)} = \frac{b_z}{\rho^2} \quad (20.25b)$$

Hence, the slope of the regression of relative fitness on PBV (\hat{a}) differs from that using phenotypic value (z). Thus, when $\rho^2 < 1$ (as would always be expected in wild pedigrees), $b_{\hat{a}} > b_A$, showing that a selection gradient based on predicted breeding values ($b_{\hat{a}}$) overestimates the gradient expected for true breeding values (b_A), thus compromising the Rausher-Simms equality test (Equation 20.20) for selection entirely on phenotypes.

To circumvent this problem, Postma (2006) suggested that the consistency test $h^2S_z = S_A$ (Equation 20.18) be used instead, as when selection is based entirely on the phenotype of the focal trait, then

$$S_A = \sigma(A, w) = S_{\hat{a}} = \sigma(\hat{a}, w)$$

A caveat with this approach is that $\sigma(\hat{a}, w)$ is a biased estimate of $\sigma(A, w)$ in a univariate animal model because the breeding values are estimated *separately* from fitnesses (Hadfield 2008). When the components are estimated separately, $\sigma(\hat{a}, w)$ is unbiased only when Equation 20.16b is satisfied (i.e., exactly one of the Robertson consistency conditions is tested). Fortunately, a solution to both these of problems is achieved by *jointly* modeling the trait and fitness in a bivariate animal model, and then using REML-estimated variance components for consistency tests, as detailed in the following section.

Bivariate Animal Models: REML Estimates of $\sigma(A_z, A_w)$, S_A , and S_z

LW Chapter 26 introduced the multivariate animal model, in which a set of potentially correlated traits is measured in a pedigree of individuals. For trait j , a standard animal model is fit,

$$\mathbf{y}_j = \mathbf{X}_j \mathbf{b}_j + \mathbf{Z}_j \mathbf{a}_j + \mathbf{e}_j \quad (20.26a)$$

where \mathbf{X}_j and \mathbf{Z}_j are, respectively, the design and incidence matrices (Chapter 19; LW Chapter 26) associated with trait j , \mathbf{a}_j is the vector of breeding values for trait j , and the covariance model for the random effects associated with j is

$$\begin{pmatrix} \mathbf{a}_j \\ \mathbf{e}_j \end{pmatrix} \sim \begin{pmatrix} \mathbf{0} \\ \mathbf{0} \end{pmatrix}, \begin{pmatrix} \sigma^2(A_j) \mathbf{A} & \mathbf{0} \\ \mathbf{0} & \sigma^2(e_j) \mathbf{I} \end{pmatrix} \quad (20.26b)$$

Consider the bivariate case, where $\mathbf{y}_1 = \mathbf{z}$ is the vector of phenotypes for the trait of interest and $\mathbf{y}_2 = \mathbf{w}$ is the vector of corresponding relative fitnesses, so (z_i, w_i) are the values of the focal trait and relative fitness for individual i . The resulting bivariate mixed model becomes

$$\begin{pmatrix} \mathbf{y}_1 \\ \mathbf{y}_2 \end{pmatrix} = \begin{pmatrix} \mathbf{z} \\ \mathbf{w} \end{pmatrix} = \begin{pmatrix} \mathbf{X}_z & \mathbf{0} \\ \mathbf{0} & \mathbf{X}_w \end{pmatrix} \begin{pmatrix} \mathbf{b}_z \\ \mathbf{b}_w \end{pmatrix} + \begin{pmatrix} \mathbf{Z}_z & \mathbf{0} \\ \mathbf{0} & \mathbf{Z}_w \end{pmatrix} \begin{pmatrix} \mathbf{a}_z \\ \mathbf{a}_w \end{pmatrix} + \begin{pmatrix} \mathbf{e}_z \\ \mathbf{e}_w \end{pmatrix} \quad (20.27a)$$

Note that the structure of this model allows the trait and fitness to have different fixed effects. The model can logically be extended to include more complex designs, such as maternal effects or repeated measures (e.g., Morrissey et al. 2012). The resulting covariance structure for the stacked vector of breeding values is

$$\boldsymbol{\sigma}(\mathbf{a}) = \boldsymbol{\sigma}\begin{pmatrix} \mathbf{a}_z \\ \mathbf{a}_w \end{pmatrix} = \begin{pmatrix} \sigma^2(A_z)\mathbf{A} & \sigma(A_z, A_w)\mathbf{A} \\ \sigma(A_z, A_w)\mathbf{A} & \sigma^2(A_w)\mathbf{A} \end{pmatrix} = \mathbf{G} \otimes \mathbf{A} \quad (20.27b)$$

where \otimes denotes the Kronecker (or direct) product (LW Chapter 26) and

$$\mathbf{G} = \begin{pmatrix} \sigma^2(A_z) & \sigma(A_z, A_w) \\ \sigma(A_z, A_w) & \sigma^2(A_w) \end{pmatrix} \quad (20.27c)$$

is the matrix of genetic covariances of interest. Similarly, the covariance structure for the stacked vectors of residuals is

$$\boldsymbol{\sigma}\begin{pmatrix} \mathbf{e}_z \\ \mathbf{e}_w \end{pmatrix} = \mathbf{E} \otimes \mathbf{I}, \quad \text{where} \quad \mathbf{E} = \begin{pmatrix} \sigma^2(e_z) & \sigma(e_z, e_w) \\ \sigma(e_z, e_w) & \sigma^2(e_w) \end{pmatrix} \quad (20.27d)$$

Finally, we need to specify any covariances between \mathbf{a} and \mathbf{e} . By construction $\sigma(A_z, e_z) = \sigma(A_w, e_w) = 0$, while the standard assumption is $\sigma(A_z, e_w) = \sigma(A_w, e_z) = 0$, yielding an assumed covariance structure of

$$\boldsymbol{\sigma}\begin{pmatrix} \mathbf{a}_z \\ \mathbf{a}_w \\ \mathbf{e}_z \\ \mathbf{e}_w \end{pmatrix} = \begin{pmatrix} \mathbf{G} \otimes \mathbf{A} & \mathbf{0} \\ \mathbf{0} & \mathbf{E} \otimes \mathbf{I} \end{pmatrix} \quad (20.27e)$$

The resulting six variance components for \mathbf{G} (Equation 20.27c) and \mathbf{E} (Equation 20.27d) are estimated by REML, and these components are our main interest. For example, $\sigma(A_z, A_w)$ is the expected selection response under the 1968 version of Robertson's theorem (Equation 6.24a). From the assumption that $\sigma(A_z, e_w) = \sigma(A_w, e_z) = 0$,

$$S_z = \sigma(z, w) = \sigma(A_z + e_z, A_w + e_w) = \sigma(A_z, A_w) + \sigma(e_z, e_w) \quad (20.28a)$$

is a direct estimate of the selection differential on the phenotypic value (z) of the focal trait, while

$$S_A = \sigma(A_z, w) = \sigma(A_z, A_w + e_w) = \sigma(A_z, A_w) \quad (20.28b)$$

is an estimate of the selection differential on the breeding value (A_z) of the focal trait. By using these variance components directly, we avoid the pitfalls associated with working with individual PBVs, and Postma's (Equation 20.18) and Morrissey's (Equation 20.21c) consistency conditions are easily computed from these variance components. Ideally, this is done within a Bayesian setting, so that the posterior distribution reflects all of the model uncertainty (from pedigree estimation on down). For example, draws from the MCMC sampler for such an analysis (Appendix 3) can be used to compute the posterior distribution of (say) $S_A - h^2 S_z$, and thus test whether there is sufficient support to include (consistent with $S_A = h^2 S_z$) or exclude (consistent with $S_A \neq h^2 S_z$) a zero value for the difference, $S_A - h^2 S_z$.

Removing the assumption that $\sigma(A_z, e_w) = \sigma(A_w, e_z) = 0$, the covariance structure given by Equation 20.27e is replaced by

$$\boldsymbol{\sigma} \begin{pmatrix} \mathbf{a}_z \\ \mathbf{a}_w \\ \mathbf{e}_z \\ \mathbf{e}_w \end{pmatrix} = \begin{pmatrix} \mathbf{G} \otimes \mathbf{A} & \mathbf{C} \\ \mathbf{C}^T & \mathbf{E} \otimes \mathbf{I} \end{pmatrix} \quad (20.29a)$$

where

$$\mathbf{C} = \begin{pmatrix} \sigma(\mathbf{a}_z, \mathbf{e}_z) & \sigma(\mathbf{a}_z, \mathbf{e}_w) \\ \sigma(\mathbf{a}_w, \mathbf{e}_z) & \sigma(\mathbf{a}_w, \mathbf{e}_w) \end{pmatrix} = \begin{pmatrix} \mathbf{0} & \sigma(A_z, e_w)\mathbf{A} \\ \sigma(A_w, e_z)\mathbf{A} & \mathbf{0} \end{pmatrix} \quad (20.29b)$$

These two additional variance components allow us to use the more general consistency condition given by Equation 20.21b. Likewise, to apply Postma's test (Equation 20.18), the phenotypic and breeding-value selection differentials now become

$$S_z = \sigma(A_z, A_w) + \sigma(e_z, e_w) + \sigma(A_z, e_w) + \sigma(A_w, e_z) \quad (20.29c)$$

and

$$S_A = \sigma(A_z, A_w) + \sigma(A_z, e_w) \quad (20.29d)$$

Next-generation Analysis: Generalized Mixed Models

This bivariate analysis of a trait and fitness makes two critical assumptions that are starting to be relaxed by using the more sophisticated analyses that are possible within a Bayesian framework. The first is that the standard mixed model assumes normally distributed random variables. Such is clearly *not* the case with fitness, in which random variables are often expected to be **zero-inflated**, with a point mass at zero fitness (which can be substantial). One way to handle such data is to use a zero-inflated Poisson distribution (a Poisson with an additional point mass at zero; Chapters 14 and 29). As discussed in Chapter 29, zero-inflated models are one attempt to deal with **overdispersion**. If count data follow a Poisson, then the mean and variance should be equal. Overdispersion occurs when the variance exceeds the mean, which can occur if there are an excess of zeros. Overdispersion can also occur if there are an excessive of other values, and Chapter 29 examines models that allow for both zero inflation *and* any additional overdispersion that is present after accounting

for any excess of zeros. When fitness does not follow a normal distribution, the standard general linear model is replaced by generalized linear models (Chapters 14 and 29), which extend to **generalized mixed models** (Bolker et al. 2009; de Villemereuil et al. 2016) when the distribution of random effects is nonnormal.

The basic strategy in applying a generalized linear model was seen in our discussion of threshold models in Chapter 14. Here, on some underlying (latent) scale, an individual's breeding and environmental values determine its liability value, which is then translated into a realization of the trait value. For the threshold-trait model, if the liability exceeds a critical value, a particular trait value is seen. More generally, the liability value on this latent scale can be the parameter for some distribution from which a realization is drawn. In a fitness setting, suppose that an individual's liability value is 1.5; then the number of offspring it has is (say) a random draw from a Poisson with a mean of 1.5. As with a standard mixed model, we can borrow information on (liability) breeding values from the relatives of a focal individual to estimate the additive variance on this latent scale (see Example 20.7).

As detailed in Chapter 29, while a zero-inflated Poisson may be an improvement over assuming normality, in reality fitness is expected to have a more complex distribution. The Aster model approach detailed in Chapter 29 allows for a more realistic fitness distribution to be constructed by assuming a set of appropriate distributions over each fitness episode (e.g., Bernoulli for survival data, zero-inflated and/or overdispersed discrete distributions for number of mates, etc.). Bayesian approaches (using MCMC samplers) can deal with these more complex and realistic distributions.

Next-generation Analysis: Modeling Missing Data

By their very nature, fitness data have missing values. Individuals may not be recaptured (even when still alive), the number of mates and offspring may be undercounted, and selection on a trait may occur before we measure it for the first time in a cohort. The nature of the process causing certain data to be absent is critical in determining whether ignoring these missing values yields biased estimates for parameters of interest (Little and Rubin 2002; Hadfield 2008; Nakagawa and Freckleton 2008). Consider a simple case, where egg production, y , is a linear function of body size, x , and where we have body-size measures for all individuals in a sample but some of the egg-production values are missing (Figure 20.5). Following the terminology of Little and Rubin (2002), the missing y values are said to be **missing completely at random (MCAR)** when the process generating the missing values is entirely independent of either the x or y values (i.e., the missing values are simply a random sample of the population; Figure 20.5B). In such cases, the standard process of simply ignoring data with missing values (i.e., discarding those x observations with missing y) does not bias estimates of the relationship between x and y .

In contrast, the y values are said to be **missing at random (MAR)** when the process generating the missing data depends on the observed (x) values, but *not* on the associated y values. For example, suppose individuals above a certain body size have missing y values. The regression (of y as a function of x) ignoring these missing values recovers the same regression (within sampling error) as the full data set (Figure 20.5C). In other words, we can potentially take the observed data and use them to impute the missing data. Finally, suppose that the missing data are generated by a process that depends instead on y ; for example, we do not score individuals whose egg production is outside of a certain range. Removing these data points (here based on truncated y values) results in biased estimates of the regression parameters (Figure 20.5D). Such data are said to be **missing not at random (MNAR)**. MCAR and MAR data are said to be **ignorable**, in that estimates are not biased by the missing data. Conversely, MNAR data are **nonignorable**, and one requires a model of the process generating the missing data to obtain unbiased parameter estimates.

Quantitative-genetic considerations of missing data trace back to Im et al. (1989) in animal breeding and Hadfield (2008) in evolutionary genetics. In particular, Hadfield found that viability selection data are usually MNAR, implying that one must model the censoring process to yield unbiased estimates. He showed that modeling the survival process and

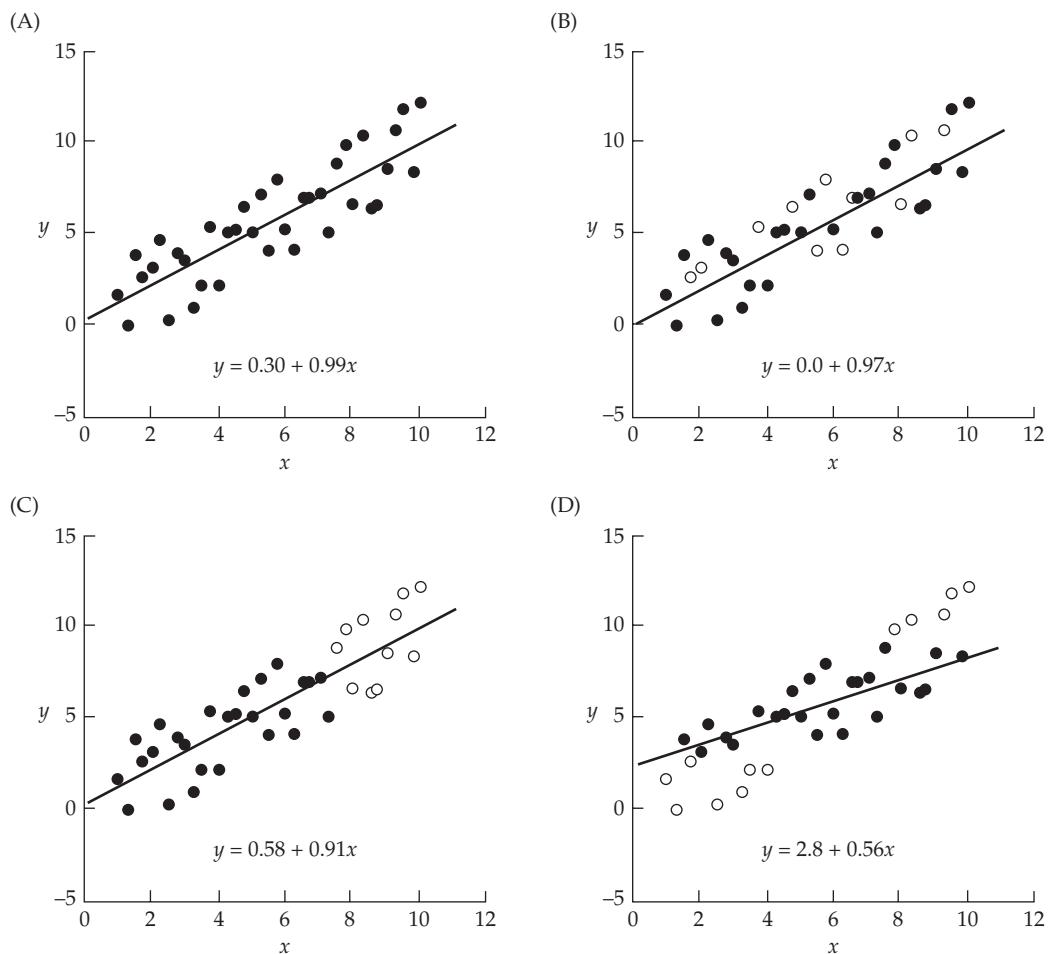

Figure 20.5 The different categories of missing data, as illustrated through a simple example where the missing data, y (vertical axes), are a linear function of x (horizontal axes). Regression lines using the observed data (filled circles) are illustrated. **A:** The uncensored full dataset. In the remaining three panels, roughly 20% of the original data is missing (unfilled circles). **B:** Here, y values were removed entirely at random. Such data are said to be missing completely at random (MCAR). **C:** The data are not missing at random, but rather missing as a function of x (the y values for large x values are missing). Note, however, that in this setting (because y is a function of x), our estimate of the relationship between x and y (as in **B**) is not biased. Such data are said to be missing at random (MAR). In the settings **(B)** and **(C)**, namely MCAR and MAR data, the missing data are said to be ignorable, as estimates of the regression parameters are not biased by the missing data. **D:** Here the data are missing as a function of y (culled for extreme values). The resulting estimated regression is seriously biased in both its slope and its intercept. Such data are said to be missing not at random (MNAR), and said to be nonignorable, as estimates of the regression parameters *are indeed* biased by the missing data.

using an animal-model framework (wherein information can be borrowed from measured relatives) improves estimation. Papaïx et al. (2010) and Steinsland et al. (2014) developed missing-data extensions for capture-recapture analysis and for the invisible fraction (selection before traits are measured; Chapter 29), respectively. The coupling of non-Gaussian distributions for fitness with the modeling of the missing-data process represent an important extension towards more realistic models for the analysis of trait-fitness data from natural populations.

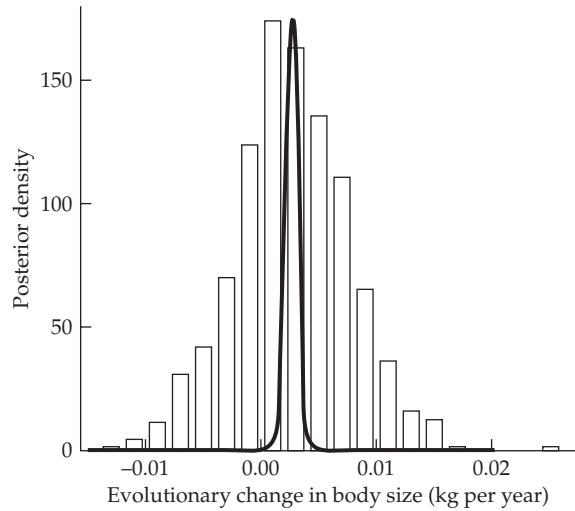

Figure 20.6 The anticonservative nature of using mean PBVs regressed on time to detect a genetic trend, with support for a trend given by a significantly nonzero slope for this regression. Here, the trait is body weight in Soay sheep. The peak of the thick smooth curve centered slightly to the right of zero represents the OLS estimate of the slope for the regression of mean BLUP-PBVs on generation number (i.e., time), and the spread of the curve represents the associated sampling error, which is almost entirely to the right of zero. This shows that the OLS slope estimate is significantly positive. Conversely, the histogram gives samples from the posterior distribution of slopes from a Bayesian analysis (details in the text). While this distribution has the same mean as the BLUP-based slope estimates, its variance is significantly greater. Indeed, 28% of the probability mass is less than zero, showing that the Bayesian estimate of the slope (which more fully accounts for the uncertainty and correlations among individual estimates) is not significantly different from zero. (After Hadfield et al. 2010.)

Detecting Genetic Trends

The gold standard for detecting a genetic change is to grow two populations in a common-garden experiment, ensuring that any change is genetic, rather than environmental. With the exception of the use of remnant seed (or, for other organisms where we can freeze or otherwise immortalize individuals), making contemporaneous comparisons of the genetic composition of different generations is usually not possible. However, as we saw in Chapter 19, it is often possible to make this comparison statistically through the animal model, *provided the population is sufficiently connected across the generations by sampled relatives*. Due to their pedigree depth and connectedness, this is reasonable for most breeding programs and artificially selected populations. The reliability of PBVs in such settings is fairly high, as these conditions reduce the environmental influence on PBVs. Further, PBVs are unbiased (provided individuals are randomized over environments), and taking their average for a sample (such as a generation) smooths out some of the environmental noise associated with individual estimates, thus allowing a plot of mean PBVs over time to show a trend (or lack thereof). In theory, this same approach can be applied to natural populations, provided the genotype-environment correlations are largely ignorable.

The more delicate issue is that of *inference*. As we saw in Chapter 18, both OLS and GLS regressions of the selection response on the selection differential gave unbiased *estimates* of the realized heritability, but because the residuals are heteroscedastic and correlated, the sampling variances under OLS are too small relative to the correct values under GLS (see Example 18.4). As a result, OLS-based tests are **anticonservative**; namely, the *p* values (testing for a potential genetic trend by regressing mean breeding value on time) are heavily biased toward smaller, more significant, values. The same issue arises with the error structure of PBVs (Hadfield et al. 2010), as Figure 20.6 illustrates.

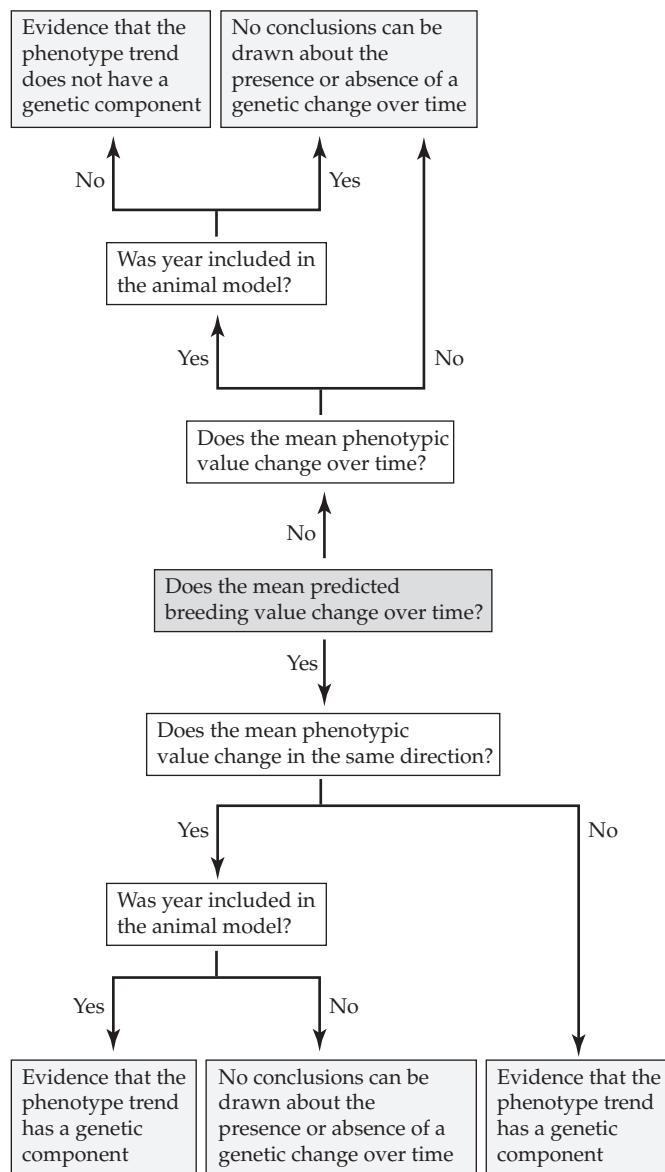

Figure 20.7 Postma and Charmantier's (2007) recommendations for the interpretation of genetic trends.

Fortunately, there is a simple solution (Hadfield et al. 2010), again within the powerful Bayesian framework that (additionally) accounts for all levels of uncertainty in our analysis. A vector, $\hat{\alpha}$, from the posterior PBV distribution is drawn from a given iteration of the MCMC sampler (Appendix 3). Then the resulting series of PBVs is used to regress (using OLS) mean PBV on generation number (i.e., time) and the resulting slope is recorded. This sampling process is repeated thousands of times to construct an empirical histogram of the posterior slope distribution, which is then used for inference (see Figure 20.6). The resulting empirical distribution of slopes fully accounts for the correlated structure among the PBVs.

Detection of a significant genetic trend is not, by itself, evidence of a selection response, as this could arise simply from drift. A powerful feature of the MCMC approach is that it allows for a straightforward test of drift versus selection (Hadfield et al. 2010). First, a value for $\sigma^2(A)$ is sampled from its marginal posterior. Breeding values are then drawn from a normal distribution (with a mean of zero, and the sampled value of $\sigma^2[A]$) and assigned

to individuals in the pedigree with no past relatives. These parental BVs, coupled with Mendelian sampling (Equation 16.8a), are then used to generate random breeding values (RBVs) for their downstream relatives, generating a set of RBVs over the specific pedigree under the assumption of drift (as the BVs are chosen at random). With a set of RBVs in hand, a genetic trend is computed as above (regression of mean RBVs over generations), and the slope is recorded. Extracting many such samples (redrawing $\sigma^2(A)$ at the start of each run) generates an empirical histogram of the posterior slope distribution under drift alone, which can be compared with those generated from the MCMC using the full data.

An issue debated in the literature is whether one should also include a year (or generation) effect in models for trends. When PBVs have low reliability, they are strongly influenced by the environment, with the PBV trend partly reflecting any underlying environmental trend (Postma 2006). Incorporation of a year effect (a fixed value for each year or generation) can account for such an environmental trend, but it will also partly absorb any true genetic trend, thus reducing the power. Postma and Charmantier (2007) offered some guidelines as to how to proceed (Figure 20.7). Given that PBVs are biased toward an environmental trend when their reliability is low, the finding of genetic and environmental trends in opposite directions provides evidence of a genetic trend. If the change is in the same direction and still persists after a year effect has been incorporated, this is also supportive of a genetic trend. Figure 20.7 presents a flow chart for the interpretation of other combinations of trends.

A final issue is that if one has individuals throughout the pedigree with missing parents, these are treated as de facto founders and their BVs come from a common distribution of those older individuals at the top of the pedigree that really are biologically founders. This effect will generally dampen any inferred trend in breeding values (M. Morrissey, pers. comm.)

Example 20.7. Milot et al. (2011) examined the evolution of age at first reproduction (AFR) of human settlers in the isolated island of île aux Coudres in Québec. This island was populated by thirty families between 1720 and 1772. Because of careful church records, it has a very detailed chronicle of births, marriages, and deaths, which allowed the authors to construct a bivariate animal model for AFR and lifetime reproductive success (LRS). The latter is a proxy for total fitness and was defined in this study as the total number of a woman's offspring reaching age 15. The authors assumed a normal distribution for AFR but a latent Poisson model for LRS. Under this model (discussed in Chapter 14), the breeding value for AFR was defined on an underlying latent scale, with the distribution of LRS for an individual with a liability score of $y = \mu + A + e$ following a Poisson distribution with a mean of e^y . MCMC methods were used in a Bayesian analysis of this bivariate model, which found significant heritability in both AFR and LRS (the latter as measured on the latent scale). Further, these two traits showed a significant negative genetic correlation (posterior mode of -0.81 , 95% credible interval of -0.97 to -0.48). Thus, Robertson's theorem (Equation 6.24a) suggests direct selection to reduce the age of first reproduction, which declined from ~ 26 to ~ 22 years over a 140-year period. The regression of predicted breeding value over time (measured as eight 20-year cohorts) is given in Figure 20.8, with the diamonds representing the average of 1,000 MCMC samples from the marginal posterior (\pm their standard errors).

As also shown in Figure 20.8, the authors tested whether this trend could be due to drift, using the approach suggested by Hadfield et al. (2010) discussed above. Given the posterior distribution of the additive variance for AFR, RBVs were generated over the known pedigree, and the regression of the RBVs over time was compared to that for PBVs for each run of the sampler. The proportion of times during which the absolute regression slope of the RBVs exceeded the slope based on PBVs was taken as the posterior probability that the response is due to drift, and was found to be less than 0.01. The average slope for RBVs is given by the solid line in Figure 20.8.

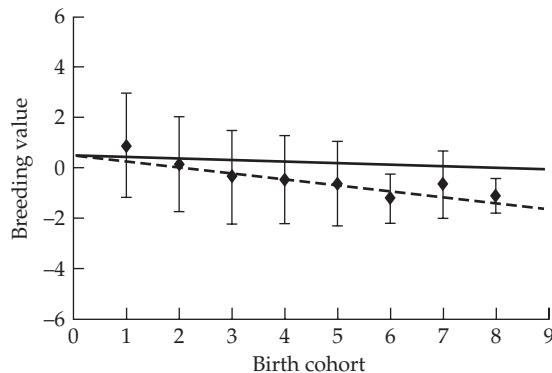

Figure 20.8 An application of Hadfield et al.’s (2010) approach for testing whether a genetic trend is significantly different from that expected under drift alone. Data are for age at first reproduction (AFR) for human settlers on an isolated island in Québec. Diamonds represent the average of 1,000 MCMC samples from the marginal posterior (\pm their standard errors) of the mean predicted breeding value for AFR for each of the eight 20-year cohorts. The regression of these mean PBVs on cohort number is given by the dashed line. As a test for drift, a posterior-sampled value for the additive variance is drawn, and then used to generate random breeding values (RBVs), given the pedigree structure. The average slope for mean RBVs is given by the solid line, showing that the observed PBV trend (dashed line) is more excessive than that expected by drift. This was confirmed by a comparison of the posterior distribution of regression slopes based on observed PBVs and RBVs (Example 20.7).

CAUSES OF APPARENT FAILURES OF RESPONSE IN NATURAL POPULATIONS

Given the above concerns on the suitability of the breeder’s equation in natural populations, what do the data say? A detailed review of well-studied mammal and bird populations by Merilä et al. (2001c) noted a number of cases where: (i) there was a consistent selection differential on a particular trait; (ii) the trait was heritable; and (iii) yet no selection response (or worse, response in the opposite direction) was observed over a lengthy period (many generations) (Table 20.3). While there are several classic examples of natural populations responding either to imposed artificial selection (Example 18.1; Semlitsch and Wilbur 1989), a new environmental challenge (such as a habitat shift, major weather event, or introduction of a novel selective agent, e.g., Example 20.2; Losos et al. 1997; Reznick et al. 1997), or even to the introduction of a new competitor species (Grant and Grant 2006), Merilä et al. (2001c) lamented the apparent lack of response outside of these situations, raising the central question as to the basis for apparent **stasis** in response in the face of apparent selection.

Table 20.4 summarizes possible (and not mutually exclusive) explanations for this apparent failure, most of which have been discussed previously. The most obvious is that the phenotype of the focal trait is not the sole target of selection. However, an apparent lack of response could be as trivial as a lack of sufficient power to detect a small expected change (e.g., Gienapp et al. 2006; Postma et al. 2007). A related design issue is that most studies only sampled a small part of an open population, meaning that immigration and differential dispersal could either mask or enhance any local selection response (Garant et al. 2005).

Likewise, changing environments can result in multiple effects that can cause apparent stasis. First, the selection differential could be changing sign over generations, resulting in a net long-term differential close to zero. Second, deterioration in the environment can mask underlying genetic change. Third, when $G \times E$ interactions are present, heritabilities can

Table 20.3 Examples of natural populations of mammals and birds in which apparent strong directional selection on a heritable trait fails to show response. Duration is the length of the study (in years), and $\bar{i} = S/\sigma$ is the selection intensity. (After Merilä et al. 2001c and Gienapp et al. 2008.)

change with the environment, raising the possibility of low heritabilities when selection is most intense. The tools developed in this chapter may help an investigator sort through these possible explanations, as the following case studies illustrate.

Table 20.4 Possible causes for an observed stasis in response, despite heritable variation and a significant selection differential.

Genetic response has occurred, but not is detected.
Low power to detect a genetic trend.
Genetic gain countered by environmental deterioration.
The focal trait is not the target of selection.
Trait and fitness are correlated through an environmental variable.
Selection on a phenotypically, but not genetically, correlated trait (i.e., $S \neq 0, \beta = 0$).
Consequence of open population structure.
Immigration from populations outside of the study area.
Consequence of fluctuating environmental conditions.
Fluctuating selection differential, with little net selection.
Fluctuating h^2 , with smallest h^2 when selection is strongest.
Constraints and tradeoffs.
Direct response on a trait countered by correlated responses from other traits.
Measured fitness component is an incomplete measure of total fitness.

Cryptic Evolution: Genetic Change Masked by Environmental Change

One explanation for stasis is that change in the environment can dilute, and indeed even swamp, any underlying genetic gain. In the extreme, one can have **cryptic evolution**: significant genetic change that does not show up as phenotypic change because it is countered by environmental change. Levins (1968) and Conover and Schultz (1995) coined the phrase **countergradient variation** for situations in which the environmental trend is opposite to the direction of selection. Such situations can increase the strength of selection on a trait, as the population struggles to keep pace with the declining environment. In the extreme, a population faces the risk of extinction if the environment is deteriorating at a faster rate than the rate at which compensating trait values can evolve. Obviously, this is an important issue for populations when attempting to track climate change.

One striking example of apparent cryptic evolution is the study by Merilä et al. (2001b) on the Gotland population of collared flycatchers. These authors examined body condition (a measure of relative body weight) at fledging. They defined condition as the residual from the regression of body mass on tarsus (leg) length, and found that this trait has substantial heritable genetic variation (estimated $h^2 = 0.30$). Further, it appears to be under constant positive selection, with an average selection intensity of 0.23 (i.e., survivors, on average, were 0.23 standard deviations above the mean before selection). Despite the heritable nature of this trait, which was coupled with strong positive selection, mean condition *declined* over time (Figure 20.9), with the regression of mean condition from 1981 to 1999 showing a significant negative slope ($b = -0.036$ per year). Merilä et al. found that the covariance between fitness, w , and the breeding value of condition, A_z , was nonzero, meaning that selection for condition indeed occurred directly on the breeding values. Because $\sigma(A_z, w) \neq 0$, Robertson's secondary theorem predicts a nonzero response (Equation 6.25a). Why, then, is there an apparent lack of response? As shown in Figure 20.9, the regression of predicted breeding values on time has a positive slope ($b = 0.0022$), with the population showing genetic improvement, despite the mean phenotype declining over time. The environmental component of condition has been declining over time, and at a rate faster than the genetic improvement, resulting in a net phenotypic decline. Merilä et al. (2001b) suggested this is likely attributable to reductions in the caterpillar food supply due to climatic trends.

Apparent stasis can also actually mask a *decrease* in mean genetic value. Such an example was seen by Timothée et al. (2017), who examined body mass in snow voles (*Chionomys nivalis*). While the predicted response (based upon the observed values of S and h^2)

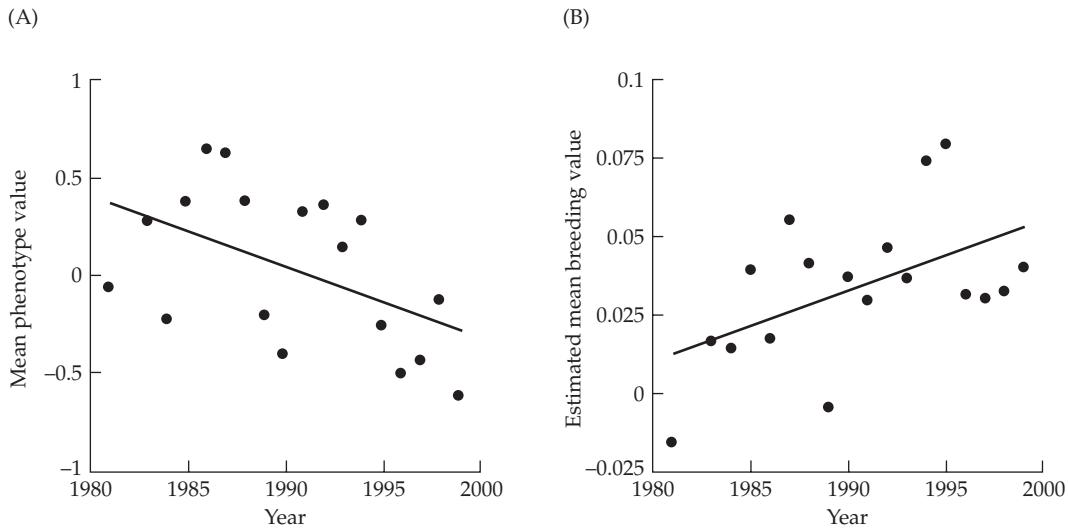

Figure 20.9 Body condition at fledging for a Gotland population of collared flycatchers between 1980 and 1999. **A:** Trend for the mean phenotype. **B:** Trend for the mean breeding value (the average of the individual PBVs in a given year). (After Merilä et al. 2001b.)

was for an increase of ~ 0.17 grams per year, the actual change over a nine year window was slightly positive, but not significant. A mixed-model analysis showed that mean breeding value had in reality significantly *decreased* over this period, with the apparent status in body mass the result of phenotypic plasticity. Selection appeared to be largely on rapidly maturity in juveniles, which leads to low potential adult mass.

Example 20.8. A second example of a negative environmental trend was offered by Larsson et al. (1998), who examined body size in the barnacle goose (*Branta leucopsis*). The natural colonization of the Baltic area of Sweden by this normally Arctic species started with a single breeding pair in 1971, followed by subsequent rapid increase in the population size. The authors studied the two largest Baltic colonies from 1984 to 1996. Head size and tarsus length were measured to extract a structural body-size index, and larger females were found to have larger, and earlier, clutches (with larger eggs, resulting in more and heavier young). Further, juvenile body mass was significantly positively correlated with post-fledging survival. Both size measures were highly heritable, but average body size declined over the 13-year study period (by 0.7 and 0.5 standard deviations for head and tarsus length, respectively). The authors concluded (from a variety of evidence) that the environment had declined due to growth of the colony. For example, the values of birds from the earlier (and smaller) colony were initially around a standard deviation larger than the values of birds from the older (and larger) colony. Thus, the declining environment seems to involve density-dependent effects on individual growth brought on by the overall success of the colony itself.

As Example 20.8 highlights, as organisms evolve, they can change at least part of their environment. Indeed, van Valen's (1973) **Red Queen hypothesis** states that organisms have to evolve just to stay where they are relative to the evolving biosphere around them. (The Red Queen, a character from Lewis Carroll's *Through the Looking Glass*, had to run simply to stay in place.) Cooke et al. (1990) suggested that the lack of response to selection on clutch size in birds may be explained by the Red Queen hypothesis. While Price and Liou (1989) suggested that apparent selection for clutch size is largely based on selection for nutritional state (Example 20.3), Cooke countered that birds with better-quality territories have larger

clutches and higher fitness, so a component of selection for clutch size involves the ability to compete for such territories. Although competitive ability may increase over time, average territory quality, and hence average clutch size, remains relatively constant, and hence no response is seen (this is an example of selection of associative effects, examined in detail in Chapter 22). Under the Cooke et al. model, if one could hypothetically let ancestral and current populations compete for territories, current individuals, which possess higher breeding values for competitiveness, would win.

Building on this theme, Hadfield et al. (2011) noted that a number of distinct biological processes may present the appearance of cryptic evolution (no apparent change in mean phenotype, while the mean breeding value changes), such as sib competition and selection on a trait before it is scored (the so-called invisible fraction discussed in Chapter 29). In particular, they stress the importance of **evolutionary environmental deterioration**, namely, an adaptive response resulting in a harsher biotic environment (following Cooke et al. 1990 and Fisher 1958). We consider this process in detail in Chapter 22, in the context of selection under the joint action of both direct and associative genetic effects.

Antler Size in Red Deer: The Focal Trait Is Not the Target of Selection

Free-living red deer (*Cervus elaphus*) on the Isle of Rum in Scotland are another well-studied natural population with a largely complete pedigree spanning several decades. Males fight to compete for mates, suggesting antler size as a potential trait under selection. Males shed antlers in the early spring, and given that antler shape is very individual-specific, cast antlers found in the field can easily be assigned to a specific stag. Kruuk et al. (2002, 2014) found that males with larger antlers (measured as the mass of the annually shed antlers) had increased lifetime breeding success (total number of offspring), with a selection differential of $S/\sigma_z = \bar{i} = 0.445 \pm 0.094$. Although body size (measured by leg length) also had an effect on lifetime breeding success, antler size still had a significant effect on fitness even after accounting for body size, with a standardized (scaled to unit variance) selection gradient of $\beta = 0.44 \pm 0.18$. Antler size was heritable ($h^2 = 0.329 \pm 0.12$), and the breeder's equation would suggest a response of $R/\sigma_z = h^2 S/\sigma_z = 0.329 \cdot 0.445 = 0.146$ standard deviations per generation. Given a generation time of roughly 8 years and a standard deviation of 163 grams for antler mass, this suggests an expected change of roughly 2.3 grams per year. However, the average mass of antlers actually *declined* by 6.7 grams per year over the study period. One apparent reason for the decline was an environmental change due to increased population density over the study period, with antler size decreasing with increasing density.

Was this also a case of genetic change being masked by this environmental change? Apparently it was not. The REML estimate of the genetic correlation between lifetime breeding success and antler size was not significant, -0.254 ± 0.289 . Thus the significant selection differential appears to be generated through selection on some feature that is phenotypically, but not genetically, correlated with antler size. The authors suggested that male fighting ability is, at least in part, a function of the nutritional condition of a male, and males with better nutritional value may be both better fighters and also more likely to grow larger antlers. Being better fighters, they have a greater lifetime reproductive success, which generates a correlation between antler mass and fitness.

Lower Heritabilities in Environments with Stronger Selection?

A more subtle implication of environmental change arises when genotype \times environment interactions are present. As the environment changes, so can heritabilities, due to either changes in the environmental or in the genetic components of variance (Hoffmann and Parsons 1991, 1997a, 1997b; Hoffmann and Merilä 1999; Merilä and Sheldon 2001; Sgrò and Hoffmann 2004; Charmantier and Garant 2005). There are some suggestions of a weak trend in the direction of change in h^2 . Data from wild vertebrate populations show increased heritabilities for morphological traits in more favorable environments, while traits more closely associated with fitness show no pattern (Merilä and Sheldon 2001; Charmantier and

Garant 2005). Charmantier and Garant examined 46 traits, 38 of which showed no significant difference in heritabilities in good versus poor environments, but of the remaining 8 traits that were significant, all were higher in the more favorable environment. Roughly 65% of the traits showed decreased additive variation in less favorable environments, but most differences were not significant. In contrast, environmental variances tended to increase under poor conditions. Lower values of h^2 in more unfavorable environments suggests that there is less response in more stressful environments, exactly those that are likely to impose more selective pressures (Example 20.9).

These surveys of wild populations are at odds with older laboratory experiments in *Drosophila*, which found higher additive genetic variance (and heritabilities) in stressed environments (Hoffmann and Merilä 1999). While this observation may simply suggest that there are no general trends, it may also be a reflection of conditions in the lab versus the field. This observation is also consistent with **Holloway's conjecture**, which states that adaptive traits may show higher additive variance and reduced genetic correlations in novel environments, as an environmental change might disrupt the genetic architecture that evolved in response to a different set of environments (Holloway et al. 1990). One could view the laboratory *Drosophila* experiments in this light, in that many of the artificially imposed stresses create novel environments, especially for laboratory-adapted strains. Holloway's conjecture is also consistent with some results for Soay sheep, which exhibit smaller genetic correlations in more favorable environments (measured by first year population-wide survival) than in poorer environments (Robinson et al. 2009).

Example 20.9. Charmantier et al. (2004) examined chick tarsus length and body mass at fledging in three French populations of blue tits (*Cyanistes caeruleus*), two on the island of Corsica, and a third on the mainland. Their study followed ~ 8000 banded chicks from ~ 1200 individual broods, representing three different habitats, which the authors were able to rank in quality. They found that poorer habitats showed weak selection to increase tarsus length and strong selection to increase body mass, while in good habitats there was no significant selection on either trait. It is interesting that heritability for body mass increased with habitat quality, with the lowest heritability occurring in the poor habitats that experienced the strongest selection for increased body weight. In such low-quality environments, strong selection would be at least partly countered by lower heritabilities, leading to a weaker response.

A similar situation was observed by Wilson et al. (2006) for birthweight in Soay sheep (*Ovis aries*). These authors used a random-regression animal model (Volume 3), which allowed for the estimation of maternal performance over a continuous environmental variable (here the population-wide neonatal mortality for a given year). Harsh environmental conditions generated strong selection for higher birthweights but also resulted in a lower genetic variance in this trait. More benign environments resulted in weaker selection but higher birthweight heritabilities. A counterexample to these two studies was provided by Husby et al. (2011), who found, in a population of great tits (*Parus major*), that both the selection differential on earlier breeding and the heritability in this trait increased with increasing spring temperatures.

Fitness Tradeoffs and Multivariate Constraints

Finally, we note that our discussion of the selection response in natural populations has neglected two extremely important issues that will be addressed later. The first is the estimation of fitness, which is examined in detail in Chapters 29 and 30. Because lifetime (or total) fitness is very difficult to measure, a component of fitness (such as viability or fecundity) is often measured and assumed to be a faithful proxy of the total fitness. This, however, raises concerns about fitness **tradeoffs**, wherein a trait has a positive effect on one fitness component but a negative effect on another, so that its *net* effect on fitness is far less than expected when considering the effect of either component separately. Similarly, one might imagine sex-specific tradeoffs, wherein a trait has a positive fitness effect in one sex and a

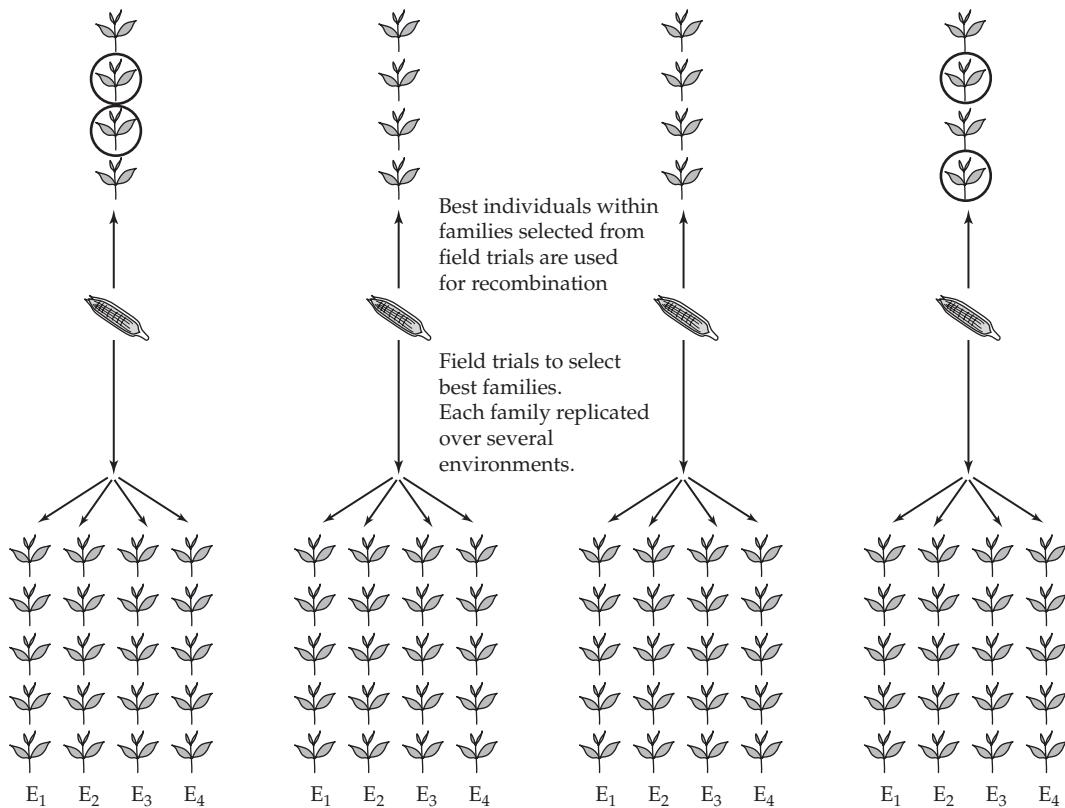

negative effect in the other. Because selection tends to remove additive variation in fitness (Chapters 5, 6, and 28), there is a widespread view that such tradeoffs likely occur. The logic behind this assumption is that selected alleles lacking tradeoffs are either quickly lost or fixed, so that alleles with roughly constant total-fitness effects segregate in a population for a longer amount of time, and hence might be expected to comprise some of the standing genetic variation. However, despite an obsession among ecologists and evolutionary biologists with such tradeoffs, they have proven rather elusive to detect (Chapters 29 and 30; Volume 3). A full discussion of this topic touches on the very vexing question of what maintains quantitative-genetic variation, which we return to in Chapter 28.

The second issue, **multivariate constraints**, is a potential concern because all selection response is inherently multivariate. A critical observation is that each component in a vector of traits under selection can have genetic variation ($h_i^2 \neq 0$), but the multivariate direction favored by response (the selection gradient vector, β) may contain little, or no, usable additive variation. To see this, suppose that only two traits are under selection, yielding a response in trait 1 of $\sigma^2(A_1)\beta_1 + \sigma(A_1, A_2)\beta_2$ (Equation 20.1b). This shows that direct selection on the phenotype of trait 1 ($\beta_1 \neq 0$), coupled with heritable variation ($\sigma^2(A_1) \neq 0$), is *not* sufficient to ensure that $R_1 \neq 0$. If trait 1 is genetically correlated with trait 2, then for certain combinations of selection, namely, $\sigma^2(A_1)\beta_1 \simeq -\sigma(A_1, A_2)\beta_2$, the selection response in trait 1 is effectively zero. In this setting, even if the phenotype of trait 1 is a focal target of selection and the trait is heritable, there will still be essentially no response. It is worth noting that in this case, Robertson's theorem would predict a small to absent response, with $\sigma(A_z, w)$ being very close to zero. Although it is a univariate treatment, the covariance of the breeding value of trait 1 with fitness would be nearly zero in this case, as Robertson's theorem fully accounts for all of the genetically correlated traits that impact the focal trait-fitness covariance.

The general multivariate-constraint problem is examined in some detail in Volume 3, expressed in terms of matrix geometry (Appendix 5). A lack of response implies that the G matrix (of the genetic variances and covariances in the multivariate breeder's equation; Equation 13.23b) has eigenvectors (axes of variation) whose associated eigenvalues are close to (or at) zero, implying essentially no variation in these directions. If the angle between these nearly null eigenvectors of G and the direction, β , favored by selection is very small, there is essentially no response in *any* of the component traits.

V

Selection in Structured Populations

21

Family-Based Selection

*Practical breeding programs must be commercially optimal,
not theoretically maximal.* Fairfull and Muir (1996)

Up to now, we have focused on **individual selection**, wherein selection decisions are based solely on the phenotypes of single individuals (this is also referred to as **mass selection** or **phenotypic selection**, and we use all three terms interchangeably). Selection decisions can also incorporate the phenotypic values of an individual's measured relatives, and in fact, most plant- and animal-breeding schemes do so. The focus of this chapter is on **family-based** selection—using family information to select individuals. While we restrict discussion in this chapter to using sibs, the culmination of this approach is BLUP selection using an index based on the entire known pedigree of an individual, which is the major route for artificial selection in most domesticated animals (Chapters 13 and 19). While our focus here is on short-term selection response (formally, the single-generation response), certain family-based schemes can give a greater long-term response than individual selection, even when their initial response is less. This long-term advantage arises because of larger effective population sizes associated with selection schemes that down-weight among-family differences, a point examined in detail in Chapter 26.

There are a variety of reasons for using family-based schemes. Employing mass selection may be impractical in many settings due to difficulties in measuring trait values in single individuals (e.g., most forage crops and cereals). Family-based designs can also provide greater accuracy in predicting an individual's breeding value, and hence can give a larger (short-term) response. In particular, an appropriately weighted index of an individual's family mean and phenotypic value has an expected response at least as large as mass selection. When significant environmental heterogeneity exists (e.g., crops planted across a broad climatic range), the replication of families over environments provides a more efficient method than mass selection for choosing higher-performing genotypes. This is one major factor leading crop breeders to favor family-based schemes over individual selection.

The structure of this chapter is as follows. We start with a brief overview of the nature and types of family-based selection schemes before considering extensions of the generalized breeder's equation to accommodate these approaches. Next, we develop the variances and covariances required to apply these equations, and then consider a number of these schemes in detail. The relative efficiencies of within- and among-family selection compared to mass selection are then examined, followed by a consideration of designs in which families are replicated over environments, as is usually the case in plant breeding. We conclude by examining the properties of family-index selection. While most of the concepts in this chapter are straightforward, the bookkeeping can be tedious at times. Thus, we summarize key results at the end of various sections to allow the casual reader to more easily navigate through this material.

INTRODUCTION TO FAMILY-BASED SELECTION SCHEMES

Family-based designs are based on two approaches: **among-family** schemes, which choose entire families on the basis of their mean performance, and **within-family** schemes, which choose individuals based on their relative performance within their families. While many designs are based on just one of these components, the most general approach is **family-index selection**, wherein individuals are chosen based on a weighted index of among- and within-family components. Mass selection is a special case of a family index, where the within- and among-family components are weighted equally. (Although the phrase

“between-family selection” is widely used in the literature, “between” refers to a comparison of two items, while “among” refers to comparisons of two or more, which is the general setting here. Hence, while between- and among- are used interchangeably in the literature, we will use “among” throughout our discussion here.)

While we assume that the parents in any particular family are from the same population, in some breeding settings the parents are from different populations. Examples of this are **interpopulation improvement** schemes, where the goal is to improve the performance of *hybrids* among populations (Volume 3). The focus in this chapter is family-based schemes for **intrapopulation improvement** (increasing the performance of the population under selection).

Overview of the Different Types of Family-based Selection

The key to making sense out of the bewilderingly large number of family-based designs in the literature is to consider the individual components that together define any particular scheme. The first component is the *type of sib family providing information for selection decisions*. A family may consist of half-sibs, full-sibs, or full-sibs nested within half-sibs (e.g., the NC Design I; see LW Chapter 18). Sibs can also be generated by one (or more) generations of selfing (e.g., S_1 , S_2), and we examine such families in Chapter 23. While the family-based schemes developed in this chapter are generally used with **allogamous** species (outcrossers, cross-pollination), they can also be applied to facultatively **autogamous** species (facultative selfers, self-pollination) through the use of controlled pollination and/or the introduction of male-sterile genes under open pollination (e.g., Gilmore 1964; Doggett and Eberhart 1968; Brim and Stuber 1973; Burton and Brim 1981; Sorrells and Fritz 1982).

Once a particular family type has been chosen, the second component is *how sib data are used for selection decisions*. One could use among-family selection, choosing the best families (i.e., those with the largest family means). Alternatively, one could use within-family selection, choosing either the best individuals within each family (**strict within-family [WF] selection**), or the individuals with the largest *deviations* from their family means (**family-deviations [FD] selection**). While WF and FD selection are very similar, there are subtle differences between the two schemes, as they do not necessarily select the same individuals. One could also consider an index weighting both family mean and family deviations.

The final design component is the *relationship between the measured sibs and the individuals serving as parents for the next generation*. Under either within-family or family-index selection, the selected individuals are used to form the next generation. However, in among-family selection, we can use any number of relatives of the chosen (selected) families to form the next generation. The most straightforward approach is to use measured sibs from the chosen families (**family selection**). However, some characters cannot be scored on living organisms, such as carcass traits in production animals, or can only be scored after reproduction. In such cases, one can use unmeasured sibs from the best families as the parents of the next generation (**sib selection**), which is often used to improve selection on sex-specific traits. For example, milk production can be selected for in males by choosing sires from families whose sisters show high levels of production. An important variant of sib selection is the use of **remnant seeds** from the best families, which are planted and subsequently crossed to form the next generation. In perennial species and in annual species that can be asexually propagated (cloned), one can select the best parents by the performance of their offspring (**parental selection or progeny testing**). Finally, an option available for facultatively autogamous species is to both self an individual to generate S_1 progeny (S_1 seeds) and likewise outcross it to one or more individuals to generate a family for testing. For such species, one can grow and intercross the remnant S_1 seed from the chosen families to form the next generation (the **S_1 seed design**).

Plant Versus Animal Breeding

While animal breeders typically employ only a few standard sib-based designs (Turner and

Young 1969), plant breeders can choose from a vast array of options (e.g., Hallauer and Miranda 1981; Schnell 1982; Nguyen and Sleper 1983; Wricke and Weber 1986; Hallauer et al. 1988; Aastveit and Aastveit 1990; Nyquist 1991; Vogel and Pedersen 1993; Holland et al. 2003; Hallauer et al. 2010). Furthermore, the final product desired by a plant breeder can vary considerably: it could be an open-pollinated population, an F_1 hybrid, a pure (i.e., fully inbred) line, or a synthetic line. Thus, it is not surprising that the literatures on family-based selection in the two fields are rather divergent. Much of the animal-breeding literature is expressed in terms of the phenotypic (t) and additive-genetic (r) correlations among sibs, while much of the plant-breeding literature is expressed in terms of variance components. As our discussion attempts to interweave both approaches, we will typically present selection-response equations in both forms.

Reproductive differences between plants and animals underlie many of the differences in the designs that are available to breeders. Historically, plant breeders have had more options than animal breeders because of the reproductive flexibility of many plants (i.e., selfing, stored seed, vegetation propagation; see Fehr and Hadley 1980). With the cloning of several domesticated animals, animal breeders now have the option of exploiting some of these classical plant-breeding schemes.

One obvious difference between plants and many animals is the ability to easily store progeny for many generations in the form of seed. Generally speaking, plants also produce far more offspring than domesticated animals, providing more offspring per family, and thus allowing for more extensive replication of families across environments. Another reproductive advantage of plants is that asexual propagation (cloning) is straightforward in many species, allowing individual genotypes to be preserved over generations.

Yet another key difference is in the control of crosses. While simple isolation will prevent most undesirable crosses in animals, either complete isolation or extensive manual control may be required to prevent pollination vectors from generating undesirable crosses in plants. When studying facultatively autogamous species, the investigator may be faced with either trying to prevent selfing or trying to prevent outcrossing, or to allow for both while identifying which seed came from which type of cross. Options for controlled crosses range from complete manual control over pollination at one extreme to open pollination at the other. Given that most plants have multiple flowers (which are often both numerous and small), large-scale controlled crosses can be much more labor intensive than similar crosses among animals, as hand pollination and the control of external and/or self-pollinators may be required. Even under **open pollination** (allowing seed plants to be pollinated at random), the investigator still has different levels of control over the pollen spectrum that a seed plant experiences. In a **test cross** or **topcross** design, the population of plants supplying the pollen is controlled. For example, individual maize plants can be **detasseled** by hand (removing the pollen-producing tassels) or have their tassels bagged to prevent the plants from either selfing or pollinating other plants. Such plants serve only as seed plants and are intergrown with rows of the **tester** strain, which provide the pollen. Under true open pollination, seed parents are randomly pollinated from the population, with no control of the pollen parent. A consequence of open pollination is that while most half-sib families in animal breeding are paternal, most half-sib families in plant breeding are maternal (they share a common seed parent).

There are also more subtle biological differences between plants and animals that drive differences in designs. While one can usually score many traits in individual animals, this is often not done in plants. For example, many traits of forage grasses, grains, and legumes are scored as **plot totals**, which involves measuring the mean performance of an entire family (or line) instead of each separate individual. When individuals cannot be directly scored, among-family selection is possible, but within-family and family-index selection are not. Similarly, many selected traits in plants can be scored only after reproduction (seed or fruit yield being prime examples), and this influences the types of relatives that can be used to form the next generation.

Among- Versus Within-family Selection

When the heritability of a trait is high, an individual's phenotype is an excellent predictor of its breeding value, and mass selection is more efficient than either strict within- or among-family selection. When heritability is low, individual phenotypic value is a poor predictor of breeding value, in which case an individual's family mean or its relative performance within its family may be better predictors.

The relative efficiencies of among- versus within-family selection depend on the relative magnitudes of the common-family (E_c) and individual-specific (E_s) environmental variances. A large common-family effect severely compromises the phenotype as a predictor of breeding value. However, *within* each family, all members share the same environmental effect, and differences between individuals more accurately reflect differences in breeding value. In this case, selection within families (for example, by choosing the largest individuals from each family) can yield a larger response than individual selection. Many mouse selection experiments use within-family selection, especially for traits with suspected maternal effects, such as body weight (Falconer and Latyszewski 1952; Falconer 1953, 1960a; Eisen and Hanrahan 1972; von Butler and Pirchner 1984; Nielsen and Anderson 1987; Siewert et al. 1999), litter size (Falconer 1960b), and nesting behavior (Lynch 1980).

Conversely, suppose that environmental effects unique to each individual account for a large fraction of the phenotypic variance ($\sigma_{E_s}^2 \gg \sigma_{E_c}^2$). In this case, selecting whole families as units can give a larger response than individual selection, as the family mean averages out differences based on environmental values, revealing those families with the most extreme breeding values. An important example of this family-averaging of environmental effects is the use of among-family selection to improve performance across multiple environments. Under mass selection, a genotype is represented by a single individual in a single environment, while family-based approaches allow the performance of different families to be compared over multiple environments. Such studies are by no means restricted to plant breeding, as animal selection experiments examining phenotypic plasticity (norms of reaction), in which genotypes must also be assessed over multiple environments, almost exclusively use among-family selection (e.g., Waddington 1960; Kindred 1965; Waddington and Robertson 1966; Druger 1967; Scharloo et al. 1972; Brumpton et al. 1977; Minawa and Birley 1978; Scheiner and Lyman 1991).

DETAILS OF FAMILY-BASED SELECTION SCHEMES

Selection and Recombination Units

Under mass selection, individuals are scored and those with the best phenotypic values are used as parents to form the next generation. Here groups of individuals upon which selection decisions are based and those used for **recombination** (gamete production to form the next generation) are one and the same, and a single **cycle of selection** takes a single generation. In family-based selection schemes, the individuals used for selection decisions may be entirely separate from those used as parents to form the next generation. Further, a single cycle of selection may take two (or more) generations, as one must generate, score, and recombine families. For perennial species (such as forage crops), traits may be scored over several years before selection decisions are made, such as selecting for winter hardiness (Vogel and Pedersen 1993).

Following the convention of plant breeders, we distinguish between an individual, x_i , in the **selection unit** (those measured individuals upon which selection decisions are made, which throughout this chapter are we assume are sibs) and an individual, \mathcal{R}_i (a relative of x_i , potentially including x_i itself), from the **recombination unit** (individuals serving as parents for the next generation) whose resulting offspring are y . Even though we may not *directly* select on the parents ($\mathcal{R}_1, \mathcal{R}_2$) of y , we expect some response in y due to the genetic correlation between x_i and \mathcal{R}_i caused by their sharing of (at least) one common relative, P_i (Figure 21.1). An equivalent way to think about this distinction is that selection response occurs due to

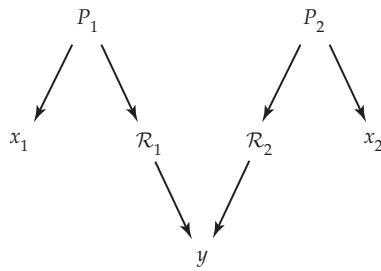

Figure 21.1 Under family-based schemes, selection decisions are based on some function of the values of measured sibs (x_i) in the selection unit. An offspring, y , in the next generation has parents, \mathcal{R}_1 and \mathcal{R}_2 , that are chosen on the basis of the selection unit. Members of the selection (x_i) and recombination (\mathcal{R}_i) units are related as they both share a common relative, P_i , which in this case is the parent of sib x_i . Under within-family or family-index selection, \mathcal{R} is simply one of the measured sibs, while under among-family selection, \mathcal{R} is often an *unmeasured* relative. See Figure 21.2 for specific examples.

observations on the selection unit, x , providing information to predict the breeding value of \mathcal{R} .

As mentioned in the introduction, the variety of family-based schemes appearing in the literature arises from the combination of four specific components:

1. **Type of sib family** comprising the selection unit. Sibs can be half- or full-sibs, full-sibs nested within half-sibs (NC Design I), or selfed sibs (which are considered in Chapter 23).
2. **Nature of the selection decisions** based on the sib information. Selection can be based on sib-family means, the deviations of individuals within families, an index of both, or strict rank within families.
3. **Selection on one versus both parents.** Often selection decisions involve only one sex, with the parents of the opposite sex chosen at random (and hence being unselected). For example, a trait may not be scorable until after pollination, resulting in selection on seed parents (females) but not on pollen parents (males). In such cases, we are only concerned with one side of the pedigree, for example, involving \mathcal{R}_1 but not \mathcal{R}_2 (Figure 21.1). More generally, the two parents (\mathcal{R}_1 and \mathcal{R}_2) of the offspring, y , may be chosen using different schemes, which generates a variety of family-based schemes.
4. **Nature of the relationship between a measured sib, x_i , in the selection unit and a parent, \mathcal{R}_i , of the next generation.** Under within-family or family index selection, \mathcal{R} is one of the measured sibs ($\mathcal{R}_i = x_i$), while under among-family selection, \mathcal{R} is often an unmeasured relative. For example, \mathcal{R}_i could be the parent of the sibs ($\mathcal{R}_i = P_i$), meaning that the relationship between x and \mathcal{R} is that of parent-offspring, or it could be an unmeasured sib, meaning that the relationship between x and \mathcal{R} is that of either half- or full-sib (depending on the type of family).

While the variety of family-based selection schemes may seem a bit overwhelming at first (especially in the plant-breeding literature), considering each design in terms of these four components greatly simplifies matters.

Variations of the Selection Unit

Once the type of family (half-sib, full-sib, nested, or inbred S_i) has been specified, there is still the issue of how to incorporate sib information when making selection decisions. To distinguish between a particular sib and the *trait value* of that sib, we use x_i to denote the i th sib and z_i to denote its trait value, and more generally, x_{ij} and z_{ij} for the j th individual

from the i th family. We select the uppermost fraction, p , of the relevant population, with m families each with n sibs, for a total of $M = mn$ scored individuals, which we use to choose N parents. Four different approaches for weighting sib information are commonly used:

1. **Among-family selection:** Individuals are selected solely on the basis of their family means, \bar{z}_i , with the result that all individuals from the same family have the same selective rank. Here, the best $N = pm$ families are chosen.
2. **Strict within-family (WF) selection.** The best pn individuals from *each* family are chosen ($N = pnm = pM$), so that individuals are ranked within each family. WF selection increases the effective population size because the among-family variance in offspring number is zero (Chapters 3 and 26).
3. **Selection on within-family deviations (FD):** Individuals are ranked solely on the basis of their within-family deviation, $z_{ij} - \bar{z}_i$. The $N = pM$ individuals with the largest deviations (regardless of family) are chosen.
4. **Family-index selection:** Individuals are ranked using an index weighting within- and among-family components

$$I = b_1(z_{ij} - \bar{z}_i) + b_2\bar{z}_i = b_1 z_{ij} + (b_2 - b_1)\bar{z}_i$$

The pM individuals with the best index scores are chosen. Note that the index with weights (cb_1, cb_2) chooses the same individuals as an index with weights (b_1, b_2) . Thus, one of the index weights is often set to one, as the indices with weights (b_1, b_2) , $(1, b_2/b_1)$, and $(b_1/b_2, 1)$ are all equivalent (in that they all choose the same individuals). Individual selection, among-family selection, and selection on family deviations (FD) are special cases, being indices with weights $(b_1, b_2) = (1,1)$, $(0,1)$, and $(1,0)$, respectively. Note, however, that strict within-family (WF) selection cannot be expressed in terms of an index. Family-index selection is also referred to as **combined selection**, which is unfortunate, as the same term is also used by breeders to refer to approaches that combine *different types* of selection schemes in a single cycle (such as modified ear-to-row selection, discussed below).

The choice of the particular scheme has implications for the selection intensity (Example 21.1). When the fraction saved (p) is fixed, among-family and strict within-family selection have lower selection intensities than family-deviations, index, or mass selection. The former selects the best pm of m families and pn of n sibs, while the latter three select the best pM of M individuals. Because M is greater than either n or m , the finite-sample value for \bar{t} is larger when sampling from M than from n or m (Chapter 14).

Example 21.1. Suppose that a total of 100 sibs are measured and the fraction that is selected is $p = 0.2$. As a benchmark, for this level of selection, the infinite-population value for the selection intensity is $\bar{t} = 1.40$ (Equation 14.3a). Suppose that the $M = 100$ total measured sibs are distributed into 20 families of five sibs each ($m = 20$, $n = 5$). Under within-family selection, the top 1 of 5 within each family is selected. Under among-family selection, the top 4 of the 20 families are selected. Finally, under family-deviations or index selection, the top 20 of the 100 measured individuals are selected. Using the finite-size correction approximation offered by Equation 14.4b yields the following selection intensities:

Individual selection (infinite population)	Best 20%	$\bar{t}_\infty = 1.40$
Individual selection, index selection,		
family-deviations (FDs) selection	Best 20 of 100	$\bar{t}_{(20,100)} = 1.39$
Among-family selection	Best 4 of 20	$\bar{t}_{(4,20)} = 1.33$
Strict within-family selection (WF)	Best 1 of 5	$\bar{t}_{(1,5)} = 1.16$

As shown later (Equations 21.40 and 21.57), additional corrections to the selection intensity are required in some cases, as family members are correlated, which changes the variance

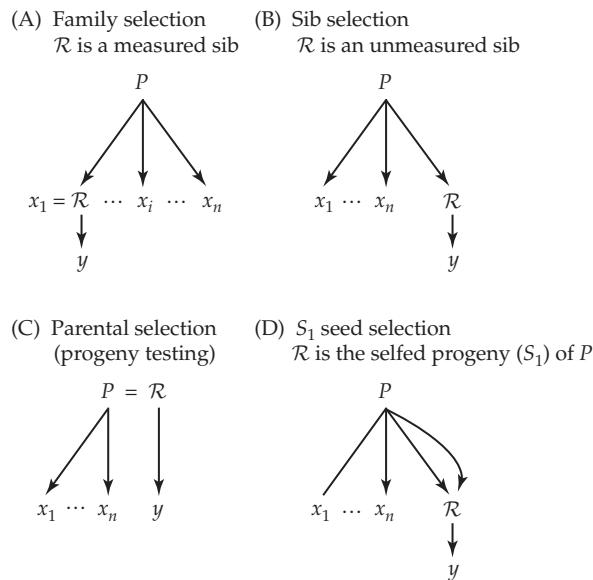

Figure 21.2 Under among-family selection, decisions as to which families to choose are made on the basis of observations from sibs, while the next generation is formed by crossing relatives (\mathcal{R}) of sibs from the chosen families. The measured sibs upon which selection decisions are based are denoted by x_1, \dots, x_n , while y denotes a random offspring from a random member, \mathcal{R} , from the recombination unit. Different types of relatives can be used for \mathcal{R} , with a few of the most common types illustrated here. Let P denote the shared parent(s) of x_i and \mathcal{R} . The pedigrees illustrated here all focus on just one parent of y , with a corresponding pedigree for the other parent. **A:** Family selection: \mathcal{R} is one of the measured sibs ($x_1 = \mathcal{R}$). **B:** Sib selection: \mathcal{R} is an unmeasured sib. **C:** Parental selection (also known as progeny testing): \mathcal{R} is the parent of the sibs ($\mathcal{R} = P$). **D:** S_1 seed selection: \mathcal{R} is the selfed progeny of the parent of the sibs, but \mathcal{R} is then outcrossed to generate the offspring, y . In this chapter, we assume offspring are generated by outcrossing (\mathcal{R}_1 and \mathcal{R}_2 are unrelated), whereas in Chapter 23 we examine the setting wherein y is obtained by selfing \mathcal{R} , as well as more general inbreeding schemes (such as the tested sibs being the result of selfing).

relative to n unrelated individuals. Ignoring this correction (for now), note that strict within-family (WF) selection has only 83% of the selection intensity (for this example) as family-deviations (FDs) selection.

Finally, the choice of the selection scheme also influences the long-term effective population size (and hence the long-term response; see Chapter 26), with schemes that place more weight on among-family components resulting in smaller effective population sizes (due to larger among-family offspring variances) than those that place more weight on within-family components (Chapter 3).

Variations of the Recombination Unit

Under either within-family or index selection, measured individuals are selected as the parents for the next generation, which forms the recombination unit. By contrast, with among-family selection there are a variety of options for the nature of the relatives that comprise the recombination unit (Table 21.1; Figure 21.2). The most straightforward situation is **family selection**, using measured sibs from each chosen family as the parents for the next generation (Figure 21.2A). Under **sib selection**, unmeasured sibs from the chosen families are used to form the next generation (Figure 21.2B).

Table 21.1 Family-based selection schemes using outbred sibs. Families are selected based on the sib values z_{i1}, \dots, z_{in} . \mathcal{R}_i denotes a relative of the i th selected family used to form the next generation. The variables \bar{z}_{HS} and \bar{z}_{FS} denote the sample means, and μ_{HS} and μ_{FS} denote the true means, of half- and full-sib families, respectively, while P is the parent of the measured sibs, and z_{ij} denotes the j th measured sib from family i .

	Recombination Unit \mathcal{R}	Selection Unit x
Among-family Selection		
Family selection	Measured sib	
Half-sib family selection		\bar{z}_{HS}
Full-sib family selection		\bar{z}_{FS}
Sib selection / Remnant seed	Unmeasured sib	
Half-sib sib selection		\bar{z}_{HS}
Full-sib sib selection		\bar{z}_{FS}
Parental selection / Progeny testing	Parent P	\bar{z}_{HS}
S_1 Seed Selection	S_1 Seed of P	
Half-sib S_1 seed selection		\bar{z}_{HS}
Full-sib S_1 seed selection		\bar{z}_{FS}
Within-family Selection		
Family deviations (FD) selection	Measured Sib	
Half-sib family deviations selection		$z_{ij} - \bar{z}_{HS}$
Full-sib family deviations selection		$z_{ij} - \bar{z}_{FS}$
Strict within-family (WF) selection	Measured Sib	
Half-sib strict within-family selection		$z_{ij} - \mu_{HS}$
Full-sib strict within-family selection		$z_{ij} - \mu_{FS}$

In animal breeding, sib selection is often used for traits that are sex-limited or that cannot be scored without sacrificing the individual. Plant breeders routinely use sib selection in the form of **remnant seeds**. Here, seeds from a cross are split into two batches and one is planted and used to assess families while the other is held in reserve. Seeds from the chosen families are then grown and crossed to form the next generation. Under this design, a single **cycle of selection** takes (at least) two generations—(at least) one to assess the families and a second to grow and cross the remnant seeds. Given this extra generation, what is the advantage of crossing plants from remnant seeds to form the next generation? For annual plants, any traits that are expressed during or after flowering can only be directly selected in already pollinated females, with seeds from the best-performing plants forming the next generation. Because these plants were pollinated at random, selection has occurred for the seed, but not the pollen, parents. By using remnant seeds, one can choose the best families, grow their remnant seeds, and allow the resulting plants to randomly intercross. Because both seed and pollen parents have now been selected (through their families), a single cycle of selection using remnant seed has double the response of family selection on seed from open pollinated plants. This doubling of response per cycle exactly counters the extra generation in each cycle, so open-pollinated family selection and sib selection using remnant seed have the same expected response per generation. One potential advantage with the use of remnant seed is that the extra generation to grow the seeds to mature plants for crossing can be used for selection on other characters, for example, culling those otherwise elite families that show poor disease or insect resistance.

Another common among-family design is **parental selection** (or **progeny testing**), where $\mathcal{R} = P$, the parent of the measured sibs (Figure 21.2C). This design typically involves evaluation of half-sib families with selection on just one sex. In animal breeding, these are typically sires, elite males chosen by the performance of their half-sib families, which is greatly facilitated by the use of artificial insemination and frozen semen. The ability to clone domesticated animals (e.g., sheep, Campbell et al. 1996; goats, Baguisi et al. 1999;

and cattle, Wells et al. 1999a, 1999b) is likely to further increase the importance of progeny testing in animal-breeding settings. (The most elaborate, and widely used, extension of progeny testing is BLUP selection wherein the entire pedigree is used for information on selection decisions; Chapter 19). Plant breeders typically perform progeny testing using maternal half-sib families (seed from the common parent). Vegetative propagation (cloning) allows even some annual plants to be used as parents in future generations. Depending on reproductive timing, if the species being selected is **monoecious** (single individuals produce both seed and pollen), one potentially may be able to obtain elite plants for both seed and pollen on the basis of female (seed) performance, and hence select on both sexes.

Finally, with self-compatible species, an alternative to vegetative propagation is the **S₁ seed design** (Figure 21.2D). For each parent, a subset of flowers is selfed to produce S₁ seed and the remainder are outcrossed. The outcrossed seed is then grown to produce the sibs in which the trait of interest is assessed. Following selection of the best families, their S₁ seed grown and the adults from different families are crossed to form the next generation. As with remnant seed, a single cycle takes two generations. In maize, the S₁ seed design requires the use of **prolific plants** (those with more than one ear), as one ear is selfed, and the other(s) outcrossed. Hallauer and Mirana (1981) noted that the use of such plants also results in selection for prolificacy, which by itself can increase yield. An advantage of designs using remnant seed is that traits can be scored over several years before selection, providing the opportunity to select over temporal variation in the environment. As presented in this chapter, the S₁ seed design has a random-mated family as the selection unit. Obviously, one could collect only S₁ seed from a plant and use some for selection decisions (i.e., the selection unit is an S₁ family) and the rest for future breeding. Such designs, where the selection unit is a selfed family, are examined in Chapter 23.

THEORY OF EXPECTED SINGLE-CYCLE RESPONSE

Response is typically given on a *per-cycle*, rather than per-generation, basis. A cycle begins with choosing the parents, P , to form the sib families and ends with the creation of offspring, y , formed by crossing members, \mathcal{R} , from the recombination unit. The expected response is the difference in the means of these two populations (P vs. y). When comparing the efficiencies of different schemes, response per cycle should be converted to a response per generation (for discrete generations) or per unit time (for overlapping generations).

Our treatment of the theory of response starts by developing several equivalent modifications of the breeder's equation (Chapter 13) to accommodate family-based selection. To apply these expressions, we require the **selection unit-offspring covariance**, $\sigma(x, y)$, and the **variance of the selection unit**, σ_x^2 , for various family-based designs. The full development of these variances and covariances is straightforward but involves a fair amount of bookkeeping. The reader wishing to skip the details can find the results summarized below in Tables 21.3 and 21.4.

Modifications of the Breeder's Equation for Predicting Family-based Response

Response is a function of how selection decisions based on the sib families (x_1 and x_2) translate into selection on the corresponding parents (\mathcal{R}_1 and \mathcal{R}_2) of the offspring, y . Phrased in terms of breeding values, we predict response by using the sib information to predict the breeding values of the parents, \mathcal{R} , for the next generation. Under the infinitesimal model, the expected mean of the offspring equals the mean breeding value of the chosen parents (Chapters 6 and 13).

Making the standard assumption that all appropriate regressions are linear (which follows under the infinitesimal model assumptions; Chapters 6 and 24), the expected response is given by the general form of the breeder's equation (Equations 13.4a and 13.4b),

$$R_y = \frac{\sigma(x_m, y)}{\sigma_{x_m}^2} S_{x_m} + \frac{\sigma(x_f, y)}{\sigma_{x_f}^2} S_{x_f} \quad (21.1a)$$

Here x_m and x_f correspond to individuals from the selection units associated with the male (sire/pollen) and female (dam/seed) parents (\mathcal{R}_m and \mathcal{R}_f) of the offspring, y . Equation 21.1a allows the male and female parents to be chosen by completely different schemes. For example, sib selection could be used on males and individual selection on females when selecting for a female-limited character (Example 13.5). The selection unit-offspring covariance, $\sigma(x, y)$, can be directly computed from the pedigree connecting P , a sib in x , and \mathcal{R} through the use of path analysis (LW Appendix 2). The path (or correlation) between selection on the unit, x_f , through the female parent, \mathcal{R}_f , and its offspring, y , is

$$x_f \leftarrow P \rightarrow \mathcal{R}_f \rightarrow y$$

Because the path connecting x_f and y is through \mathcal{R}_f , we often write $\sigma(x, y | \mathcal{R}_f)$ in place of $\sigma(x_f, y)$ to remind the reader of this fact. Path(s) connecting x_m and y through \mathcal{R}_m are similarly defined. If P consists of multiple relatives, each path connecting x_i and \mathcal{R}_i (and hence y) needs to be counted. For example, if x_i and \mathcal{R}_i are full-sibs, we must compute the paths through each of the common parents (e.g., Figure 21.3D). If the selection unit-offspring covariances are the same for both parents, Equation 21.1a simplifies to

$$R_y = \frac{\sigma(x, y)}{\sigma_x^2} S_x \quad (21.1b)$$

where $S_x = (S_{x_m} + S_{x_f})/2$ is the average selection differential on the unit(s) leading to the parents and

$$\sigma(x, y) = \sigma(x, y | \mathcal{R}_f) + \sigma(x, y | \mathcal{R}_m) = 2\sigma(x, y | \mathcal{R}) \quad (21.1c)$$

is the covariance between the value of selection unit, x , and the offspring, y , counting the paths through both parents (\mathcal{R}_m and \mathcal{R}_f). When covariances are equal, this is twice the single parent-covariance, $\sigma(x, y | \mathcal{R}_1)$. By analogy with the breeder's equation, Equation 21.1b is often written as

$$R_y = h_{x,y}^2 S_x \quad (21.2a)$$

where the **generalized heritability** of y given x ,

$$h_{x,y}^2 = \frac{\sigma(x, y)}{\sigma_x^2} = 2 \left[\frac{\sigma(x, y | \mathcal{R})}{\sigma_x^2} \right] \quad (21.2b)$$

is twice the slope of the regression of y on x (LW Chapter 3). Just as the individual heritability, h^2 , is the accuracy in using an individual's phenotypic value to predict the breeding value (Chapter 13), the generalized heritability is the accuracy of using the sib data, x , to predict the breeding value of \mathcal{R} .

Example 21.2. Consider family selection, wherein the selection unit is the family mean, \bar{z}_i , and the recombination units are measured sibs (those whose trait values have been scored) from this family. Assuming the covariance between the sib mean and an individual sib is independent of sex, Equations 21.1b and 21.1c yield a response of

$$R_b = \frac{2\sigma(\bar{z}_i, y | \mathcal{R}_i)}{\sigma^2(\bar{z}_i)} S_b$$

Recall (Equation 21.1c) that the numerator is twice the covariance between the value of the family mean, \bar{z}_i , and the offspring, y , from a parent chosen from this family, \mathcal{R}_i , which (in this case) is one of the measured sibs. The preceding expression can be more compactly written as $R_b = h_b^2 S_b$, where the **among-family heritability** is

$$h_b^2 = \frac{2\sigma(\bar{z}_i, y | \mathcal{R}_i)}{\sigma^2(\bar{z}_i)}$$

We used the notation R_b and h_b^2 for “between family” in keeping with the literature (although this is formally among families, as it generally involves more than two families). Similarly, for selection on within-family deviations, the value of the selection unit is $z_{ij} - \bar{z}_i$, which yields

$$R_{FD} = \frac{2\sigma(z_{ij} - \bar{z}_i, y | \mathcal{R}_i)}{\sigma^2(z_{ij} - \bar{z}_i)} S_{FD}$$

where $\mathcal{R}_i = x_{ij}$. Response can also be expressed in terms of the **family-deviations heritability**, with $R_{FD} = h_{FD}^2 S_{FD}$, where

$$h_{FD}^2 = \frac{2\sigma(z_{ij} - \bar{z}_i, y | \mathcal{R}_i)}{\sigma^2(z_{ij} - \bar{z}_i)}$$

Tables 21.3 and 21.4 (below) give expressions for these variances and covariances.

Other (equivalent) versions of Equations 21.1a and 21.2a appear in the literature. The **selection-intensity version** allows for standardized comparisons of different selection schemes. Defining the selection intensity on x by $\bar{i}_x = S_x/\sigma_x$, Equation 21.1a becomes

$$R_y = \frac{\sigma(x_m, y)}{\sigma_{x_m}} \bar{i}_{x_m} + \frac{\sigma(x_f, y)}{\sigma_{x_f}} \bar{i}_{x_f} \quad (21.3a)$$

If the regressions are the same for both parents,

$$R_y = \frac{\sigma(x, y)}{\sigma_x} \bar{i}_x \quad (21.3b)$$

where $\bar{i}_x = (\bar{i}_{x_m} + \bar{i}_{x_f})/2$ is the average selection intensity. This expression is frequently written in terms of the selection unit-offspring correlation, $\rho(x, y)$,

$$R_y = \sigma_z \bar{i}_x \rho(x, y) \quad (21.4a)$$

where (counting both parents) $\rho(x, y) = 2\rho(x, y | \mathcal{R})$. Equation 21.4a follows immediately from Equation 21.3b by recalling that $\rho(x, y) = \sigma(x, y)/(\sigma_x \sigma_y)$ and that the trait variance in the offspring, y , is simply the phenotypic variance of the character ($\sigma_y^2 = \sigma_z^2$). A variant of Equation 21.4a commonly seen in the literature is

$$R_y = \sigma_A \bar{i}_x \rho(x, A_{\mathcal{R}}) \quad (21.4b)$$

where $\rho(x, A_{\mathcal{R}})$, the correlation between the value of the selection unit, x , and the breeding value of a parent, \mathcal{R} , of y , is the accuracy of selection (Equation 13.11a). Equation 21.4b holds in the absence of epistasis, while Equations 21.1–21.3 hold for arbitrary epistasis. Recall that the accuracy of individual selection (the correlation between an individual’s phenotypic and breeding values) is $\rho(z_{\mathcal{R}}, A_{\mathcal{R}}) = h$. A particular family-based approach is favored over individual selection if x is a more accurate predictor of the breeding value of \mathcal{R} than is \mathcal{R} ’s phenotypic value, that is when $\rho(x, A_{\mathcal{R}}) > h$.

Equation 21.4b follows by first recalling that the mean value of an offspring is the average of its parental breeding values, $y = \mu + (A_{\mathcal{R}_m}/2) + (A_{\mathcal{R}_f}/2) + e_y$. Hence,

$$\sigma(x, y) = \frac{1}{2}\sigma(x, A_{\mathcal{R}_m}) + \frac{1}{2}\sigma(x, A_{\mathcal{R}_f}) + \sigma(x, e_y)$$

In the absence of epistasis, inbreeding, and shared environmental effects, $\sigma(x, e) = 0$. If the regression is the same for both sexes, then $\sigma(x, y) = \sigma(x_1, A_{\mathcal{R}_1})$. Recalling that $\sigma_y = \sigma_z$,

$$\rho(x, y) = \frac{\sigma(x, y)}{\sigma_x \sigma_z} = \left(\frac{\sigma_A}{\sigma_z} \right) \frac{\sigma(x_1, A_{\mathcal{R}_1})}{\sigma_x \sigma_A} = h \rho(x, A_{\mathcal{R}}) \quad (21.5)$$

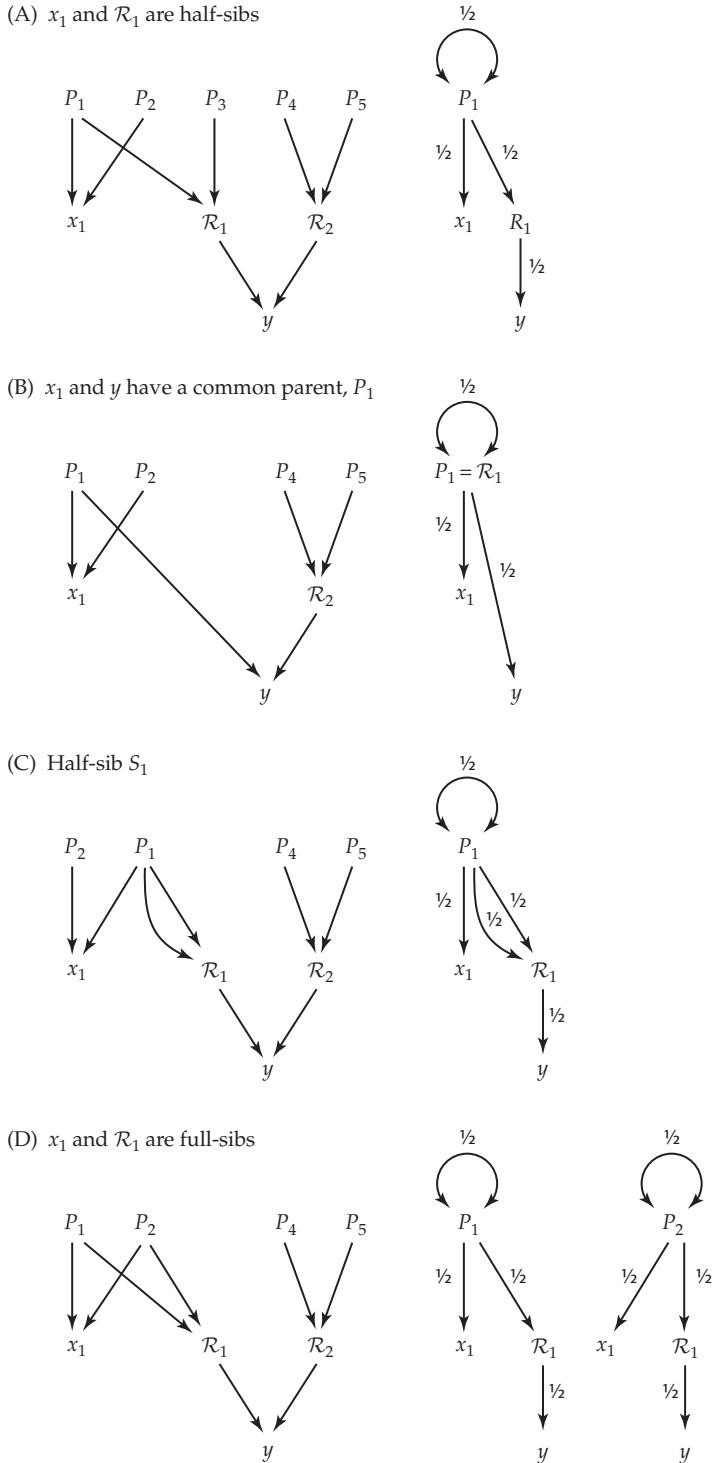

Figure 21.3 Derivation of the coefficient of coancestry, Θ , values in Table 21.2, showing pedigrees (left) and associated path diagrams (right) for computing Θ between a measured sib, x_1 , and an offspring, y , from the parent, \mathcal{R}_1 . P_1 to P_5 are assumed to be unrelated and noninbred.

A: x_1 and \mathcal{R}_1 are half-sibs. The product of the path coefficients yields $\Theta_{x_1y} = (1/2)^4 = 1/16$.

B: x_1 and y are half-sibs, with $\Theta_{x_1y} = (1/2)^3 = 1/8$.

C: \mathcal{R}_1 is a selfed progeny from the common parent, P_1 . There are two separate paths between x_1 and y (two different routes through P_1), yielding $\Theta_{x_1y} = 2 \cdot (1/2)^4 = 1/8$.

D: x_1 and \mathcal{R}_1 are full-sibs. Again there are two paths between x_1 and y (one through each parent), each being $(1/2)^4$, giving a total of $\Theta_{x_1y} = 2 \cdot (1/2)^4 = 1/8$.

Table 21.2 Coefficients of coancestry, Θ , between an offspring, y (of parent \mathcal{R}_1), and a member of the selection unit, x_1 . Genetic covariances, $\sigma_G(x_1, y)$, are computed with the assumption of no epistasis. Derivations are given in Figure 21.3.

Relationship between x_1 and \mathcal{R}_1	Θ_{x_1y}	$\sigma_G(x_1, y) = 2\Theta_{x_1y} \sigma_A^2$
$x_1 = \mathcal{R}_1$ (the sib is also the parent of y)	1/4	$\sigma_A^2/2$
x_1 and \mathcal{R}_1 are half-sibs (Figure 21.3A)	1/16	$\sigma_A^2/8$
x_1 and \mathcal{R}_1 are full-sibs (Figure 21.3D)	1/8	$\sigma_A^2/4$
\mathcal{R}_1 is the parent of both x_1 and y (Figure 21.3B)	1/8	$\sigma_A^2/4$
\mathcal{R}_1 is an S_1 offspring of the parent of x_1 (Figure 21.3C)	1/8	$\sigma_A^2/4$

Substitution into Equation 21.4a recovers Equation 21.4b (as $\sigma_z h = \sigma_z (\sigma_A/\sigma_z) = \sigma_A$). Equations 21.1–21.4 provide equivalent expressions for computing the expected selection response. To apply these expressions to a particular selection scheme, we need to compute the selection unit-offspring covariance, $\sigma(x, y)$, and the variance of the selection unit, σ_x^2 .

The Selection Unit-offspring Covariance, $\sigma(x, y)$

Recall that the genetic covariance between two (noninbred) relatives is a function of their **coefficients of coancestry**, Θ , and **fraternity**, Δ , (LW Chapter 7). If we ignore epistasis (for now), the genetic covariance between a particular sib, x_i , and y is $\sigma_G(x_i, y) = 2\Theta_{x_iy} \sigma_A^2 + \Delta_{x_iy} \sigma_D^2$ (LW Equation 7.12). In the absence of inbreeding in y (the parents \mathcal{R}_1 and \mathcal{R}_2 are from different, unrelated families; $\Theta_{\mathcal{R}_1, \mathcal{R}_2} = 0$), Δ_{xy} is zero. Note that $\Delta = 0$ even when \mathcal{R}_1 and/or \mathcal{R}_2 are themselves inbred, provided that they are unrelated. For dominance effects to be shared by relatives, there must be paths wherein *both* alleles from an individual, x , in the selection unit are passed onto the offspring, y , which cannot occur if the parents of y (\mathcal{R}_1 and \mathcal{R}_2) are unrelated.

The coefficient of coancestry between x_1 and y depends upon the relationship between \mathcal{R}_1 and x_1 . The designs covered in Table 21.1 involve four different relationships (Figure 21.2): (i) $x_1 = \mathcal{R}_1$ (a measured sib is a parent of y), (ii) x_1 and \mathcal{R}_1 are sibs, (iii) $\mathcal{R}_1 = P_1$ (the parent of x_1), and (iv) \mathcal{R}_1 is the selfed-progeny of the parent of x_1 . The path diagrams for computing Θ_{x_1y} for these four relationships are given in Figure 21.3, and Table 21.2 summarizes the resulting genetic covariances. The parents, P_i , are assumed to be non-inbred (i.e., $\Theta_{P_i P_i} = 1/2$). If they are inbred, then $\Theta_{P_i P_i} = (1 + f_i)/2$, where i is the inbreeding coefficient on that parent, and the expressions in Table 21.2 are multiplied by this additional factor (for each inbred parent).

As an example of how the coefficients of coancestry given in Table 21.2 are used, consider family selection. Ignoring epistasis,

$$\begin{aligned} \sigma(\bar{z}_i, y | \mathcal{R}_1 = x_{ij}) &= \frac{1}{n} \sum_k \sigma(z_{ik}, y | \mathcal{R}_1 = x_{ij}) = \frac{1}{n} \sigma(z_{ij}, y) + \left(1 - \frac{1}{n}\right) \sigma(z_{ik}, y) \\ &= \sigma_A^2 \left[\frac{1/2}{n} + \left(1 - \frac{1}{n}\right) 2\Theta_{z_{ik}y} \right] \end{aligned} \quad (21.6a)$$

This follows because the first covariance, $\sigma(z_{ij}, y)$, is for parent and offspring ($\sigma_A^2/2$), while the second covariance, $\sigma(z_{ik}, y)$, follows using the appropriate value of 2Θ from Table 21.2 (1/8 for half-sibs and 1/4 for full-sibs). Using the results from Table 21.2, expressions for the sib selection, parental selection (progeny testing), and S_1 seed designs follow in similar fashion. These are summarized in Table 21.3.

In much of the animal-breeding literature, **Wright's coefficient of relationship**, r , is used in place of 2Θ . Assuming no inbreeding, $r = 1/4$ for half-sibs and 1/2 for full-sibs.

Table 21.3 Summary of the covariances between the selection unit and one parent (\mathcal{R}_1) from the recombination unit. As given by Equation 21.6b, $r_n = r + (1 - r)/n$, where (for non-inbred sibs), $r = 1/2$ and $1/4$, for full-sibs and half-sibs, respectively.

Among-family Selection:

Family selection (\mathcal{R}_1 is a measured sib from family i)

$$\sigma(\bar{z}_i, y | \mathcal{R}_1) = r_n (\sigma_A^2/2) = \begin{cases} (1 + 3/n)(\sigma_A^2/8) & \text{half-sibs} \\ (1 + 1/n)(\sigma_A^2/4) & \text{full-sibs} \end{cases}$$

Sib selection / Remnant seed (\mathcal{R}_1 is an unmeasured sib from family i)

$$\sigma(\bar{z}_i, y | \mathcal{R}_1) = r (\sigma_A^2/2) = \begin{cases} \sigma_A^2/8 & \text{half-sibs} \\ \sigma_A^2/4 & \text{full-sibs} \end{cases}$$

Parental selection / Progeny testing (\mathcal{R}_1 is a parent of the measured sibs)

$$\sigma(\bar{z}_i, y | \mathcal{R}_1) = \sigma_A^2/4$$

S₁ seed design (\mathcal{R}_1 is a selfed progeny of a parent of the measured sibs)

$$\sigma(\bar{z}_i, y | \mathcal{R}_1) = \sigma_A^2/4$$

Within-family Selection:

Selection on family deviations (FD)

$$\sigma(z_{ij} - \bar{z}_i, y | \mathcal{R}_1) = (1 - r_n) (\sigma_A^2/2) = \begin{cases} (1 - 1/n)(3/8)\sigma_A^2 & \text{half-sibs} \\ (1 - 1/n)(\sigma_A^2/4) & \text{full-sibs} \end{cases}$$

Strict within-family selection (FW)

$$\sigma(z_{ij} - \mu_i, y | \mathcal{R}_1) = (1 - r) (\sigma_A^2/2) = \begin{cases} (3/8)\sigma_A^2 & \text{half-sibs} \\ \sigma_A^2/4 & \text{full-sibs} \end{cases}$$

Using Wright's coefficient, Equation 21.6a simplifies to

$$\sigma(\bar{z}_i, y | \mathcal{R}_1 = x_{ij}) = r_n \frac{\sigma_A^2}{2} \quad \text{where} \quad r_n = r + \frac{1 - r}{n} \quad (21.6b)$$

Considering the paths through both parents (\mathcal{R}_1 and \mathcal{R}_2) of y ,

$$\sigma(\bar{z}_i, y) = 2 \sigma(\bar{z}_i, y | \mathcal{R}_1) = r_n \sigma_A^2 \quad (21.6c)$$

Likewise, the covariance between an individual's family deviation and its offspring's phenotypic value is

$$\sigma(z_{ij} - \bar{z}_i, y | \mathcal{R}_1 = x_{ij}) = \sigma(z_{ij}, y | \mathcal{R}_1) - \sigma(\bar{z}_i, y | \mathcal{R}_1) = (1 - r_n) \frac{\sigma_A^2}{2} \quad (21.7a)$$

which follows because $\sigma(z_{ij}, y | \mathcal{R}_1)$ is the parent-offspring covariance, $\sigma_A^2/2$. Doubling the single-parent contribution yields a total contribution (considering both parents of y) of

$$\sigma(z_{ij} - \bar{z}_i, y) = (1 - r_n) \sigma_A^2 \quad (21.7b)$$

The covariance for strict within-family (WF) selection is slightly different (with r replacing r_n ; see Table 21.3), as the appropriate covariance here is $\sigma(z_{ij} - \mu_i, y)$, with μ_i in place of \bar{z}_i . The rankings of individuals under WF selection is simply their ranking within each family,

while their ranking under FD selection further depends on how much an individual actually deviates from its family mean. Thus, the top-ranked individuals in two families are always chosen under WF selection, but may not be chosen under FD selection. As a consequence, FD selection is influenced by the observed family mean, \bar{z}_i , while WF selection is a function of the true mean, μ_i (Dempfle 1975, 1990; Hill et al. 1996).

A few simple rules emerge from Table 21.3. The number, n , of measured sibs only influences the covariance for family selection and family-deviations selection. Even in these cases, its effect is small unless the number of sibs is small. Under sib selection (and family selection ignoring terms of order $1/n$), the selection unit-offspring covariance contributed through one parent (R_i) is $\sigma_A^2/8$ when the selection unit consists of half-sibs and $\sigma_A^2/4$ when the selection unit consists of full-sibs. For parental selection and S_1 seed designs, this covariance is $\sigma_A^2/4$ (independent of whether full-sibs or half-sibs are used in the selection unit). The covariance under WF selection (and FD selection when ignoring terms of order $1/n$) is $3\sigma_A^2/8$ for half-sibs and $\sigma_A^2/4$ for full-sibs.

Variance of the Selection Unit, σ_x^2

The variance, σ_x^2 , of the selection unit is a function of the within- and among-family variances, and obtaining it requires a bit of bookkeeping. We start by assuming that the total environmental value can be partitioned as $E = E_c + E_s$, a common-family effect (E_c) plus an individual-specific effect (E_s). This decomposes the total environmental variances into among- and within-family components, $\sigma_E^2 = \sigma_{E_c}^2 + \sigma_{E_s}^2$. When families are replicated over plots and environments, the environmental variance contains additional structure and is usually partitioned into further components (Equations 21.41 and 21.42).

The among-family variance σ_b^2 (the variance among the expected family means, μ_i) is

$$\sigma_b^2 = \sigma^2(\mu_i) = \sigma_{GF}^2 + \sigma_{E_c}^2 \quad (21.8a)$$

where σ_{GF}^2 , the among-family genetic variance (the variance in the expected mean genotypic value among families), is developed below (Equations 21.11a and 21.26a). Likewise, the within-family variance about the expected family mean is

$$\sigma_w^2 = \sigma^2(z_{ij} - \mu_i) = \sigma_{Gw}^2 + \sigma_{E_s}^2 \quad (21.8b)$$

where σ_{Gw}^2 is the within-family genetic variance (Equations 21.11b and 21.26b). Note that σ_b^2 and σ_w^2 are functions of the true family mean, μ_i , while the variance of the selection unit usually relies upon the variances about the *observed* mean, \bar{z}_i , of each family. Replacing μ_i with \bar{z}_i results in a slight inflation of the among-family variance and a slight reduction in the within-family variance (this is formally shown below in Example 21.3). With n sibs in each family, the among-family variance based on the observed means becomes

$$\sigma^2(\bar{z}_i) = \sigma^2(\mu_i + \bar{e}_i) = \sigma_b^2 + \sigma_w^2/n \quad (21.8c)$$

namely, the among-family variance, $\sigma^2(\mu_i) = \sigma_b^2$, plus the variance, $\sigma^2(\bar{e}_i) = \sigma_w^2/n$, in the error from estimating μ_i from \bar{z}_i . Because the total variance is the sum of the among- and within-family variances ($\sigma_b^2 + \sigma_w^2$), the within-family variance (about the observed, rather than expected, mean) is correspondingly reduced to

$$\sigma^2(z_{ij} - \bar{z}_i) = (1 - 1/n)\sigma_w^2 \quad (21.8d)$$

Equation 21.8c thus implies

$$\sigma^2(\bar{z}_i) = \sigma_{GF}^2 + \sigma_{E_c}^2 + \frac{\sigma_{Gw}^2 + \sigma_{E_s}^2}{n} \quad (21.9a)$$

In the animal-breeding literature, this equation is often more compactly written in terms of t , the phenotypic correlation between sibs (the **intraclass correlation coefficient**; see

Table 21.4 Within- and among-family variances as functions of the genetic and environmental variance components. Epistasis is assumed to be absent and the environmental value is partitioned as $E = E_c + E_s$, a common-family value plus an individual-specific value; n is the number of measured sibs.

Half-sib among-family variance

$$\sigma^2(\bar{z}_{HS}) = \frac{\sigma_A^2}{4} + \frac{(3/4)\sigma_A^2 + \sigma_D^2 + \sigma_{E_s}^2}{n} + \sigma_{E_c(HS)}^2$$

Full-sib among-family variance

$$\sigma^2(\bar{z}_{FS}) = \frac{\sigma_A^2}{2} + \frac{\sigma_D^2}{4} + \frac{(1/2)\sigma_A^2 + (3/4)\sigma_D^2 + \sigma_{E_s}^2}{n} + \sigma_{E_c(FS)}^2$$

Half-sib with nested full-sibs (nested sibs) among-family variance

(n_f females per male, n_s offspring per female, $n = n_f n_s$ offspring per male)

$$\sigma^2(\bar{z}_{HS(FS)}) = \frac{\sigma_A^2}{4} \left(1 + \frac{1}{n_f} + \frac{2}{n}\right) + \frac{\sigma_D^2}{4n_f} \left(1 + \frac{3}{n_s}\right) + \frac{\sigma_{E_s}^2}{n} + \frac{\sigma_{E_c(FS)}^2}{n_f} + \sigma_{E_c(HS)}^2$$

Half-sib within-family variance

$$\sigma^2(z_{ij} - \bar{z}_i | HS) = \left(1 - \frac{1}{n}\right) \left(\frac{3}{4} \sigma_A^2 + \sigma_D^2 + \sigma_{E_s}^2\right)$$

Full-sib within-family variance

$$\sigma^2(z_{ij} - \bar{z}_i | FS) = \left(1 - \frac{1}{n}\right) \left(\frac{1}{2} \sigma_A^2 + \frac{3}{4} \sigma_D^2 + \sigma_{E_s}^2\right)$$

LW Chapter 7). The phenotypic covariance between sibs can be expressed as $t\sigma_z^2 = \sigma_b^2 = \sigma_{GF}^2 + \sigma_{E_c}^2$ (Example 21.3), implying that

$$\sigma^2(\bar{z}_i) = t_n \sigma_z^2 \quad (21.9b)$$

where, akin to our use of r_n (Equation 21.6b),

$$t_n = t + \frac{1-t}{n}. \quad (21.9c)$$

Likewise, the within-family variance (about the observed mean) is

$$\sigma^2(z_{ij} - \bar{z}_i) = \left(1 - \frac{1}{n}\right) (\sigma_{Gw}^2 + \sigma_{E_s}^2) \quad (21.10a)$$

which is usually written as

$$\sigma^2(z_{ij} - \bar{z}_i) = (1 - t_n) \sigma_z^2 \quad (21.10b)$$

Table 21.4 gives these family variances in terms of genetic and environmental variance components, which follow upon expressing the within- and among-family genetic variances in terms of additive and dominance variance components. Recalling from ANOVA theory that the among-group variance equals the within-group covariance (LW Chapter 18), the among-family component, σ_{GF}^2 , equals the genetic covariances between sibs. If, for now, we ignore epistasis,

$$\sigma_{GF}^2 = \begin{cases} \frac{1}{4}\sigma_A^2 & \text{half-sibs} \\ \frac{1}{2}\sigma_A^2 + \frac{1}{4}\sigma_D^2 & \text{full-sibs} \end{cases} \quad (21.11a)$$

Because the total genetic variance (σ_G^2) equals the among-family genetic variance plus the within-family variance,

$$\sigma_{Gw}^2 = \sigma_G^2 - \sigma_{GF}^2 = \begin{cases} \frac{3}{4}\sigma_A^2 + \sigma_D^2 & \text{half-sibs} \\ \frac{1}{2}\sigma_A^2 + \frac{3}{4}\sigma_D^2 & \text{full-sibs} \end{cases} \quad (21.11b)$$

Finally, under a **nested-sib design** (the **North Carolina Design I** of Comstock and Robinson 1948), one sex (typically a male or a pollen plant) is mated to each of n_f (unrelated) females (or seed parents), each of which produces n_s sibs, for a total of $n = n_f n_s$ sibs per male. The expression in Table 21.4 for the among-family variance under the nested-sib design follows, with similar logic as in Example 21.3, and with

$$\sigma^2(\bar{z}_{HS(FS)}) = \sigma_{GF(HS)}^2 + \frac{\sigma_{G(f|m)}^2}{n_f} + \frac{\sigma_{Gw(FS)}^2}{n_s n_f} + \frac{\sigma_{Es}^2}{n} + \frac{\sigma_{Ec(FS)}^2}{n_f} + \sigma_{Ec(HS)}^2 \quad (21.12a)$$

where $\sigma_{G(f|m)}^2$, the genetic variances of females nested within males, is

$$\sigma_{G(f|m)}^2 = \sigma_{GF(FS)}^2 - \sigma_{GF(HS)}^2 = \frac{\sigma_A^2 + \sigma_D^2}{4} \quad (21.12b)$$

When epistasis is present, Equation 21.26a (below) provides the appropriate additional genetic variance terms in $\sigma_{G(f|m)}^2$. The among-family variance under a nested design is bounded below by the half-sib variance ($n_f = n$ and $n_s = 1$) and above by the full-sib variance ($n_f = 1$ and $n_s = n$).

Example 21.3. To obtain the within- and among-family variances for families with n sibs, decompose the phenotypic value of the j th individual from family i as

$$z_{ij} = G_{ij} + E_{ij} = \mu + GF_i + Gw_{ij} + Ec_i + Es_{ij}$$

where the genotypic value, $G_{ij} = \mu + GF_i + Gw_{ij}$, has both a family genotypic effect, GF_i (the expected genotypic value of a random sib from that family), and a deviation, Gw_{ij} , the departure of j th individual's genotypic value from its family average. The environmental value is similarly decomposed, with $E_{ij} = Ec_i + Es_{ij}$, an environmental effect, Ec_i , common to family i , and a special environmental effect, Es_{ij} , unique to the j th individual from this family. Because $GF_i + Ec_i = b_i$ are the effects common to a family, the among-family variance becomes

$$\sigma_b^2 = t\sigma_z^2 = \sigma_{GF}^2 + \sigma_{Ec}^2$$

The equality $\sigma_b^2 = t\sigma_z^2$ follows from the ANOVA identity that the among-group variance equals the covariance among group members (LW Chapter 18).

Similarly, $Gw_{ij} + Es_{ij} = w_{ij}$ are the within-family effects, yielding a within-family variance (around the expected family mean) of

$$\sigma_w^2 = (1-t)\sigma_z^2 = \sigma_{Gw}^2 + \sigma_{Es}^2$$

The equality $\sigma_w^2 = (1-t)\sigma_z^2$ again follows from ANOVA theory, as the total variance equals the among-group variances plus the within-group variances, $\sigma_z^2 = \sigma_b^2 + \sigma_w^2 = t\sigma_z^2 + \sigma_w^2$.

Using these results, we can decompose the observed mean of a family of size n as

$$\begin{aligned} \bar{z}_i &= \frac{1}{n} \sum_{j=1}^n z_{ij} = \frac{1}{n} \sum_{j=1}^n (\mu + GF_i + Gw_{ij} + Ec_i + Es_{ij}) \\ &= \mu + GF_i + Ec_i + \sum_{j=1}^n \frac{(Gw_{ij} + Es_{ij})}{n} \end{aligned}$$

Because they are deviations from the mean, Es_{ij} and Gw_{ij} are uncorrelated with each other, yielding

$$\begin{aligned}\sigma^2(\bar{z}_i) &= (\sigma_{GF}^2 + \sigma_{Ec}^2) + \frac{1}{n^2} \sum_{j=1}^n (\sigma_{Gw}^2 + \sigma_{Es}^2) = \sigma_b^2 + \frac{n\sigma_w^2}{n^2} \\ &= \left(t + \frac{1-t}{n} \right) \sigma_z^2 = t_n \sigma_z^2\end{aligned}$$

which recovers Equation 21.9b.

Now consider the variance of the within-family deviations from the observed means. Recalling the expression for the variance of a sum (LW Equation 3.11a), we have

$$\sigma^2(z_{ij} - \bar{z}_i) = \sigma_z^2 + \sigma^2(\bar{z}_i) - 2\sigma(z_{ij}, \bar{z}_i)$$

To refine this further, first note (Equation 21.9b) that $\sigma^2(\bar{z}_i) = t_n \sigma_z^2$, and that the covariance term simplifies to

$$\sigma(z_{ij}, \bar{z}_i) = \frac{1}{n} \left[\sigma(z_{ij}, z_{ij}) + \sum_{k \neq j}^n \sigma(z_{ij}, z_{ik}) \right] = \frac{\sigma_z^2}{n} + \frac{n-1}{n} t \sigma_z^2 = t_n \sigma_z^2$$

as $\sigma(z_{ij}, z_{ik}) = t \sigma_z^2$ (for $j \neq k$). Thus, the variance of within-family deviations reduces to

$$\sigma^2(z_{ij} - \bar{z}_i) = \sigma_z^2 + t_n \sigma_z^2 - 2t_n \sigma_z^2 = (1 - t_n) \sigma_z^2$$

which recovers Equation 21.10b.

RESPONSE FOR PARTICULAR DESIGNS

The formal development of the response equations for any particular design follows from the generalized breeder's equation (Equations 21.1 through 21.4), using the appropriate selection-unit variance (Table 21.4) and selection unit-offspring covariance (Table 21.3). Results for a number of standard among- and within-family designs are developed below, with family-index selection examined at the end of the chapter.

Overview of Among- and Within-family Response

The selection response for a particular family-based scheme depends on how the additive-genetic (breeding value) and total (phenotypic) variances are partitioned within and among families. When the number, n , of sibs per family is large (meaning that the observed mean will be very close to the true mean), these variances are partitioned as

	Within-family	Among-family
Breeding values	$(1 - r) \sigma_A^2$	$r \sigma_A^2$
Phenotypic values	$(1 - t) \sigma_z^2$	$t \sigma_z^2$

where t and r are, respectively, the phenotypic and additive-genetic correlations between sibs ($r = 1/4$ for noninbred half-sibs and $1/2$ for noninbred full-sibs). When the number of measured sibs within each family is small, $t_n = t + (1-t)/n$ replaces t , and r_n (similarly defined) replaces r . Because the response to selection depends on the ratio of the available additive genetic variance to the phenotypic variance, the response, R_b , to among-family selection is of the form

$$R_b = \frac{r_n \sigma_A^2}{t_n \sigma_z^2} S = \sigma_A \left(\frac{\sigma_A}{\sigma_z} \right) \left(\frac{r_n}{\sqrt{t_n}} \right) \left(\frac{S}{\sqrt{t_n} \sigma_z} \right) = \sigma_A h \frac{r_n}{\sqrt{t_n}} \bar{r} \quad (21.13a)$$

Equation 21.13a is the exact expression for family selection and is due to Lush (1947). Expressions for the predicted selection response under other among-family designs (e.g., sib, parental, or S₁ seed selection) are very similar (see below).

Similarly, the response to within-family selection is a function of the within-family additive-genetic and phenotypic variances, leading us to expect that the response will be in the form of

$$R_{FD} = \frac{(1 - r_n) \sigma_A^2}{(1 - t_n) \sigma_z^2} S = \sigma_A h \frac{1 - r_n}{\sqrt{1 - t_n}} \bar{t} \quad (21.13b)$$

Indeed, this is the exact expression for selection on family deviations (FD), while the response under strict within-family (WF) selection is given by replacing r_n and t_n with r and t .

Equations 21.13a and 21.13b are the standard response equations that appear in much of the elementary animal-breeding literature, as the use of r and t allows these results to be presented in a very compact fashion. When the design is more complicated, such as when it involves the replication of families over environments or the use of nested-sib families, expressions are given in terms of variance components, as shown below.

Among-family Selection

Here the selection unit is \bar{z} , the mean of a half-, full-, or nested-sib family. The type of sib family, together with the relatives used to produce the next generation, specifies the particular among-family design (Table 21.1). Tables 21.3 and 21.4 and Equation 21.13a yields the selection response, R_b , to a single cycle of among-family selection as

$$R_b = \frac{\gamma}{\sqrt{t_n}} \frac{\sigma_A}{2} h (\bar{t}_{x_m} + \bar{t}_{x_f}) = \frac{\gamma}{\sigma(\bar{z})} \frac{\sigma_A^2}{2} (\bar{t}_{x_m} + \bar{t}_{x_f}) \quad (21.14a)$$

The left equality holds when the sib families are not nested and the families are not replicated, while the rightmost expression is completely general (using $\sigma^2(\bar{z})$ in place of $t_n \sigma_z^2$). The selection unit-offspring covariance is $\gamma \sigma_A^2 / 2$, where

$$\gamma = \begin{cases} r_n = r + (1 - r)/n & \text{family selection} \\ r & \text{sib selection} \\ 1/2 & \text{parental or S}_1 \text{ seed selection} \end{cases} \quad (21.14b)$$

Recall that these different values arise because r is the genetic correlation among sibs (1/4 and 1/2, respectively, for half- and full-sibs), and that parental and S₁ selection correspond to the case where $r = 1/2$. Under strict sib selection, no measured individual is a parent of the next generation and hence all the correlations between an individual in the selection unit and a parent of the next generation are the same (namely, $r \sigma_A^2$). Under family selection, one of the n measured individual sibs is also the parent of the next generation, and hence has a genetic covariance of $\sigma_A^2 / 2$, while the other $n - 1$ individuals are sibs of this parent, each with a genetic covariance of $r \sigma_A^2 / 2$ with the offspring (a covariance of $r \sigma_A^2$ between sibs times 1/2 for that between parent and offspring).

The variance of the selection unit, $\sigma^2(\bar{z}) = t_n \sigma_z^2$, depends only on the types of sibs that are measured and is independent of the types of relatives used to form the next generation. The theory of expected response to among-family selection traces back to Lush's classic 1947 paper, and Equation 21.14a is a generalization of his results. Table 21.5 expresses the response in terms of variance components.

Several variants of Equation 21.14a appear in the literature. Noting that $\sigma_A h = \sigma_z h^2$, the response can be expressed as

$$R_b = \frac{\gamma}{\sqrt{t_n}} \sigma_z h^2 \bar{t} \quad (21.15a)$$

where $\bar{t} = (\bar{t}_{x_f} + \bar{t}_{x_m})/2$. Similarly, the response can be expressed in terms of the among-

Table 21.5 Variance-component expressions of the expected response to among-family selection schemes using outbred sibs. Here \bar{t}_{x_m} is the selection intensity on individuals in the selection unit used to choose the male parent of the offspring, y (similarly, \bar{t}_{x_f} for the female parent). The number, n , of measured sibs is assumed to be sufficiently large that terms of order $1/n$ can be ignored (i.e., $r_n \simeq r$ and $t_n \simeq t$). We also assume no epistasis and a simple structure, $E = E_c + E_s$, for environmental values. We allow the within-family common environmental factor (E_c) to vary over the type of family, with $\sigma_{E_c(HS)}^2$ and $\sigma_{E_c(FS)}^2$, respectively, as the corresponding variances for half- and full-sib families.

	Half-sibs	Full-sibs
Family or sib selection	$\frac{(\sigma_A^2/8)(\bar{t}_{x_m} + \bar{t}_{x_f})}{\sqrt{\sigma_A^2/4 + \sigma_{E_c(HS)}^2}}$	$\frac{(\sigma_A^2/4)(\bar{t}_{x_m} + \bar{t}_{x_f})}{\sqrt{\sigma_A^2/2 + \sigma_D^2/4 + \sigma_{E_c(FS)}^2}}$
Parental or S_1 -seed selection	$\frac{(\sigma_A^2/4)(\bar{t}_{x_m} + \bar{t}_{x_f})}{\sqrt{\sigma_A^2/4 + \sigma_{E_c(HS)}^2}}$	$\frac{(\sigma_A^2/4)(\bar{t}_{x_m} + \bar{t}_{x_f})}{\sqrt{\sigma_A^2/2 + \sigma_D^2/4 + \sigma_{E_c(FS)}^2}}$

family heritability, with

$$R_b = h_{b,\gamma}^2 S, \quad \text{where} \quad h_{b,\gamma}^2 = \frac{\gamma}{t_n} h^2 \quad (21.15b)$$

and with $S = (S_f + S_m)/2$ being the average selection differential on the parents.

Turning now to particular among-family designs, we start with family selection. Here, measured sibs (either all or a random subset) from the chosen families form the parents for the next generation. To reduce the effects of inbreeding, crosses between sibs from the same family are typically avoided (Chapter 23 examines the response when sibs are crossed, resulting in offspring that are inbred). With family selection, Equation 21.14a becomes

$$R_b = \begin{cases} \frac{(1+3/n)\sigma_A}{\sqrt{t_n(HS)}} \frac{h}{8} (\bar{t}_{x_m} + \bar{t}_{x_f}) & \text{half-sibs} \\ \frac{(1+1/n)\sigma_A}{\sqrt{t_n(FS)}} \frac{h}{4} (\bar{t}_{x_m} + \bar{t}_{x_f}) & \text{full-sibs} \end{cases} \quad (21.15c)$$

as first obtained by Lush (1947). While full-sibs have twice as much usable among-family additive variance relative to half-sibs ($\sigma_A^2/2$ vs. $\sigma_A^2/4$), this advantage is reduced somewhat because half-sibs have a smaller among-family phenotypic variance, with $t_{HS}/t_{FS} \leq 1$. This inequality follows by recalling that $\sigma^2(\bar{z}) = t\sigma_z^2$ and noting that $(t_{FS} - t_{HS})\sigma_z^2 = \sigma^2(\bar{z}_{FS}) - \sigma^2(\bar{z}_{HS})$, where

$$\sigma^2(\bar{z}_{FS}) - \sigma^2(\bar{z}_{HS}) = \frac{\sigma_A^2 + \sigma_D^2}{4} + \left(\sigma_{E_c(FS)}^2 - \sigma_{E_c(HS)}^2 \right) \quad (21.16a)$$

Given that full-sibs share a common mother (and hence potentially share maternal effects), we expect $\sigma_{E_c(FS)}^2 \geq \sigma_{E_c(HS)}^2$ and, hence $\sigma^2(\bar{z}_{FS}) > \sigma^2(\bar{z}_{HS})$. Assuming the same selection intensity, Equation 21.15c yields the ratio of response for full- to half-sib family selection as

$$\frac{R_b(FS)}{R_b(HS)} = \left(\frac{1+1/n}{1+3/n} \right) \left(\frac{8\sqrt{t_n(HS)}}{4\sqrt{t_n(FS)}} \right) < 2\sqrt{\frac{t_n(HS)}{t_n(FS)}} < 2 \quad (21.16b)$$

with the last equality following from Equation 21.16a.

If the character can only be measured after reproduction, females (or seed parents) from the chosen families have already been fertilized, and hence selection has occurred on only one sex ($S_m = \bar{t}_{x_m} = 0$). Planting these seeds (or, in animals, examining the offspring from fertilized females) and evaluating the resulting families allows for half-sib selection (under

random pollination). Full-sib selection can also be accomplished, but each cycle takes an additional generation. Here seeds from open-pollinated selected females are grown and controlled crosses are made between the offspring from different seed parents to create full-sib families for the next cycle of selection.

Example 21.4. Clayton et al. (1957) examined family selection on abdominal bristle number in *Drosophila melanogaster* (LW Figure 14.1). Their estimated intraclass correlations for half- and full-sibs were 0.121 and 0.265, respectively, while the estimated additive variance and heritability were 5.59 and 0.52, respectively. Hence,

$$t_{HS} = 0.121, \quad t_{FS} = 0.265, \quad \text{and} \quad \sigma_A h = \sqrt{5.59 \cdot 0.52} = 1.70$$

Clayton et al. performed selection in two different settings: (i) the top 2 of 10 half-sib families were saved; and (ii) the top four of 20 full-sib families were saved. The expected selection intensities under these two schemes were, respectively, $\bar{t}_{HS} = \bar{t}_{(2,10)} = 1.27$, and $\bar{t}_{FS} = \bar{t}_{(4,20)} = 1.33$ (Equation 14.4b). The family sizes, n , used were 20 half-sibs and 12 full-sibs. Because of the laboratory mating design used by the authors, there was a 1 in 10 chance that the half-sibs are actually full-sibs, resulting in a slight inflation of r from 0.25 to 0.275 ($= 0.25 \cdot [9/10] + 0.5 \cdot [1/10]$). To summarize:

	Half-sibs	Full-sibs
r	0.275	0.5
n	20	12
t_n	0.165	0.326
r_n	0.311	0.542

Equation 21.13a gives an expected response to half-sib family selection of

$$R_b(HS) = (\sigma_A h) \frac{r_n}{\sqrt{t_n}} \cdot \bar{t}_{HS} = 1.70 \frac{0.311}{\sqrt{0.165}} \cdot 1.27 = 1.67$$

while the expected response to full-sib family selection is

$$R_b(FS) = 1.70 \frac{0.542}{\sqrt{0.326}} \cdot 1.33 = 2.15$$

Clayton et al. obtained slightly different estimated responses (1.33 and 2.02 for half- and full-sibs, respectively). This occurred because they used $R = h_b^2 S_b$, with $S_b = \sigma_b \bar{t}$ computed by taking the observed among-family variance, σ_b^2 (in place of the estimates σ_A^2 , t , and h^2). The observed responses (averaged over the first five generations) were, respectively, 1.38 and 0.94 for up- and down-selected half-sibs, and 1.62 and 1.36 for up- and down-selected full-sibs. The authors noticed a fairly sizable reduction in the estimated additive variance during generations two through four, which (in addition to sampling error; Chapter 18) likely accounts for the discrepancy between observed and predicted response.

Under sib selection, unmeasured sibs from each chosen family are used to form the next generation. The most common response equation for sib selection in the literature, which is due to Robertson (1955a), is

$$R_{sib} = \bar{t} \sigma_A h \frac{n r}{\sqrt{n(1 + [n - 1] t)}} \tag{21.17}$$

where \bar{t} denotes the average selection intensity used to choose both parents. Equation 21.17 follows from Equation 21.15a because $\gamma = r$ for sib selection and we use $\sigma_A h$ in place of

$\sigma_z h^2$. The use of remnant seed is a variant of sib selection. Forming offspring for the next cycle of selection by randomly crossing plants grown from the remnant seeds of the selected families allows these offspring to be the product of selection on both sexes of parents, but at the cost of an extra generation.

Under parental selection (progeny testing), parents are chosen based on the performance of a trial set of their offspring. Historically (until it was replaced by BLUP selection), this was the approach used to select the top bulls for dairy production. Typically, half-sib families are used and selection is on only one sex. In this case, the expected response is

$$R_{pt} = \frac{\sigma_A/4}{\sqrt{t_n(HS)}} h \bar{t} \quad (21.18a)$$

where \bar{t} is the intensity on the selected sex. In monoecious species, the expected response is double that given by Equation 21.18a if one uses the selected parents for both seed and pollen. The use of maternal half-sib families (as commonly occurs in plant breeding) is expected to inflate $t(HS)$ relative to paternal half-sibs (and hence reduce response), as common-family environmental effects can be rather significant due to shared maternal effects.

If males (sires or pollen plants) are progeny tested using a nested-sib design, wherein each male is crossed to n_f (unrelated) females (dams or seed plants), each of which has n_s sibs, the among-family variance is given in Table 21.4, and the response becomes

$$\begin{aligned} R_{pt} &= \frac{h \bar{t} \sigma_A^2 / 4}{\sqrt{\sigma_{GF(HS)}^2 + \frac{\sigma_{G(f|m)}^2}{n_f} + \frac{\sigma_{Gw(FS)}^2}{n_f n_s} + \frac{\sigma_{E_s}^2}{n_f n_s} + \frac{\sigma_{E_c(FS)}^2}{n_f} + \sigma_{E_c(HS)}^2}} \\ &= \frac{h \bar{t} \sigma_A^2 / 4}{\sqrt{\frac{\sigma_A^2}{4} \left(1 + \frac{1}{n_f} + \frac{2}{n_f n_s}\right) + \frac{\sigma_D^2}{4n_f} \left(1 + \frac{3}{n_s}\right) + \frac{\sigma_{E_s}^2}{n_f n_s} + \frac{\sigma_{E_c(FS)}^2}{n_f} + \sigma_{E_c(HS)}^2}} \end{aligned} \quad (21.18b)$$

For progeny testing of females using a nested design, the roles of males and females are reversed in the above expression. Because $\sigma^2(\bar{z}_{HS}) \leq \sigma^2(\bar{z}_{HS(FS)}) \leq \sigma^2(\bar{z}_{FS})$, the response using a nested progeny test is intermediate to that for schemes using half- or full-sibs. All these comments for parental selection equally apply to the S_1 seed design, as the expected response is the same.

Among-family Selection: Which Scheme Is Best?

Given the number of among-family selection designs, which scheme should be used? Biological and economic restriction may preclude the use of certain designs and make others more feasible. These logistical considerations aside, there are three issues that must be weighed: (i) cycle time versus selection on one or both sexes, (ii) performance evaluation using half- versus full-sib families (the value of t_n , and more generally, $\sigma^2[\bar{z}]$), and (iii) choice of relatives for the recombination unit (the value of γ in Equation 21.14a). As mentioned above, a common reason for using a two-generation cycle (e.g., crossing plants grown from remnant seed from superior families) is the inability to select on both sexes. In such cases, the doubling of the cycle time is countered by selection on both sexes doubling the response per cycle, which yields the same expected rate of progress on a per-generation basis. In many cases, a multigenerational method is used because selection on other characters beside the primary one of interest is also performed during one (or both) generations of the cycle.

The second choice is the type of family comprising the selection unit. While the type of sibs changes the value of γ under family- and sib-selection, it does not influence γ under parental or S_1 selection (Equation 21.14b). Indeed, for these last two designs, it is more efficient to use half-sib families, as (from Equation 21.14a) the ratio of response of a parental half-sib to a parental full-sib scheme is $\sqrt{t(FS)/t(HS)} > 1$.

Provided that the same type of families (half-, full-, or nested-sibs) are measured, choosing relatives that increase the recombination unit-offspring covariance (by increasing γ) increases the expected response. For half-sib families, both parental and S_1 selection yield twice the response per cycle as sib or family selection (assuming the same number of sexes are under selection in the comparison). With full-sibs, Table 21.5 shows that, given the same selection intensity, the response per cycle under all four methods (family, sib, parental, and S_1 selection) is the same. While the response to selection using full-sib families is greater than that of family or sib selection using half-sibs, the use of full-sibs does not result in a doubling of the response (Equation 21.16b). This less-than-twofold increase in response per cycle using full-sibs is thus not sufficient to cover the cost of the extra generation that is often required to create full-sib families.

Once one has chosen a particular design, there is also the issue of allocation of the number of sibs (n) per each of the m families, given constraints on the total number of sibs, $N = mn$, measured over each cycle of selection. One increases the accuracy by increasing the number of sibs per family, but one does so by decreasing the selection intensity (for fixed N , increasing n decreases m , and hence \bar{t} ; see Example 21.1). Robertson (1957, 1960b), Rendel (1959), and Lindgren et al. (1997) examined this problem of optimal family size. To maximize response, the breeder usually has two fixed constraints: the total number of sibs, N , examined and the number, n_p , of families used to form the next generation. A low value of n_p increases inbreeding, and thus not only invites inbreeding depression, but also reduces the eventual long-term response (Chapter 26). For fixed n_p and N , the goal is to find the number of sibs, n , per family that maximizes response. Noting that $\sigma_z h^2$ is fixed, while $n_p = mp$ (with p being the fraction saved) and $m = N/n$, Equation 21.15a shows that the single-generation response is maximized by maximizing the quantity $\gamma[\bar{t}_{(n_p, N/n)} / \sqrt{t_n}]$ with respect to n . With the exception of family selection (where $\gamma = r_n$), γ is a fixed constant with respect to n . Maximizing of the long-term response (or more generally, the expected response after $k > 1$ generations) also needs to consider the differences in the effective populations sizes. This is examined in Chapter 26.

Within-family Selection

Within-family selection chooses individuals based on their relative performance within families. Under family-deviations (FD) selection, individuals with the largest family deviations are chosen, independent of which family they come from. In contrast, strict within-family (WF) selection chooses the largest individuals from each family, independent of how much they actually deviate from their family means. Suppose that in family one the deviations for three measured sibs are 4, 3, and -7, while the deviations in family two are 1, 0, and -1. If we select the upper one-third, then under WF selection, the top individual from each family is chosen, while under FD selection, two individuals from family one and none from family two are chosen. The result of this rather subtle distinction is that FD selection is influenced by the observed mean, \bar{z}_i , while WF selection is not. Family deviations and strict within-family selection have been confused in the literature, and the correct expression for WF selection was provided by Dempfle (1975, 1990) and Hill et al. (1996). Because WF selection ensures an equal representation of families, while FD selection does not, WF selection has a larger effective population size (Equation 3.4), and hence an expected larger long-term response (Chapter 26).

Under family-deviations (FD) selection, the selection unit is the value of an individual's within-family deviation, $z_{ij} - \bar{z}_i$. Using the results from Tables 21.3 and 21.4, Equation 21.1a yields an expected response of

$$\begin{aligned} R_{FD} &= \frac{\sigma(z_{ij} - \bar{z}_i, y | \mathcal{R}_m)}{\sigma(z_{ij} - \bar{z}_i)} \bar{t}_{x_m} + \frac{\sigma(z_{ij} - \bar{z}_i, y | \mathcal{R}_f)}{\sigma(z_{ij} - \bar{z}_i)} \bar{t}_{x_f} \\ &= \frac{1 - r_n}{\sqrt{1 - t_n}} \sigma_A h \left(\frac{\bar{t}_{x_m} + \bar{t}_{x_f}}{2} \right) \end{aligned} \quad (21.19)$$

with the last equality following from $\sigma_A^2 / \sigma_z^2 = \sigma_A h$.

Under strict within-family (WF) selection, individuals are chosen entirely on their rank within each family, resulting in the observed mean, \bar{z}_i , being replaced by the true (and unobserved) mean, μ_i (Dempfle 1975, 1990; Hill et al. 1996). The response becomes

$$\begin{aligned} R_{WF} &= \frac{\sigma(z_{ij} - \mu_i, y | \mathcal{R}_m)}{\sigma(z_{ij} - \mu_i)} \bar{t}_{x_m} + \frac{\sigma(z_{ij} - \mu_i, y | \mathcal{R}_f)}{\sigma(z_{ij} - \mu_i)} \bar{t}_{x_f} \\ &= \frac{1-r}{\sqrt{1-t}} \sigma_A h \left(\frac{\bar{t}_{x_m} + \bar{t}_{x_f}}{2} \right) \end{aligned} \quad (21.20)$$

Noting that

$$\frac{1-r_n}{\sqrt{1-t_n}} = \frac{(1-1/n)(1-r)}{\sqrt{(1-1/n)(1-t)}} = \frac{1-r}{\sqrt{1-t}} \sqrt{1-\frac{1}{n}}$$

it follows that

$$R_{FD} = R_{WF} \frac{\bar{t}_{FD}}{\bar{t}_{WF}} \sqrt{1-\frac{1}{n}} \quad (21.21)$$

Thus, when the number of measured sibs in each family is modest to large (meaning that the selection intensities are essentially equal, $\bar{t}_{FD} \simeq \bar{t}_{WF}$; see Example 24.1), the difference between the expected responses under WF versus FD selection is very small. For large values of n , Equation 21.20 yields a resulting response for strict within-family (WF) selection using half- and full-sib families of

$$R_{WF} = \begin{cases} \frac{(3/8)\sigma_A}{\sqrt{1-t(HS)}} h (\bar{t}_{x_m} + \bar{t}_{x_f}) & \text{half-sibs} \\ \frac{(1/4)\sigma_A}{\sqrt{1-t(FS)}} h (\bar{t}_{x_m} + \bar{t}_{x_f}) & \text{full-sibs} \end{cases} \quad (21.22a)$$

When expressed in terms of variance components,

$$R_{WF} = \begin{cases} \frac{(3/8)\sigma_A^2}{\sqrt{(3/4)\sigma_A^2 + \sigma_D^2 + \sigma_{E_s}^2}} (\bar{t}_{x_m} + \bar{t}_{x_f}) & \text{half-sibs} \\ \frac{(1/4)\sigma_A^2}{\sqrt{\sigma_A^2/2 + (3/4)\sigma_D^2 + \sigma_{E_s}^2}} (\bar{t}_{x_m} + \bar{t}_{x_f}) & \text{full-sibs} \end{cases} \quad (21.22b)$$

With their smaller amounts of among-family genetic variance, there is more usable within-family variance among half-sibs, namely, a within-family additive variance of $(3/4)\sigma_A^2$. Only half of this variance is passed from parent to offspring, giving the $(3/8)\sigma_A^2$ term in Equations 21.22a and 21.22b. For full-sibs, the within-family additive variance is $(1/2)\sigma_A^2$, again only half of which is passed onto offspring, which results in the $\sigma_A^2/4$ term in these equations.

The **within-family heritability**, h_w^2 , is the same under both FD and WF within-family selection because

$$\frac{1-r_n}{1-t_n} = \frac{(1-1/n)(1-r)}{(1-1/n)(1-t)} = \frac{(1-r)}{(1-t)}$$

yielding

$$h_w^2 = \frac{2\sigma(z_{ij} - \bar{z}_i, y | \mathcal{R}_1)}{\sigma^2(z_{ij} - \bar{z}_i)} = \frac{(1-r_n)\sigma_A^2}{(1-t_n)\sigma_z^2} = \frac{(1-r)}{(1-t)} h^2 \quad (21.23)$$

Example 21.5. Using the data of Clayton et al. (1957) from Example 21.4, what is the expected response under the two within-family selection schemes (WF and FD)? Suppose we assume

that there is a full-sib family design, with 10 families of 20 sibs each, and that we perform strict within-family selection, with the upper 20% chosen from each family (the top 4 of the 20 measured sibs). Correcting for finite population size (Equation 14.4b), the expected selection intensity is $\bar{t}_{(4,20)} = 1.33$, and from Equation 21.20, the predicted response is

$$R_{WF} = \bar{t} \cdot (\sigma_A h) \frac{1 - r}{\sqrt{1 - t}} = 1.33 \cdot 1.70 \frac{1 - 0.275}{\sqrt{1 - 0.121}} = 1.75$$

If we use within-family deviations (FD), selecting the uppermost 20% of all 200 individuals gives a corrected selection intensity of $\bar{t}_{(40,200)} = 1.39$, and Equation 21.19 returns a predicted response of

$$R_{FD} = \bar{t} \cdot (\sigma_A h) \frac{1 - r_n}{\sqrt{1 - t_n}} = 1.39 \cdot 1.70 \frac{1 - 0.311}{\sqrt{1 - 0.165}} = 1.78$$

The selection intensity values used here can be further corrected to account for correlations among sibs, and we do so later in the chapter (Equation 21.57b).

Realized Heritabilities

By analogy with individual selection, one can estimate the realized heritability (Chapter 18) associated with a particular family-based scheme from the ratio of observed response to selection differential, namely,

$$\hat{h}_{r,x}^2 = \frac{R_x}{S_x} \quad (21.24a)$$

Falconer and Latyszewski (1952) used this approach to estimate a realized within-family heritability for response to selection on body size in mice. These authors computed the standard error of this estimate by noting that

$$\sigma^2 \left(\hat{h}_{r,wf}^2 \right) = \sigma^2 \left(\frac{R_{wf}}{S_{wf}} \right) = \frac{\sigma^2(R_{wf})}{S_{wf}^2} \quad (21.24b)$$

The last equality follows by assuming that the error variance in measuring S can be ignored.

Because the among- and within-family heritabilities can be expressed as a function of the individual heritability, h^2 (Equations 21.15b and 21.23), we can similarly translate a realized heritability estimate for a particular family-based design into a realized individual heritability, \hat{h}_r^2 . With among-family selection,

$$\hat{h}_r^2 = \left(\frac{t_n}{\gamma} \right) \hat{h}_{r,wf}^2 \quad (21.25a)$$

where γ is given by Equation 21.14b. For within-family selection, these two heritabilities are connected by

$$\hat{h}_r^2 = \left(\frac{1 - t}{1 - r} \right) \hat{h}_{r,wf}^2 \quad (21.25b)$$

These expressions apply to a single generation of selection. Additional uncertainty is introduced into the estimate if the sib phenotypic correlation (t) is unknown and must itself be estimated. Equations 21.25a and 21.25b should be used with caution when multiple cycles of selection have occurred, as the sib additive-genetic correlation (r) increases in each successive generation due to inbreeding, which in turn changes the phenotypic correlation, t (Chapter 26).

Accounting for Epistasis

The response to within- and among-family selection in the presence of epistasis was briefly examined by Nyquist (1991), and we expand upon his results here. As with individual selection, additive epistasis contributes to the initial response under family-based selection, but its contribution to the ultimate response rapidly decays over time as recombination breaks up favorable combinations of alleles at different loci (Chapter 15). We first consider the single-generation response and then briefly examine the transient dynamics.

Recalling that the among-group variance equals the within-group covariance (LW Chapter 18), the among-family genetic variance, σ_{GF}^2 , with arbitrary epistasis immediately follows from the genetic covariance between sibs (LW Table 7.2),

$$\sigma_{GF}^2 = \begin{cases} \frac{1}{4}\sigma_A^2 + \frac{1}{16}\sigma_{AA}^2 + \frac{1}{64}\sigma_{AAA}^2 + \dots & \text{half-sibs} \\ \frac{1}{2}\sigma_A^2 + \frac{1}{4}\sigma_D^2 + \frac{1}{4}\sigma_{AA}^2 + \frac{1}{8}\sigma_{AD}^2 + \frac{1}{16}\sigma_{DD}^2 + \frac{1}{8}\sigma_{AAA}^2 + \dots & \text{full sibs} \end{cases} \quad (21.26a)$$

Likewise, the within-family genetic variance, $\sigma_{Gw}^2 = \sigma_G^2 - \sigma_{GF}^2$, becomes

$$\sigma_{Gw}^2 = \begin{cases} \frac{3}{4}\sigma_A^2 + \sigma_D^2 + \frac{15}{16}\sigma_{AA}^2 + \sigma_{AD}^2 + \sigma_{DD}^2 + \frac{63}{64}\sigma_{AAA}^2 + \dots & \text{half-sibs} \\ \frac{1}{2}\sigma_A^2 + \frac{3}{4}\sigma_D^2 + \frac{3}{4}\sigma_{AA}^2 + \frac{7}{8}\sigma_{AD}^2 + \frac{15}{16}\sigma_{DD}^2 + \frac{7}{8}\sigma_{AAA}^2 + \dots & \text{full-sibs} \end{cases} \quad (21.26b)$$

The among- and within-family variances, $\sigma^2(\bar{z}_i)$ and $\sigma^2(z_{ij} - \bar{z}_i)$, immediately follow if we substitute Equations 21.26a and 21.26b into Equations 21.9a and 21.10a, respectively.

The genetic covariance between an individual (x) from the selection unit and the offspring (y) under epistasis follows if we use LW Equation 7.12,

$$\sigma_G(x, y) = (2\Theta_{xy})\sigma_A^2 + (2\Theta_{xy})^2\sigma_{AA}^2 + \dots = \sum_{u=1} (2\Theta_{xy})^u \sigma_{A^u}^2$$

The previous expression assumed that $\Delta_{xy} = 0$, meaning that terms involving dominance are not included. Using the values of Θ_{xy} from Table 21.2, the parent-offspring covariance is

$$\sigma(\mathcal{R}_1, y) = \frac{\sigma_A^2}{2} + \frac{\sigma_{AA}^2}{4} + \frac{\sigma_{AAA}^2}{8} + \dots = \sum_{u=1} \left(\frac{1}{2^u} \right) \sigma_{A^u}^2 \quad (21.27a)$$

Table 21.2 shows that $\Theta_{xy} = 1/16$ and $1/8$ when x is a half- or full-sib, respectively, of \mathcal{R} . Expressed in terms of Wright's coefficient of relationship, r ,

$$\sigma(x_1, y | \mathcal{R}_1) = (r/2)\sigma_A^2 + (r/2)^2\sigma_{AA}^2 + (r/2)^3\sigma_{AAA}^2 + \dots = \sum_{u=1} \left(\frac{r}{2} \right)^u \sigma_{A^u}^2 \quad (21.27b)$$

Substituting Equation 21.27a and 21.27b into Equation 21.6a yields a covariance for family selection of

$$\begin{aligned} \sigma(\bar{z}, y | \mathcal{R}_1) &= \frac{1}{n} \sum_{u=1} \left(\frac{1}{2^u} \right) \sigma_{A^u}^2 + \left(1 - \frac{1}{n} \right) \sum_{u=1} \left(\frac{r}{2} \right)^u \sigma_{A^u}^2 \\ &= \sum_{u=1} \left(\frac{1}{2^u} \right) r_n^u \sigma_{A^u}^2 \end{aligned} \quad (21.28)$$

where $r_n^u = r^u + (1 - r^u)/n$. For a large family size, the coefficient for u -fold additive epistasis approaches $r^u/2^u$, which is the value under sib selection. Taking $r = 1/2$ returns the coefficients for parental and S_1 seed selection. Applying Equation 21.28, the single-parent covariance for half-sib family selection ($r = 1/4$) becomes

$$\sigma(\bar{z}_{HS}, y | \mathcal{R}_1) = \left(1 + \frac{3}{n} \right) \frac{\sigma_A^2}{8} + \left(1 + \frac{15}{n} \right) \frac{\sigma_{AA}^2}{64} + \left(1 + \frac{63}{n} \right) \frac{\sigma_{AAA}^2}{512} + \dots \quad (21.29a)$$

Likewise, the single-parent covariance for full-sib family selection ($r = 1/2$) is

$$\sigma(\bar{z}_{FS}, y | \mathcal{R}_1) = \left(1 + \frac{1}{n}\right) \frac{\sigma_A^2}{4} + \left(1 + \frac{3}{n}\right) \frac{\sigma_{AA}^2}{16} + \left(1 + \frac{7}{n}\right) \frac{\sigma_{AAA}^2}{64} + \dots \quad (21.29b)$$

For sib-selection, $\sigma(\bar{z}_1, y | \mathcal{R}_1)$ is directly provided by Equation 21.27b, and Equations 21.29a and 21.29b apply if terms of order $1/n$ are ignored. For among-family selection using parental selection or S_1 seed, the covariance is the same as that for full-sibs under sib selection, namely, Equation 21.29b (as all three have the same value of Θ_{xy}).

The covariance for within-family deviations (again considering the contribution through a single parent of y) becomes

$$\begin{aligned} \sigma(z_{ij} - \bar{z}_i, y | \mathcal{R}_1) &= \sigma(\mathcal{R}_1, y) - \sigma(\bar{z}_i, y | \mathcal{R}_1) \\ &= \sum_{u=1}^n \left(\frac{1}{2}\right)^u \left(1 - r_n^u\right) \sigma_{A^u}^2 \\ &= \left(1 - \frac{1}{n}\right) \sum_{u=1}^n \left(\frac{1}{2}\right)^u (1 - r^u) \sigma_{A^u}^2 \end{aligned} \quad (21.30)$$

where we have used the identity $(1 - r_n) = (1 - 1/n)(1 - r)$. Ignoring the common $(1 - 1/n)$ factor found in all terms, for half-sibs we have

$$\sigma(z_{ij} - \bar{z}_{HS}, y | \mathcal{R}_1) = \left(\frac{3}{8}\right) \sigma_A^2 + \left(\frac{15}{64}\right) \sigma_{AA}^2 + \left(\frac{63}{512}\right) \sigma_{AAA}^2 + \dots \quad (21.31a)$$

while for full-sibs

$$\sigma(z_{ij} - \bar{z}_{FS}, y | \mathcal{R}_1) = \left(\frac{1}{4}\right) \sigma_A^2 + \left(\frac{3}{16}\right) \sigma_{AA}^2 + \left(\frac{7}{64}\right) \sigma_{AAA}^2 + \dots \quad (21.31b)$$

Equations 21.29 and 21.31 show that additive epistasis contributes to the short-term response. However, as with individual selection, this contribution is transient and decays over time as recombination breaks up linkage groups of favorable alleles (Chapter 15). For u -locus additive epistasis ($\sigma_{A^u}^2$), the per-generation decay rate for unlinked loci is $[1 - (1/2)^{u-1}]$, or one minus the probability that a parental gamete containing specific alleles at u unlinked loci will be passed onto an offspring. The probability that such a gamete remains unchanged after τ generations is $2^{-\tau(u-1)}$, which rapidly converges to zero. Thus, if R_{A^u} is the contribution due to u -locus additive epistasis, after τ generations, the contribution from a single generation of selection becomes $2^{-\tau(u-1)} R_{A^u}$.

Response with Autotetraploids

Recall from Chapter 15 that selection response with autotetraploids (which are common among crop plants) has similar features to selection in the presence of additive epistasis—there is a transient component to the response contributed by nonadditive gene action. In the case of autotetraploids, this is the dominance variance, which occurs because autotetraploid parents pass along two alleles at each locus to their offspring. As with epistasis, the contribution to the selection response from nonadditive variance arises because the genotypes are not in Hardy-Weinberg equilibrium. After several generations of random mating, the selection-induced allele frequencies remain unchanged (and hence, any additive contribution is permanent), but any nonadditive contributions decay away as the population approaches Hardy-Weinberg.

This section is a bit technical, with some of the details developed in Examples 21.6 and 21.7, so we will first review the key results. Except in the case of selfing (using S_1 seed), the permanent response to selection is the same as with a diploid. The transient contribution from dominance is generally small (indeed, it is smaller than its contribution

under individual selection; Equation 15.9) and is only significant when the dominance variance is substantially larger than the additive variance. Further, this (generally small) transient contribution quickly decays under random mating. An additional complication involving autotetraploids is deferred until Chapter 23, namely, that the offspring from a cross of two (unrelated) autotetraploid parents from S_1 seed are inbred, as the two alleles from each parent can be identical by descent.

Using the results from Example 21.6, we find that

$$\sigma_G(x, y) = \begin{cases} \frac{1}{2}\sigma_A^2 + \frac{1}{6}\sigma_D^2 & \text{parent, offspring} \\ \frac{1}{4}\sigma_A^2 + \frac{1}{36}\sigma_D^2 & \text{half-sibs} \\ \frac{1}{2}\sigma_A^2 + \frac{2}{9}\sigma_D^2 + \frac{1}{12}\sigma_T^2 + \frac{1}{36}\sigma_Q^2 & \text{full-sibs} \end{cases} \quad (21.32a)$$

where σ_T^2 and σ_Q^2 are the variances of third- and fourth-order interactions within loci (see Example 21.6; LW Chapters 5 and 7, for details). Using these covariances and following the same logic leading to Equations 21.26a and 21.26b yields an among-family genetic variance of

$$\sigma_{GF}^2 = \begin{cases} \frac{1}{4}\sigma_A^2 + \frac{1}{36}\sigma_D^2 & \text{half-sibs} \\ \frac{1}{2}\sigma_A^2 + \frac{2}{9}\sigma_D^2 + \frac{1}{12}\sigma_T^2 + \frac{1}{36}\sigma_Q^2 & \text{full-sibs} \end{cases} \quad (21.32b)$$

The within-family genetic variances follow from $\sigma_{Gw}^2 = \sigma_G^2 - \sigma_{GF}^2$, which yields

$$\sigma_{Gw}^2 = \begin{cases} \frac{3}{4}\sigma_A^2 + \frac{35}{36}\sigma_D^2 + \sigma_T^2 + \sigma_Q^2 & \text{half-sibs} \\ \frac{1}{2}\sigma_A^2 + \frac{7}{9}\sigma_D^2 + \frac{11}{12}\sigma_T^2 + \frac{35}{36}\sigma_Q^2 & \text{full-sibs} \end{cases} \quad (21.32c)$$

The among- and within-family variances, $\sigma^2(\bar{z}_i)$ and $\sigma^2(z_{ij} - \bar{z}_i)$, immediately follow, respectively, if we substitute Equations 21.32b and 21.32c into Equation 21.9a, and Equation 21.32c into Equation 21.10a. One of the few attempts to measure variance components in a tetraploid (alfalfa) was done by Dudley et al. (1969), who found that only σ_A^2 was significant for the five yield-related traits that they measured. While estimates of σ_D^2 were negative, estimates of σ_T^2 and σ_Q^2 were of the same order as σ_A^2 , but they had standard errors an order of magnitude higher than those of σ_A^2 , and hence were not significant.

To proceed further, we need to compute the expected genetic covariance between y (an offspring of \mathcal{R}) and x , a sib upon which selection decisions are made. This requires us to compute two additional genetic covariances for autotetraploids, namely, for a half-uncle or half-aunt and a nephew (when x and \mathcal{R} are half-sibs, x and y are related as half-uncle or half-aunt and nephew) and for an uncle or aunt and nephew (when x and \mathcal{R} are full-sibs, x and y are related as uncle or aunt and a nephew). Example 21.7 carries out the bookkeeping.

Using the results from Example 21.7, the covariance between the family mean and an offspring generated using family selection again has two terms: a parent-offspring contribution $1/n$ (from the measured sib serving as a parent, \mathcal{R} , of y), and the covariance between x and y when \mathcal{R} is an unmeasured sib of x , yielding

$$\begin{aligned} \sigma(\bar{z}, y | \mathcal{R}_1) &= \frac{1}{n}\sigma(y | \mathcal{R}_1) + \left(1 - \frac{1}{n}\right)\sigma(x, y | \mathcal{R}_1) \\ &= \frac{1}{n} \left(\frac{1}{2}\sigma_A^2 + \frac{1}{6}\sigma_D^2 \right) + \left(1 - \frac{1}{n}\right)\sigma(x, y | \mathcal{R}_1) \end{aligned} \quad (21.33a)$$

Using the results from Example 21.7, when x and \mathcal{R} are half-sibs, we have

$$\begin{aligned} \sigma(\bar{z}, y | \mathcal{R}_1) &= \frac{1}{n} \left(\frac{1}{2}\sigma_A^2 + \frac{1}{6}\sigma_D^2 \right) + \left(1 - \frac{1}{n}\right) \left(\frac{1}{8}\sigma_A^2 + \frac{1}{216}\sigma_D^2 \right) \\ &= \frac{1}{8}\sigma_A^2 \left(1 + \frac{3}{n}\right) + \frac{1}{216}\sigma_D^2 \left(1 + \frac{35}{n}\right) \end{aligned} \quad (21.33b)$$

Turning to full-sibs,

$$\begin{aligned}\sigma(\bar{z}, y | \mathcal{R}_1) &= \frac{1}{n} \left(\frac{1}{2} \sigma_A^2 + \frac{1}{6} \sigma_D^2 \right) + \left(1 - \frac{1}{n} \right) \left(\frac{1}{4} \sigma_A^2 + \frac{1}{27} \sigma_D^2 \right) \\ &= \frac{1}{4} \sigma_A^2 \left(1 + \frac{1}{n} \right) + \frac{1}{27} \sigma_D^2 \left(1 + \frac{7}{n} \right)\end{aligned}\quad (21.33c)$$

In both cases, the additive-genetic contribution to the genetic covariance is the same as for diploids, while the extra contribution from dominance is small and transient, decaying under random mating by two-thirds each generation (Equation 15.10d). Similar expressions can be obtained for within-family selection. Again, the contribution from additive variance is the same as for diploids, while the contribution from dominance is small and decays by two-thirds each generation of random mating.

Example 21.6. For the response under family-based selection schemes involving tetraploids, we will need a bit more detailed treatment of resemblance between polyploid relatives than was given in LW Chapter 7. To begin, we label the four alleles in a tetraploid by B_1, B_2, B_3 , and B_4 . There are six possible gametes from this parent, $(B_1, B_2), (B_1, B_3), (B_1, B_4), (B_2, B_3), (B_2, B_4)$, and (B_3, B_4) . Allowing for nonadditive interaction between alleles, the genotypic value can be decomposed into four additive (single-allele) terms, six dominance (two-allele) terms, four three-way interactions, and one four-way interaction:

$$\begin{aligned}G_{1234} = a_1 + a_2 + a_3 + a_4 + d_{12} + d_{13} + d_{14} + d_{23} + d_{24} + d_{34} + \\ t_{123} + t_{124} + t_{134} + t_{234} + q_{1234}\end{aligned}\quad (21.34a)$$

The resulting total genetic variation can be partitioned as

$$\sigma_G^2 = 4\sigma_a^2 + 6\sigma_d^2 + 4\sigma_t^2 + \sigma_q^2 = \sigma_A^2 + \sigma_D^2 + \sigma_T^2 + \sigma_Q^2 \quad (21.34b)$$

If two relatives share only one allele IBD, then their genetic covariance is $\sigma_a^2 = (1/4)\sigma_A^2$. If they share exactly two IBD alleles, the genetic covariance is $2\sigma_a^2 + \sigma_d^2 = (1/2)\sigma_A^2 + (1/6)\sigma_D^2$. If we fill out the rest of these covariances and let π_i denote the probability that two relatives share exactly i IBD alleles, we will have

IBD alleles	Prob.	σ_A^2	σ_D^2	σ_T^2	σ_Q^2
1	π_1	1/4	0	0	0
2	π_2	1/2	1/6	0	0
3	π_3	3/4	1/2	1/4	0
4	π_4	1	1	1	1

Using these results, observe that the genetic covariance between any two relatives can be expressed as a function of their π_i values, namely,

$$\left(\frac{\pi_1 + 2\pi_2 + 3\pi_3 + 4\pi_4}{4} \right) \sigma_A^2 + \left(\frac{\pi_2 + 3\pi_3 + 6\pi_4}{6} \right) \sigma_D^2 + \left(\frac{\pi_3 + 4\pi_4}{4} \right) \sigma_T^2 + \pi_4 \sigma_Q^2 \quad (21.34c)$$

With a parent-offspring relationship, exactly two alleles are IBD, so that $\pi_2 = 1$. With half-sibs, by looking at the 36 entries in the 6×6 table of pairs of gametes from the same parent, we see that 6 share two alleles, 24 share one, and 6 share zero. Hence, $\pi_1 = 24/36 = 2/3$, $\pi_2 = 6/36 = 1/6$. Results for full-sibs follow from these half-sib results. Let P_1 and P_2 denote the shared parents. The probability that four alleles are shared is the probability the sibs share two alleles from P_1 times the probability they share two alleles from P_2 , or $\pi_4 = (1/6)(1/6)$, assuming the parents are unrelated and not inbred. Now consider the case of sharing exactly two alleles IBD. This can happen in three different ways: sharing one IBD allele from each

parent (probability $[2/3][2/3]$), sharing two IBD alleles from P_1 and zero from P_2 (probability $[1/6][1/6]$), or sharing two alleles from P_2 and zero from P_1 (probability $[1/6][1/6]$), yielding

$$\pi_2 = (2/3)^2 + (1/6)^2 + (1/6)^2 = 18/36 = 1/2$$

Similar logic yields $\pi_1 = 2/9$ and $\pi_3 = 2/9$. To summarize,

Relative pair	π_0	π_1	π_2	π_3	π_4
Parent-offspring	0	0	1	0	0
Half-sibs	1/6	2/3	1/6	0	0
Full-sibs	1/36	2/9	1/2	2/9	1/36

Substitution of the above results for the π_i into the general expression for the covariance yields Equation 21.32a.

Example 21.7. Example 21.6 computed the π_1, π_2, π_3 , and π_4 values for half- and full-sibs. As we saw above, expressions for the selection response under various family-based selection schemes requires the covariance between a member of the selection unit (x) and an offspring (y) of \mathcal{R} , a relative of x . We can obtain these covariances by conditioning on the number of IBD alleles shared by x and \mathcal{R} , and then computing the probability that \mathcal{R} passes along one or two of these IBD alleles to its offspring, y . For example, if x and \mathcal{R} share exactly one IBD allele, then with a probability of one-half, that allele is also transmitted to y , in which case x and y share one IBD allele. The 1/2 comes from considering the six possible gametes that \mathcal{R} can generate. Let B_1 denote the IBD allele for x and \mathcal{R} . When enumerating all six possible biallelic gametes, we see that three contain B_1 , while the other three do not. Similar enumeration fills out the table below. For example, suppose x and \mathcal{R} share two IBD alleles, B_1 and B_2 . Again counting the six possible gametes of \mathcal{R} , only one contains both alleles (1/6 have two IBD), while four of six contain either B_1 or B_2 (but not both). The values when x and \mathcal{R} share three and four IBD alleles are given below:

IBD shared by x and \mathcal{R}	Prob(IBD shared by x and y)	
	1	2
1	1/2	0
2	2/3	1/6
3	1/2	1/2
4	0	1

When x and \mathcal{R} are half-sibs, Example 21.6 shows that 2/3 of sibs share one IBD allele, while 1/6 share two. We let the notation ($I[x, y] = 1$) and ($I[x, y] = 2$) denote that the pair (x, y) share, respectively, exactly one or two IBD alleles. Using the above table, the probability that y and x share one or two IBD alleles becomes

$$\begin{aligned}\pi_1 &= \Pr(I[x, y] = 1 | I[x, \mathcal{R}] = 1) \Pr(I[x, \mathcal{R}] = 1) + \Pr(I[x, y] = 1 | I[x, \mathcal{R}] = 2) \Pr(I[x, \mathcal{R}] = 2) \\ &= (1/2)(2/3) + (2/3)(1/6) = 4/9 \\ \pi_2 &= \Pr(I[x, y] = 2 | I[x, \mathcal{R}] = 2) \Pr(I[x, \mathcal{R}] = 2) = (1/6)(1/6) = 1/36\end{aligned}$$

Substituting these into Equation 21.34c returns

$$\sigma_G(x, y) = \left(\frac{1(4/9) + 2(1/36)}{4} \right) \sigma_A^2 + \frac{1/36}{6} \sigma_D^2 = \frac{1}{8} \sigma_A^2 + \frac{1}{216} \sigma_D^2 \quad (21.34d)$$

as the genetic covariance between x and y when the relationship is that of half-uncle (x and \mathcal{R} are half-sibs) and nephew (y , an offspring of \mathcal{R}).

When x and \mathcal{R} are full-sibs, Example 21.6 showed that the probability they share one, two, three, and four IBD alleles is 2/9, 1/2, 2/9, and 1/36, respectively. Following the same logic and using the above table,

$$\pi_1 = (1/2)(2/9) + (2/3)(1/2) + (1/2)(2/9) + (0)(1/36) = 20/36 = 5/9$$

$$\pi_2 = (0)(2/9) + (1/6)(1/2) + (1/2)(2/9) + (1)(1/36) = 2/9$$

yielding

$$\sigma_G(x, y) = \left(\frac{1(5/9) + 2(2/9)}{4} \right) \sigma_A^2 + \frac{2/9}{6} \sigma_D^2 = \frac{1}{4} \sigma_A^2 + \frac{1}{27} \sigma_D^2 \quad (21.34e)$$

as the genetic covariance between x and y when the relationship is that of uncle (x and \mathcal{R} are full-sibs) and nephew (y , an offspring of \mathcal{R}).

EFFICIENCY OF FAMILY-BASED VS. INDIVIDUAL SELECTION

Intuition suggests that individual selection is better than either within- or among-family selection when h^2 is modest to large, as in this case, individual phenotypes, z , are good predictors of individual breeding values, A . When h^2 is small, we expect within-family selection to be more efficient if there is a large common family environmental effect ($\sigma_{E_c} \simeq \sigma_z^2$) and among-family selection to be more efficient if the individual-specific environmental effects are large ($\sigma_{E_s} \simeq \sigma_z^2$).

To more formally develop these points, recall that the expected response under mass (individual) selection is $R_m = \bar{\iota}_m \sigma_A h$ (Equation 13.6b). Applying Equation 21.14a, the ratio of response of among-family selection to individual selection becomes

$$\frac{R_b}{R_m} = \left(\frac{\bar{\iota}_b}{\bar{\iota}_m} \right) \left(\frac{\gamma}{\sqrt{t_n}} \right) \quad (21.35a)$$

where γ is a function of the type of among-family selection (Equation 21.14b), t is the intraclass correlation among sibs, with t_n given by Equation 21.9c, and $\bar{\iota}$ is the average selection intensity on the two sexes. Likewise, for family-deviations selection, Equation 21.19 yields

$$\frac{R_{FD}}{R_m} = \left(\frac{\bar{\iota}_{FD}}{\bar{\iota}_m} \right) \left(\frac{1 - r_n}{\sqrt{1 - t_n}} \right) \quad (21.35b)$$

where r_n is calculated by Equation 21.6b. Finally, Equation 21.20 yields a response ratio for strict within-family to mass selection of

$$\frac{R_{WF}}{R_m} = \left(\frac{\bar{\iota}_{WF}}{\bar{\iota}_m} \right) \left(\frac{1 - r}{\sqrt{1 - t}} \right) \quad (21.35c)$$

Equations 21.35a–21.35c show that the relative efficiency of any particular family-based scheme is the product of the ratio of selection intensities (the first term) and the **accuracy of selection** relative to individual selection (the second term). This accuracy ratio measures how well (relative to individual selection) the selection criterion predicts the breeding values of the parents. We focus first on the accuracy ratio, as the selection-intensity ratio is generally close to one unless sample sizes are very small (Example 21.1; Table 21.6).

The Relative Accuracies of Family-based vs. Individual Selection

Relative accuracies are typically expressed in terms of the phenotypic correlation, t , between sibs and their coefficient of relatedness, r . Under the simple environmental model ($E = E_c + E_s$), the variance of family means is $\sigma^2(\mu_i) = t\sigma_z^2 = \sigma_{GF}^2 + \sigma_{Ec}^2$. Hence,

$$t = \frac{\sigma_{GF}^2}{\sigma_z^2} + \frac{\sigma_{Ec}^2}{\sigma_z^2} = \frac{r\sigma_A^2}{\sigma_z^2} + \frac{(\sigma_{GF}^2 - r\sigma_A^2) + \sigma_{Ec}^2}{\sigma_z^2} = rh^2 + \frac{(\sigma_{GF}^2 - r\sigma_A^2) + \sigma_{Ec}^2}{\sigma_z^2} \quad (21.36a)$$

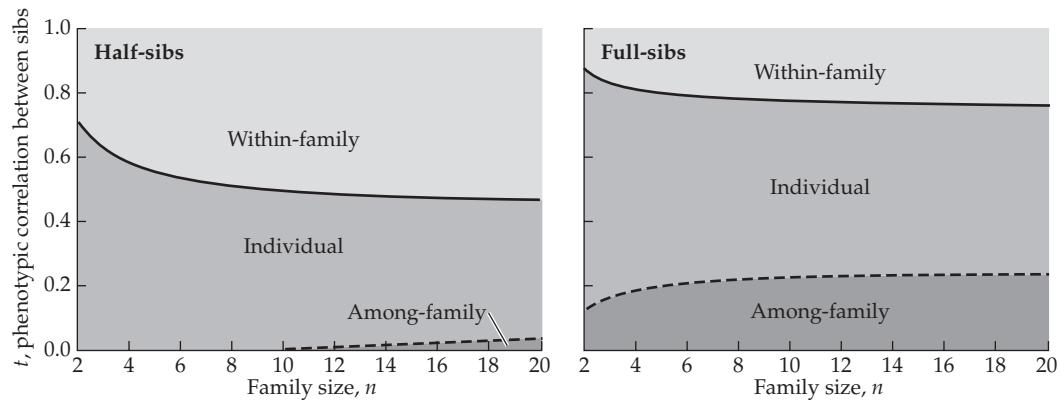

Figure 21.4 Regions of the family size (n)-sib correlation (t) space where individual, among-family (family selection) and within-family (selection of family deviations, [FD]) are the most accurate (based on Equations 21.35a and 21.35b). If t is sufficiently large, within-family selection yields the largest response (for large values of n ; $t > 7/16 = 0.4375$ for half-sibs and $t > 3/4$ for full-sibs). Among-family selection is best when t is sufficiently small (for large values of n ; $t < 1/16 = 0.0625$ for half-sibs, and $t < 1/4$ for full-sibs). Individual selection yields the largest response for intermediate values of t . For large n (t_n, r_n approaching t, r), among-family selection equals sib selection, as does parental selection (using the curve for full-sibs), while family-deviations selection approaches strict within-family (WF) selection.

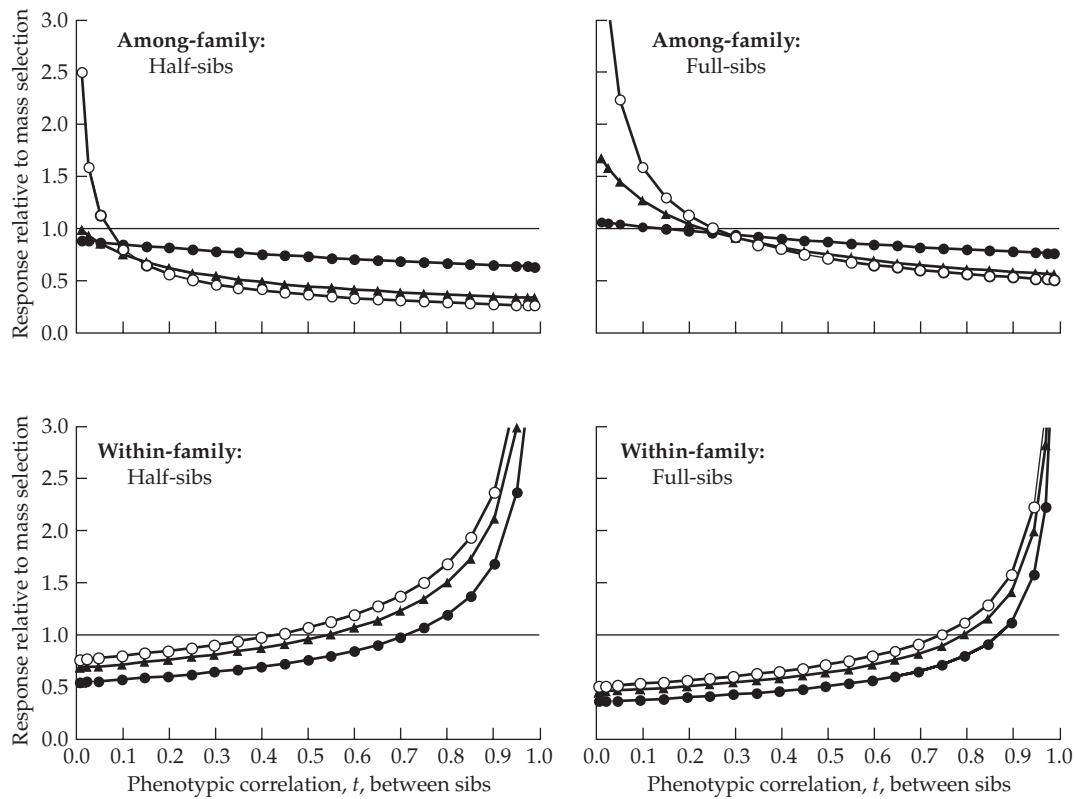

Figure 21.5 Accuracies of among-family selection (**top row**) and selection on family deviations (FD) (**bottom row**) relative to individual selection. In all graphs, filled circles correspond to $n = 2$ and open circles to large n . In the upper two graphs, the filled triangles correspond to $n = 10$ and correspond to $n = 5$ in the lower two graphs. Strict within-family selection (WF) corresponds to the large- n values for FD selection (open circles). Assuming equal selection intensities, values exceeding one indicate an increased single-generation response relative to individual selection.

In the absence of epistasis, Equation 21.11a yields

$$t = rh^2 + c^2, \quad \text{with} \quad c^2\sigma_z^2 = \begin{cases} \sigma_{Ec(HS)}^2 & \text{half-sibs} \\ \frac{1}{4}\sigma_D^2 + \sigma_{Ec(FS)}^2 & \text{full-sibs} \end{cases} \quad (21.36b)$$

where c^2 scales the residual among-family variance (upon removal of any shared additive variance). Figures 21.4 and 21.5 plot the relative accuracies and responses under among-family (family selection) and within-family (family-deviations) selection. Note that if $c = 0$, then $t = rh^2$, which is bounded above by 1/4 in half-sibs and 1/2 in full-sibs (because $h^2 \leq 1$, it follows that $t \leq r$). For t to exceed r requires that $c > 0$.

What are the exact conditions for a particular method to be more accurate than individual selection? Equation 21.35a shows that among-family selection is more accurate when $\gamma^2 > t_n$, or

$$t_n = t + \frac{1-t}{n} = (rh^2 + c^2) \left(1 - \frac{1}{n}\right) + \frac{1}{n} < \gamma^2 \quad (21.37a)$$

For values of n that are moderate to large (such that $t_n \simeq t$), among-family selection is more accurate than mass selection when c^2 , the fraction of the total due to residual among-family effects, is sufficiently small. Substituting the value of γ associated with a particular selection scheme (Equation 21.14b) into Equation 21.37a (for moderate to large values of n) yields the condition for among-family selection to be more accurate than individual selection as

$$c^2 < \begin{cases} \frac{1}{16}(1-4h^2) & \text{half-sibs (for family and sib selection; } \gamma = 1/4) \\ \frac{1}{4}(1-h^2) & \text{half-sibs (for parental and } S_1 \text{ seed selection; } \gamma = 1/2) \\ \frac{1}{4}(1-2h^2) & \text{full-sibs (} \gamma = 1/2) \end{cases} \quad (21.37b)$$

If $h^2 > 1/2$, the condition given by Equation 21.37b when full-sibs comprise the selection unit becomes $c^2 < 0$, and among-family selection is always less efficient than individual selection. With half-sibs comprising the selection unit, family- and sib-selection are always less efficient than individual selection when $h^2 > 1/4$. Among-family selection is, therefore, only more effective than mass selection when heritability is small and the fraction, c^2 , of total variation due to common-family residual variation is also small.

Turning to within-family selection, Equation 21.35b shows that family deviations (FD) selection yields a larger response than individual selection when $(1 - r_n)/\sqrt{1 - t_n} > 1$. When families are large ($n \gg 1$, such that $t_n \simeq t$ and $r_n \simeq r$), this condition reduces to

$$t = rh^2 + c^2 > 1 - (1-r)^2 \quad (21.38a)$$

or

$$c^2 > 1 - (1-r)^2 - rh^2 = \begin{cases} \frac{7}{16} - \frac{h^2}{4} & \text{half-sibs (} r = 1/4) \\ \frac{3}{4} - \frac{h^2}{2} & \text{full-sibs (} r = 1/2) \end{cases} \quad (21.38b)$$

Because $h^2 + c^2 \leq 1$ (both being fractions of the total variance due to different sources), there is an additional constraint that $1 - h^2 \geq c^2$. When $h^2 > 0.75$, within-family (half-sib) selection is always less efficient than individual selection, as here $c^2 \leq 1 - h^2 = 0.25$, while the critical c^2 value that must be exceeded is 0.25 $[(7/16) - (3/4)/4] = 1/4$. By the same logic, for full-sibs, individual selection is more efficient than within-family selection whenever $h^2 > 0.5$. Because we assumed that n is large, r and t replace r_n and t_n , respectively, and hence Equations 21.38a and 21.38b are also the conditions for strict within-family (WF) selection. Within-family selection is thus more efficient than individual selection only when

the heritability is low and the residual among-family variance ($c^2\sigma_z^2$) accounts for a very significant fraction of the total variance; in other words, common-family effects account for much of the phenotypic variance.

Willeke (1982) suggested that an excellent candidate trait for within-family selection would be litter size in pigs. Recall (Chapter 15) that mice from large litters tend to have a negative environmental value for litter size. Given that the heritability estimates for pig litter size from a grandmother-granddaughter regression are higher than those based on a mother-daughter regression, a similar situation likely occurs in pigs. Thus, there is a large family contribution that obscures prediction of the breeding value from the phenotypic value, resulting in the female's ranking within a family being a more informative predictor of her breeding value than her phenotypic value.

Example 21.8. Wilson (1974) examined family selection (using full-sibs) on larval and pupal weight in *Tribolium castaneum*. Correlations among full-sibs were estimated to be $t = 0.16$ for larval weight and $t = 0.20$ for pupal weight. Family size was $n = 12$. Under family selection, Equation 21.14b implies that $\gamma = r_n$. With noninbred full-sibs, $r = 1/2$, yielding (from Equation 21.35a) a ratio of the accuracies of family to mass selection on larval weight of

$$\frac{\gamma}{\sqrt{t_n}} = \frac{r_n}{\sqrt{t_n}} = \frac{r + (1 - r)/n}{\sqrt{t + (1 - t)/n}} = \frac{0.5 + 0.5/12}{\sqrt{0.16 + (0.84/12)}} = 1.13$$

Likewise, the relative accuracy for pupal weight is

$$\frac{0.5 + 0.5/12}{\sqrt{0.20 + (0.80/12)}} = 1.05$$

showing that both characters are expected to show a slightly larger response under family selection than under mass selection. Note from Equation 21.14b that the expected response for sib-selection using full-sibs is the same as for parental selection (as $\gamma = 1/2$ in both cases). The relative accuracy of these two methods (sib and parental selection) on larval weight is

$$\frac{\gamma}{\sqrt{t_n}} = \frac{0.5}{\sqrt{0.16 + (0.84/12)}} = 1.04$$

while their relative accuracy for pupal weight is

$$\frac{\gamma}{\sqrt{t_n}} = \frac{0.5}{\sqrt{0.20 + (0.80/12)}} = 0.97$$

Thus, for pupal weight, family selection is slightly more accurate than mass selection, while sib selection and parental selection are slightly less accurate.

Several other studies have compared family and individual selection. Campo and Tagarro (1977) compared full-sib family and individual selection on *Tribolium* pupal weight, using experiments with family sizes of 4 and 10. In both experiments, family selection gave the larger single-generation response, while mass selection had the larger response after six generations. None of these differences were significant. Two other studies compared individual and among-family selection, both using half-sib family selection in chickens. Garwood et al. (1980) examined laying rate ($h^2 = 0.22$) and egg weight ($h^2 = 0.55$) and found that individual selection yielded a greater single-generation response for both characters, but the difference for egg weight was not significant. Kinney et al. (1970) examined several characters, and found that the response under individual selection exceeded that from family selection, although again none of the differences were significant. Lack of significance is not surprising given the (often) small expected differences between methods, coupled with the large evolutionary

sampling variance in selection experiments with small to modest populations (Chapter 18).

Finally, it is informative to compare methods using the heritability version of response, $R_x = h_x^2 S_x$. From Equation 21.23, the within-family heritability exceeds the individual heritability when $1 - r > 1 - t$. Hence,

$$h_w^2 > h^2 \quad \text{when} \quad t > r \quad (21.39a)$$

Likewise, from Equation 21.15b, the among-family heritability satisfies

$$h_b^2 > h^2 \quad \text{when} \quad \gamma > t_n \quad (21.39b)$$

The careful reader may have noticed that these conditions are rather different from those given by Equations 21.37a and 21.38a. For example, Equation 21.37a implies that among-family selection yields a larger response than individual selection when $\gamma > \sqrt{t_n}$, whereas Equation 21.39b implies that the among-family heritability is greater than h^2 when $\gamma > t_n$. What is the discrepancy between these two approaches (accuracies versus heritabilities)?

The key is that the variances of the groups being selected differ. Because $\sigma_z^2 = \sigma_b^2 + \sigma_w^2$, the among-family and within-family variances are each less than the phenotypic variance of a random individual. Because $S_x = \bar{t}_x \sigma_x$, larger selection intensities are required to give a family-based approach the same selection differential as individual selection. Because the within- and among-family variances are $(1 - t_n)\sigma_z^2$ and $t_n\sigma_z^2$, respectively, it follows that

$$\frac{S_b}{S_m} = \frac{\bar{t}_b \sigma_b}{\bar{t}_m \sigma_z} = \frac{\bar{t}_b}{\bar{t}_m} \sqrt{t_n} \quad \text{and} \quad \frac{S_w}{S_m} = \frac{\bar{t}_w \sigma_w}{\bar{t}_m \sigma_z} = \frac{\bar{t}_w}{\bar{t}_m} \sqrt{1 - t_n} \quad (21.39c)$$

Under identical selection intensities, the differentials for among- and within-family selection are $\sqrt{t_n}$ and $\sqrt{1 - t_n}$, respectively, of the differential under mass selection. Thus, even when h_w^2 or h_b^2 exceeds h^2 , this advantage is partially countered by smaller selection differentials due to smaller variances. The contrast of heritabilities as a comparison of expected response assumes that there is the same selection differential, and thus has a hidden assumption of more selection under family-based selection, as the presence of identical S values implies a larger value of \bar{t} for family-based selection (Equation 21.39c).

Comparing Selection Intensities: Finite Size Corrections

While not nearly as dramatic as the above differences in the selection differentials (Equation 21.39c), the selection intensities can differ across methods even if the same fraction, p , is saved (Example 21.1). These differences arise from the finite sample-size correction of \bar{t} (Chapter 14). Suppose nine individuals are measured, three from each of three families. If we select for the upper 1/3, we keep the best one of three families under among-family selection, and the best of the three individuals within each family under WF selection, resulting in an expected selection intensity of $\bar{t}_{(1,3)} = 0.846$ (the expected value of the largest of the first three order statistics). Under family deviations (FD) and mass selection, we chose the largest three of nine values, resulting in an expected selection intensity of $\bar{t}_{(3,9)} = 0.996$. Table 21.6 summarizes the selection intensities for the different methods, and shows that $\bar{t}_b = \bar{t}_{WF} \leq \bar{t}_m \leq \bar{t}_{FD}$.

An additional subtlety in adjusting the selection intensity was pointed out by Hill (1976, 1977b). The expected selection intensity is computed by taking the expected value of the largest standardized order statistics (Chapter 14), under the assumption that the order statistics are *uncorrelated*. However, with family deviations (FD), family index, and even mass selection, there is the potential for correlations between order statistics. This arises if families contribute different numbers of individuals, resulting in correlations between those measures from the same family, and hence correlations between some of the order

Table 21.6 Selection intensities for various forms of family-based selection schemes corrected for finite sample size. The upper p of the population is saved and the population consists of m families each with n members, for a total of $M = mn$ measured individuals. Tables of exact values for $\bar{\tau}_{(K,M)}$ (the average value of the top K of the M standardized order statistics; see Chapter 14) are given by Becker (1992), and can also be easily obtained via simulations. Approximations for $\bar{\tau}_{(K,M)}$ are given by Equations 14.4a–14.4c.

Selection Type	Corrected Selection Intensity
Individual	$\bar{\tau}_m = \bar{\tau}_{(pM,M)}$
Among-family	$\bar{\tau}_b = \bar{\tau}_{(pm,m)}$
Family-deviations	$\bar{\tau}_{FD} = \bar{\tau}_{(pM,M)} \sqrt{1 + \frac{1}{M-1}}$
Within-family	$\bar{\tau}_{WF} = \bar{\tau}_{(pn,n)}$

statistics. The correction for mass selection is generally very small and will be ignored here (see Equation 21.57b). Within-family deviations are negatively correlated within a family, ($\rho = -1/[n - 1]$ for a family of size n), as they are deviations from a common family mean. As a result, Dempfle (1990) and Hill et al. (1996) found that the resulting selection intensity for within-family deviations is thus slightly larger than the intensity for mass selection $\bar{\tau}_m$, with

$$\bar{\tau}_{FD} = \bar{\tau}_m \sqrt{1 + \frac{1}{M-1}} \quad (21.40)$$

where M is the total number of measured sibs. On the other hand, with selection on a family index, the correlations between index scores are positive and can be considerable even for large n (Equation 21.58). We will consider the appropriate correction for $\bar{\tau}$ in our treatment of family index selection at the end of this chapter.

Within-family Selection Has Additional Long-term Advantages

The above discussion of the relative efficiencies of different methods focused on a single generation of response from an unselected base population. As we saw in Chapter 16, after one generation of selection, gametic-phase disequilibrium (LD for short) is generated (even among unlinked loci), which (for directional selection) results in a reduction in the additive variance. This reduction, and the resulting decrease in selection response, arises entirely from among-family effects, and thus impacts both individual selection and among-family selection. For unlinked loci, LD does not, however, impact the amount of additive variation *within* a family (Example 16.2), meaning that under strict within-family (WF) selection, there is no decrease in the additive variance from negative LD. Specifically, the amount of within-family additive variance (in the absence of drift or inbreeding) remains at $\sigma_a^2/2$ (half the genic variance, σ_a^2 , where $\sigma_a^2 = \sigma_A^2$ in the absence of LD), while the amount of among-family variance is $\sigma_a^2/2 + d$, where $d < 0$ (Chapter 16). Hence, the above comparisons for a single generation undervalue the relative short-term gains from WF selection (with respect to either mass or among-family selection). As we saw in Chapter 16, the reduction in the amount of additive variance due to among-family differences can be substantial ($|d| \gg 0$), especially for a trait that has a moderate to high heritability and is under strong selection (Figure 16.4).

A further advantage of within-family selection appears over the longer term. As mentioned previously, under strict within-family selection (WF), all families contribute the same number of offspring to the next generation, which results in a doubling of the effective population size relative to other schemes that weight among-family information (the latter generates an among-family variance in offspring number, which reduces N_e ; Equation 3.4).

As developed in Chapter 26, the long-term response to selection is a function of the effective population size, which results once again in the single-generation comparison of WF to mass or among-family selection that underestimates its relative long-term importance. We examine these issues further in Chapter 26.

RESPONSE WHEN FAMILIES ARE REPLICATED OVER ENVIRONMENTS

Family members are often raised in multiple plots and/or environments, and carefully designed family replication in such a setting offers two potential advantages. First, it allows for the selection of families that perform best over a range of environments, even when extensive genotype \times environment interactions ($G \times E$) are present. Second, replication within an environment reduces the effects of microenvironmental differences, thus increasing the predictability of a family's breeding value and resulting in a larger selection response.

Because family replication is a hallmark of plant breeding, we will examine several schemes used by breeders in detail in this section (in Chapter 23 we examine related designs under inbreeding, while both line crossing and selection in the presence of $G \times E$ are more fully examined in Volume 3). Detailed reviews of plant-breeding methodology are given by Namkoong (1979), Hallauer (1981, 1985), Hallauer and Miranda (1981), Nguyen and Sleper (1983), Wricke and Weber (1986), Mayo (1987), Hallauer et al. (1988), Gallais (1990, 2003), Nyquist (1991), Stoskopf et al. (1993), Bos and Caligari (1995), Allard (1999), Holland et al. (2003), Sleper and Poehlman (2006), Acquaah (2007), Bernardo (2010), and Hallauer et al. (2010).

Among-family Variance Under Replication

The expected response to among-family selection under replication follows from Equation 21.14a, using the appropriate among-family variance, $\sigma^2(\bar{z})$, given the replication design used by the breeder. In the simplest case, only a single macroenvironment (such as a growing region) is considered, and the family is replicated by raising n_s sibs in each of n_p separate plots (for a total of $N = n_p n_s$ sibs per family). Under this replication scheme, the total environmental value can be partitioned as $E = E_c + E_p + E_s$, representing a common-family effect (E_c), a plot-specific effect (E_p), and individual-specific effects (E_s). Following similar logic to that in Example 21.3, the resulting variance becomes

$$\sigma^2(\bar{z}) = \sigma_F^2 + \frac{\sigma_{E_p}^2}{n_p} + \frac{\sigma_w^2}{N} \quad (21.41a)$$

where $\sigma_{E_p}^2$ is the plot-to-plot variance (the environmental variance among plots in the same macroenvironment), $\sigma_F^2 = \sigma_{GF}^2 + \sigma_{E_c}^2$ is the among-family variance, and $\sigma_w^2 = \sigma_{Gw}^2 + \sigma_{E_s}^2$ is the within-plot variance of individuals about their family averages. Recall that $\sigma_{Gw}^2 = \sigma_G^2 - \sigma_{GF}^2$, and values for the among- and within-family genetic variances are given by Equations 21.11a and 21.11b, respectively, when epistasis is absent, and more generally by Equations 21.26a and 21.26b.

An alternative way to express the variance of family means is

$$\sigma^2(\bar{z}) = \sigma_{GF}^2 + \sigma_{E_c}^2 + \sigma^2(\epsilon) \quad (21.41b)$$

where for the design given by Equation 21.41a, the residual variance is

$$\sigma^2(\epsilon) = \frac{\sigma_{Gw}^2}{N} + \frac{\sigma_{E_s}^2}{N} + \frac{\sigma_{E_p}^2}{n_p} = \left(\frac{1}{N} \right) \left(\sigma_{Gw}^2 + \sigma_{E_s}^2 + n_s \sigma_{E_p}^2 \right) \quad (21.41c)$$

The critical observation is that the contribution from $\sigma^2(\epsilon)$ can be largely controlled by the experimental design (here, the choice of n_s and n_p).

More generally, if the family is replicated over n_e distinct macroenvironments, each with n_p plots and n_s sibs per plot, for a total of $N = n_p n_s n_e$ sibs, Equation 21.41b holds, with the residual variance now being

$$\begin{aligned}\sigma^2(\epsilon) &= \frac{\sigma_{Gw}^2}{N} + \frac{\sigma_{GF \times E}^2}{n_e} + \frac{\sigma_{E_p}^2}{n_e n_p} + \frac{\sigma_{E_s}^2}{N} \\ &= \left(\frac{1}{N} \right) \left(\sigma_{Gw}^2 + \sigma_{E_s}^2 + n_s \sigma_{E_p}^2 + n_p n_s \sigma_{GF \times E}^2 \right)\end{aligned}\quad (21.42a)$$

where σ_{GF}^2 is the genetic variance among family means over this set of environments, and $\sigma_{GF \times E}^2$ is the variance from the family-environment interaction (LW Chapter 22).

Plant breeders often use an alternative partition of the environment into location (L) and year (Y) effects. Suppose a family is replicated over n_ℓ locations over n_y years, where each of the $n_\ell n_y$ year-location combinations is replicated as n_p plots of n_s sibs each, for a total of $N = n_\ell n_y n_p n_s$ sibs per family. Again, Equation 21.41b holds, with a residual variance of

$$\begin{aligned}\sigma^2(\epsilon) &= \frac{\sigma_{GF \times L}^2}{n_\ell} + \frac{\sigma_{GF \times Y}^2}{n_y} + \frac{\sigma_{GF \times L \times Y}^2}{n_\ell n_y} + \frac{\sigma_{E_p}^2}{n_\ell n_y n_p} + \frac{\sigma_{Gw}^2 + \sigma_{E_s}^2}{n_\ell n_y n_p n_s} \\ &= \left(\frac{1}{N} \right) \left[\sigma_{Gw}^2 + \sigma_{E_s}^2 + n_s \sigma_{E_p}^2 + n_p n_s (n_y \sigma_{GF \times L}^2 + n_\ell \sigma_{GF \times Y}^2 + \sigma_{GF \times L \times Y}^2) \right]\end{aligned}\quad (21.42b)$$

where $\sigma_{GF \times L}^2$, $\sigma_{GF \times Y}^2$, and $\sigma_{GF \times L \times Y}^2$ are the family by environment (year, location, and year-location) interactions (Lonnquist 1964; Comstock and Moll 1973; Patterson et al. 1977; Brennan and Byth 1979; Thompson and Cunningham 1979).

The above expressions for $\sigma^2(\epsilon)$ show the importance of replication and provide some guidance as to how one should allocate resources. For a fixed number of sibs per family (N), how should one choose n_e , n_p , and n_s to minimize $\sigma^2(\bar{z})$? If N is fixed, then the relative weightings on the within-family genetic variance and individual-specific environmental variance are fixed. When the genotype \times environment interaction variance ($\sigma_{GF \times E}^2$) is large, its effect on the selection response can be reduced by replicating families across more environments (increasing n_e). More generally, when viewing environments as locations-years (Equation 21.42b), the total number of environments is $n_e = n_\ell n_y$, and preliminary estimates of the variation components ($\sigma_{GF \times L}^2$, $\sigma_{GF \times Y}^2$, and $\sigma_{GF \times L \times Y}^2$) can suggest the appropriate allocation over locations versus years for a fixed value of n_e . When the among-plot variance ($\sigma_{E_p}^2$) is large, its effect is reduced by increasing n_p or n_e . With preliminary estimates of the variance components in hand, one can numerically search for the optimal values of n_e , n_p , and n_s that give the smallest $\sigma^2(\bar{z})$ for a fixed value of $N = n_e n_p n_s$. Using replication can result in a considerable improvement over mass selection. For example, using variance components estimated for maize lines grown in several locations in India, Sanghi (1983) estimated that full-sib selection with replication would be three to sixfold times more efficient than mass selection.

One consequence of replication is that the among-family heritability, $h_b^2 = \gamma \sigma_A^2 / \sigma^2(\bar{z})$ (Equation 21.15b), is now a complex function of the design, namely, the values of n_e and n_p , in addition to the total number of sibs, which enter through $\sigma^2(\bar{z})$, via $\sigma^2(\epsilon)$. Thus, with replication, an among-family heritability does not directly translate into an individual heritability (Hanson 1963; Nyquist 1991; Holland et al. 2003). Even with the same variance components, h_b^2 changes as a function of the replication design. Hanson suggested that, when replication is present, the among-family heritability needs to be defined with respect to a particular standard design, such as his proposal in soybeans of a design with two years over two locations, with two replications in each location-year combination.

Finally, consider the among-family variance under a nested-sib design with replication. Suppose (as before) that there are n_f females per male, but now that each full-sib family is

replicated as n_s sibs over n_e environments. The resulting variance becomes

$$\sigma^2(\bar{z}) = \sigma_{GF(HS)}^2 + \frac{\sigma_{GF(HS) \times E}^2}{n_f} + \frac{\sigma_{G(f|m) \times E}^2}{n_f n_e} + \frac{\sigma_{Gw(FS)}^2 + \sigma_{E_s}^2}{N} \quad (21.43a)$$

where $N = n_f n_e n_s$ is the total number of half-sibs per male (Robertson et al. 1955; Webel and Lonnquist 1967; da Silva and Lonnquist 1968). Assuming no epistasis or genotype by environment interaction ($G \times E$), we can express this among-family variance as

$$\frac{\sigma_A^2}{4} + \frac{\sigma_A^2 + \sigma_D^2}{4 n_f} + \frac{\sigma_{A \times E}^2}{4 n_e} + \frac{\sigma_{A \times E}^2 + \sigma_{D \times E}^2}{4 n_f n_e} + \frac{(1/2)\sigma_A^2 + (3/4)\sigma_D^2 + \sigma_{E_s}^2}{N} \quad (21.43b)$$

The extension of this result to multiple plots per location when $G \times E$ is present follows in a similar fashion from our development above for Equation 21.42b.

An example of family selection with replication was provided by selection for increased grain yield in maize by the International Maize and Wheat Improvement Center (CIMMYT), summarized by Pandey et al. (1986, 1987) and Crossa and Gardner (1989). The goal of the CIMMYT selection schemes was to develop varieties of maize that yield well over a wide range of environments. Starting in 1974, 250 full-sib families, along with six local **checks** (control lines to allow for standardized comparisons), were evaluated at six lowland tropical locations (with two replications per location) in the northern and southern hemispheres. A total of 28 countries were used during the course of five cycles of selection. Selection (initially) was strictly among families with the international field trials conducted on full-sib families, while the recombination unit consisted of S_1 seed from the superior families. The selection scheme was later modified to allow for within-family selection as well. Roughly 50% of the families were selected based on the international trials, about 20% of which were subsequently rejected given their poor performance in disease- and insect-resistance trials in separate nurseries. The average gain in yield per cycle was around 2%.

Example 21.9. Eberhart et al. (1966) estimated genetic variance components for seven characters in two open-pollinated maize varieties. Using individuals grown in two locations in North Carolina, they obtained the following estimates for yield in the variety Jarvis:

$$\sigma_A^2 = 120, \quad \sigma_{A \times L}^2 = 114, \quad \sigma_D^2 = 270, \quad \sigma_{D \times L}^2 = 98, \quad \sigma_{E_s}^2 = 508$$

Estimates of epistatic variances were not significantly different from zero. Consider the expected response under a design with 25 half-sib families, each with a total of 50 offspring scored over five environments ($n_e = 5$). The top five families were selected, using S_1 seed to form the next generation (allowing for selection on both sexes). Recalling Equation 21.14a (with $\gamma = 1/2$ for S_1 seed; Equation 21.14b), the expected response will be

$$R = \frac{2\bar{\iota}_{(5,25)}(\sigma_A^2/4)}{\sigma(\bar{z})} = \frac{2 \cdot 1.345 \cdot 30}{\sigma(\bar{z})} = \frac{80.7}{\sigma(\bar{z})}$$

using Equation 14.4b to obtain $\bar{\iota}_{(5,25)}$. If we use the above variance estimates, then $\sigma_{GF \times E}^2 = \sigma_{A \times L}^2/4 = 28.5$, while Equation 21.26a and 21.26b yield, respectively, $\sigma_{GF}^2 = \sigma_A^2/4 = 30$ and $\sigma_{Gw}^2 = (3/4)\sigma_A^2 + \sigma_D^2 = 360$. If the families being scored are strict half-sibs (meaning that all offspring from a pollen parent each have a different seed parent, $n_f = N = 50$), then Equation 21.42a returns

$$\begin{aligned} \sigma^2(\bar{z}_{HS}) &= \sigma_{GF}^2 + \frac{\sigma_{Gw}^2 + \sigma_{E_s}^2}{N} + \frac{\sigma_{GF \times L}^2}{n_e} \\ &= 30 + \frac{360 + 508}{50} + \frac{28.5}{5} = 53.06 \end{aligned}$$

and the expected response becomes $80.7/\sqrt{53.06} = 11.08$.

Now suppose that the sibs are from a nested design with each male pollinating five seed parents, and with each cross producing 10 offspring ($n_f = 5$, $N = 50$). Using the above variance components, Equation 21.43b yields

$$\begin{aligned}\sigma^2(\bar{z}) &= \frac{\sigma_A^2}{4} + \frac{\sigma_A^2 + \sigma_D^2}{4n_f} + \frac{\sigma_{A \times L}^2}{4n_e} + \frac{\sigma_{A \times L}^2 + \sigma_{D \times L}^2}{4n_f n_e} + \frac{(1/2)\sigma_A^2 + (3/4)\sigma_D^2 + \sigma_{E_s}^2}{N} \\ &= \frac{120}{4} + \frac{120 + 270}{20} + \frac{114}{20} + \frac{114 + 98}{100} + \frac{(1/2)120 + (3/4)270 + 508}{50} \\ &= 72.73\end{aligned}$$

resulting in an expected response of $80.7/\sqrt{72.73} = 9.47$. Hence, the strict half-sib design has a smaller among-family variance, and thus a 117% larger expected response than expected under a nested design.

Ear-to-Row Selection

One of the earliest examples of family-based selection was the **ear-to-row** selection method in maize, first used by Hopkins (1899) to start his classic long-term selection experiment (Chapter 26). Here the seeds from each maize ear are planted in a single row (so that a row corresponds to a family), with individuals from the best rows chosen as seed parents for the next generation. Plants in the rows to be scored are either detassled or have their tassles (pollen-producing structures) bagged, removing their ability to contribute pollen. As a result, these plants can neither self nor pollinate. Pollen is provided by rows planted with bulk of all seeds (a **polycross** mating design). Assuming open pollination, the seeds on a single ear are half-sibs (with a common mother), which means that the ear-to-row method is an example of half-sib family selection, with selection on only one sex (the seed parent). In rice, **panicle-to-row** selection has been used (e.g., Ntanos and Roupakias 2001), where the **panicle** is essentially the equivalent of the maize ear, and again a row equals a family.

Suppose a total of $n = n_e n_p n_s$ sibs per family are scored, by growing n_p rows of n_s sibs, replicated over n_e distinct environments. From Equation 21.15c, the expected response under ear-to-row selection, when choosing the top K of M families ($p = K/M$), is

$$R_{ER} = \bar{t}_{(pM, M)} \frac{(1 + 3/n)(\sigma_A^2/8)}{\sigma(\bar{z}_{HS})} \simeq \bar{t}_{(pM, M)} \frac{\sigma_A^2/8}{\sigma(\bar{z}_{HS})} \quad (21.44)$$

where $\sigma^2(\bar{z}_{HS})$ is calculated by Equation 21.42a. For large values of n (in the absence of epistasis),

$$R_{ER} = \bar{t}_{(pM, M)} \frac{\sigma_A^2/8}{\sqrt{\frac{\sigma_A^2}{2} + \frac{\sigma_{GF \times E}^2}{n_e} + \frac{\sigma_{E_p}^2}{n_e n_p} + \frac{\sigma_{E_s}^2}{n}}} \quad (21.45)$$

Modified Ear-to-Row Selection

The ear-to-row method has the advantage of being fairly easy to implement for testing a family (with replication reducing the effects from the environmental variance), coupled with the same cycle time as mass selection (one generation). As a result, this method was commonly used by early maize breeders, for example, Hopkins (1899), Smith (1908, 1909), Montgomery (1909), Williams and Walton (1915), Kiesselbach (1916), and Hume (1919). While it proved effective at modifying highly heritable traits (such as kernel protein and oil content), ear-to-row selection was generally not successful in improving yield (Kiesselbach 1922; Richey 1922; Smith and Bruson 1925), and it was not regarded as a practical scheme for yield improvement. Sprague (1955) suggested that the failure for yield improvement

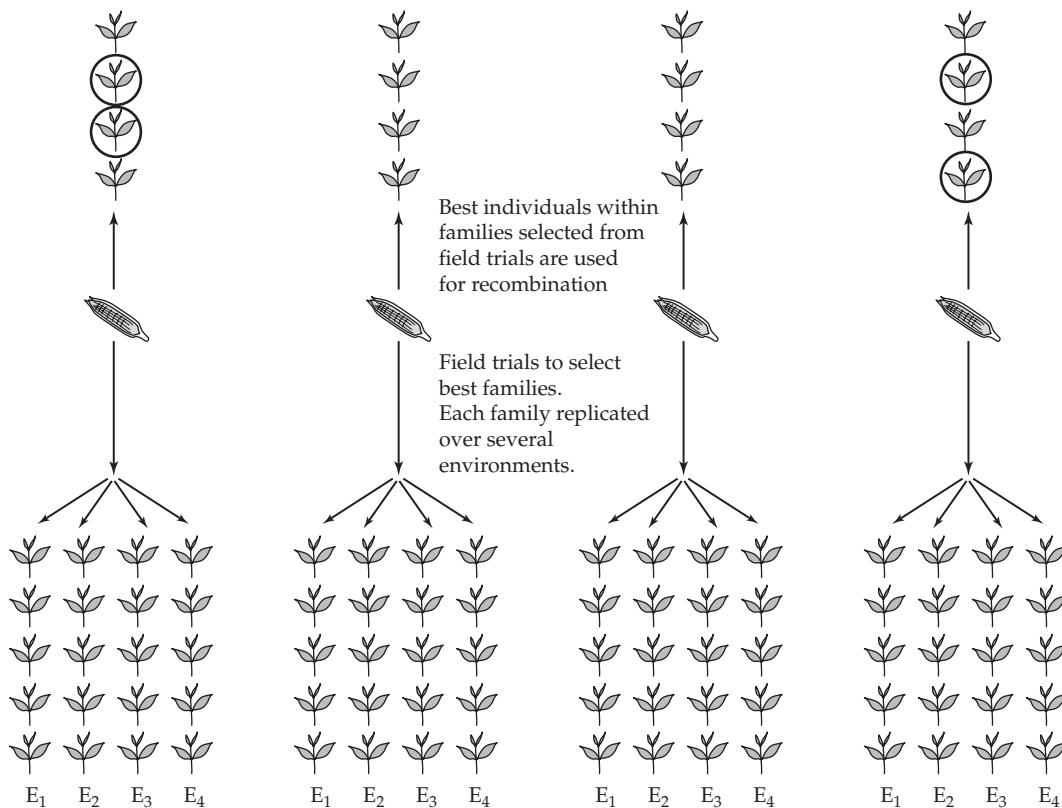

Figure 21.6 Lonnquist's (1964) modified ear-to-row selection scheme. Half-sib families (represented here by the maize ears in the middle of the figure) are planted both as rows in multiple environments (the yield trials over environments E_1 through E_4 at the bottom of the figure) and as a single additional row in yet another location, the so-called crossing block (the rows at the top of the figure). From the best families in the yield trials (the first and fourth in the above figure) one then chooses the best individuals (indicated by the circled plants) from their sibs in the crossing block (within-family selection) to form the next generation.

was largely the result of insufficient control over environmental variance, which resulted in σ_E^2 largely obscuring the additive variance. (For this same reason, mass selection was also regarded as being impractical for improving maize yield.) An alternative hypothesis was suggested by Hull (1945, 1952), who thought that the lack of response in yield was a result of most of the genetic variance being nonadditive. The finding of considerable additive variance in yield by a number of maize geneticists motivated Lonnquist's (1964) development of the **modified ear-to-row** scheme, a combined selection approach involving both among-family (ear-to-row) and within-family (within-row) selection (Figure 21.6).

Under Lonnquist's design, seed from each family is planted as rows in several environments. These form the **yield or performance trials** for selecting the best-performing families averaged over these environments. On a separate plot (the **crossing block**), additional seeds from each family are planted as a single row. Within the crossing block, the best individuals from the rows corresponding to the families with the best performance in the yield trials are used as the seed parents for the next generation. Selection is only on one parent in the crossing block, as plants are detassled and open pollinated from a random bulk of all the initially planted families. One advantage of this scheme is that one can use bulk measures over rows in the yield trials and more detailed (and labor-intensive) individual

plant measures in the smaller crossing block.

Under Lonnquist's original design, the replicated field trials and the crossing block are grown contemporaneously (planting of the crossing block may be delayed slightly to ensure that all field information from the yield trials can be gathered). Thus, one cycle of modified ear-to-row selection can be carried out in a single generation. The expected total response is the sum of the expected gains at each step in the cycle, $R_{ER(m)} = R_{ER} + R_{ER(w)}$. The response, R_{ER} , under the first step (choosing the best families) is the same as for standard ear-to-row selection (Equations 21.44 and 21.45). Because plants in the crossing block are open pollinated using a bulk of all families, selection is only on females within each row. If one chooses the best $k = qn_s$ of n_s plants within each selected row (i.e., strict within-family [FW] selection saving the upper fraction, q), the expected response to within-row selection becomes

$$R_{ER(w)} = \bar{\iota}_{(qn_s, n_s)} \frac{(3/8) \sigma_A^2}{\sigma_w(HS)} \quad (21.46)$$

Because families are not replicated within the crossing block, then

$$\sigma_w^2(HS) = \sigma_{Gw(HS)}^2 + \sigma_{E_s}^2$$

Hence, in the absence of epistasis, the component of response from within-row selection becomes (Equation 21.22b)

$$R_{ER(w)} = \bar{\iota}_{(qn_s, n_s)} \frac{(3/8) \sigma_A^2}{\sqrt{(3/4)\sigma_A^2 + \sigma_D^2 + \sigma_{E_s}^2}} \quad (21.47)$$

Ignoring any potential changes in σ_A^2 due to the first step of selection (ear-to-row), the expected response becomes

$$\begin{aligned} R_{ER(m)} &= R_{ER} + R_{ER(w)} \\ &= \bar{\iota}_{(pM, M)} \frac{\sigma_A^2/8}{\sigma(\bar{z}_{HS})} + \bar{\iota}_{(qn_s, n_s)} \frac{(3/8)\sigma_A^2}{\sigma_w(HS)} \end{aligned} \quad (21.48a)$$

where we have chosen the best $K = pM$ of M families in the yield trials and the best $k = qn_s$ of n_s within each selected family in the crossing block. With a large number of sibs per row (n_s is large) and a roughly equal selection within and among rows ($\bar{\iota}_{(pM, M)} \simeq \bar{\iota}_{(qn_s, n_s)} = \bar{\iota}$), the expected response to modified ear-to-row selection is

$$R_{ER(m)} = \frac{\bar{\iota} \sigma_A^2/8}{\sqrt{\frac{\sigma_A^2}{2} + \frac{\sigma_{F \times E}^2}{n_e} + \frac{\sigma_{E_p}^2}{n_e n_p} + \frac{\sigma_{E_s}^2}{N}}} + \frac{\bar{\iota} (3/8) \sigma_A^2}{\sqrt{\frac{3\sigma_A^2}{4} + \sigma_D^2 + \sigma_{E_s}^2}} \quad (21.48b)$$

Inspection of Equation 21.48b shows that it is not obvious which component (within- vs. among-family) contributes more to the total selection response. The threefold increase in usable additive variance in the within-family component in the numerator can be partly or fully offset by the fact that $\sigma_{Gw}^2 > \sigma_{GF}^2$ (the within-family genetic variance is greater than the among-family variance; see Equations 21.26a and 21.26b). Likewise, it is not clear whether the among- or the within-family environmental variance is expected to be larger. Some fine-tuning is possible on the among-family component, as, if estimates of the appropriate environmental variances are available, changing the experimental design (the values of n_p , n_s , and n_e) can reduce $\sigma^2(\epsilon)$.

Example 21.10. Webel and Lonnquist (1967) used modified ear-to-row selection for yield in the Hays Golden open-pollinated variety of maize. Performance of each family was evaluated

using single rows grown in three different locations. Based on these yield trials, the best 44 of roughly 220 families were identified. In the crossing block, the best 5 of the 25 (or so) plants were chosen in each of the 44 rows corresponding to the selected families. The resulting expected selection intensities for the among- and within-family components were $\bar{\imath}_{(44,220)} = 1.40$ and $\bar{\imath}_{(5,25)} = 1.35$, respectively (Equation 14.4b). Over the first four cycles of selection, Webel and Lonnquist observed a 9.4% increase in yield per cycle, compared with the 3% increase per cycle observed under mass selection (Gardner 1973). The predicted response was 8.4%, with expected contributions of 4.6% from among-families (55% of predicted response) and 3.8% from within-families. The results for 10 cycles of selection were summarized by Compton and Bahadur (1977). Paterniani (1967) also used modified ear-to-row selection for yield for three cycles in Brazilian maize populations. The average yield increased by 42% over the course of the experiment.

Compton and Comstock (1976) suggested a variant of Lonnquist's design. This approach is also referred to as **among-and-within-family selection (AWF)** or **between-and-within-family selection (B&WFS)** by forage breeders (Aastveit and Aastveit 1990; Vogel and Pedersen 1993; Casler and Brummer 2008). Families are again planted ear-to-row in performance trials, but remnant seed from each family is stored. The best families are chosen and the remnant seed for these families is planted to form the crossing block. The pollen plants in the crossing block are a bulk of the selected families. Hence, both parents in the crossing block are subjected to half-sib selection, which doubles the response from the among-family component, and yields

$$R_{ER(m)} = \bar{\imath}_{(pM,M)} \frac{(1/4)\sigma_A^2}{\sigma(\bar{z}_{HS})} + \bar{\imath}_{(qn_s,n_s)} \frac{(3/8)\sigma_A^2}{\sigma_{W(HS)}} \quad (21.49)$$

The Compton-Comstock modified ear-to-row scheme requires two generations per cycle, but it offers increased response (per cycle) as the pollen is also from selected parents. Using the predicted values of Webel and Lonnquist (Example 21.10), the expected response per cycle under the Compton-Comstock design would be $2 \cdot 4.6 + 3.8 = 13$, for an expected 155% increase per cycle over the Lonnquist design (which had a predicted response 8.4). However, the Compton-Comstock design also requires two generations per cycle, with the result that the response per generation is 6.5, 77% of that expected under the Lonnquist design. The use of **off-season** (or winter) **nurseries**, where seeds are grown in either the opposite hemisphere or in the tropics (such as the Hawaiian island of Moloka'i), can allow for two generations in the same calendar year, but this may require more resources than the breeder has available.

SELECTION ON A FAMILY INDEX

While our focus to this point has been on schemes that use either within- or among-family selection, the modified ear-to-row approach points out the advantage of using selection schemes containing both within- and among-family components. The modified ear-to-row approach is an example of **combined selection**, where the components are sequentially selected in different generations (and/or plots), and several such schemes are used by plant breeders. Alternatively, one can use both within- and among-family information to select individuals within a single generation. The most general way to do this is to select on a **family index**,

$$I_{ij} = b_1 (z_{ij} - \bar{z}_i) + b_2 \bar{z}_i \quad (21.50a)$$

where the index value, I_{ij} , is for individual j from family i . Individuals with the largest index scores are mated (avoiding within-family crosses) to form the next generation. Note that individual ($I_{ij} = z_{ij}$), family ($I_{ij} = \bar{z}_i$), and family-deviations ($I_{ij} = z_{ij} - \bar{z}_i$) selection

are all special cases of this general family index, which correspond to weights of $b_1 = b_2$, $b_1 = 0$, and $b_2 = 0$, respectively.

An important point is that the *relative values* of the index weights, not their absolute values, define the choice of individuals—if both weights are multiplied by the same constant, the same individuals are chosen by the new index. As a result, the family index is often written as

$$I_{ij} = z_{ij} + B \bar{z}_i \quad (21.50b)$$

where B is the relative weight on family mean compared to an individual's phenotype. As the reader can easily verify with a little algebra, this is equivalent to the index given by Equation 21.50a, with

$$B = \frac{b_2}{b_1} - 1 \quad (21.50c)$$

Response to Selection on a Family Index

Once again, either Equations 21.1a or 21.4a can be used to predict the single-generation response to selection. Taking $x = I$ returns

$$R_I = \frac{\sigma(I, y | \mathcal{R}_1)}{\sigma_I^2} (S_{I_m} + S_{I_f}) = \bar{r}_I \sigma_z \rho(I, y) \quad (21.51)$$

where $\sigma(I, y | \mathcal{R}_1)$ is the covariance between the index value, I , of a parent and the phenotype of its offspring, y . The variances and covariances required for Equation 21.51 are obtained as follows. Using the covariances summarized in Table 21.3,

$$\begin{aligned} \sigma(I, y | \mathcal{R}_1) &= b_1 \sigma(z_{ij} - \bar{z}_i, y | \mathcal{R}_1 = x_{ij}) + b_2 \sigma(\bar{z}_i, y | \mathcal{R}_1 = x_{ij}) \\ &= b_1 (1 - r_n)(\sigma_A^2/2) + b_2 r_n (\sigma_A^2/2) \\ &= [b_1 + r_n(b_2 - b_1)] (\sigma_A^2/2) \end{aligned} \quad (21.52a)$$

Likewise, if we recall that $\sigma^2(x + y) = \sigma_x^2 + \sigma_y^2 + 2\sigma_{x,y}$, the variances summarized in Table 21.4 yield

$$\begin{aligned} \sigma^2(I) &= b_1^2 \sigma^2(z_{ij} - \bar{z}_i) + b_2^2 \sigma^2(\bar{z}_i) + 2b_1 b_2 \sigma(z_{ij} - \bar{z}_i, \bar{z}_i) \\ &= b_1^2 (1 - t_n) \sigma_z^2 + b_2^2 t_n \sigma_z^2 + 2b_1 b_2 \sigma(z_{ij}, \bar{z}_i) - 2b_1 b_2 \sigma^2(\bar{z}_i) \\ &= (b_1^2 (1 - t_n) + b_2^2 t_n + 2b_1 b_2 t_n - 2b_1 b_2 t_n) \sigma_z^2 \\ &= [b_1^2 + t_n(b_2^2 - b_1^2)] \sigma_z^2 \end{aligned} \quad (21.52b)$$

The resulting heritability of the index becomes

$$h_I^2 = \frac{2\sigma(I, y | \mathcal{R}_1)}{\sigma^2(I)} = h^2 \left[\frac{b_1 + r_n(b_2 - b_1)}{b_1^2 + t_n(b_2^2 - b_1^2)} \right] \quad (21.53a)$$

Finally, because parents only pass along half their breeding value to an offspring (Chapters 6 and 16), it follows that $\sigma(I, y | \mathcal{R}_1) = \sigma(I, A)/2$, namely, half the covariance between the parent's index and breeding values. Hence, from Equations 21.52a and 21.52b, the correlation between an individual's index score (I) and breeding value (A) is

$$\rho(I, A) = \frac{\sigma(I, A)}{\sigma(I) \sigma(A)} = \frac{2\sigma(I, y | \mathcal{R}_1)}{\sigma(I) \sigma(A)} = h \left[\frac{b_1 + r_n(b_2 - b_1)}{\sqrt{b_1^2 + t_n(b_2^2 - b_1^2)}} \right] \quad (21.53b)$$

Given that $\rho(z, A) = h$ (Equation 13.11e), the term in the brackets represents the accuracy of the index relative to mass selection. Substituting Equation 21.53a into Equation 21.51 (and recalling that $\sigma_z h^2 = h \sigma_A$) yields an expected response of

$$R_I = \bar{r}_I h \sigma_A \frac{b_1 + r_n(b_2 - b_1)}{\sqrt{b_1^2 + t_n(b_2^2 - b_1^2)}} \quad (21.53c)$$

where $\bar{t}_I = (\bar{t}_{I_m} + \bar{t}_{I_f})/2 = (S_{I_m} + Ss_{I_f})/(2\sigma_I)$ is the average selection intensity on both sexes. Observe from Equation 21.53c that if we create a new index with weights of ab_1 and ab_2 , that the constant a cancels, and (as noted above) yields the same response.

Example 21.11. Again consider the work of Clayton et al. (1957) on abdominal bristle number in *Drosophila* (Examples 21.4 and 21.5). Here $r_n = 0.542$, $t_n = 0.326$, and $\sigma_A h = 1.70$. Suppose individuals with index scores in the upper 20% are chosen. What is the expected response if we place three times the weight on within-family deviations as we do on family means ($b_1 = 3$, $b_2 = 1$)? Because 20 families each with 12 sibs are scored, the expected selection intensity is $\bar{t}_{(48,240)} = 1.39$ (as 48 is the upper 20% of $20 \cdot 12 = 240$), and Equation 21.53c yields an expected response of

$$R_I = 1.39 \cdot 1.70 \left(\frac{3 + 0.542(1 - 3)}{\sqrt{3^2 + 0.326(1^2 - 3^2)}} \right) = 1.79$$

This is not as efficient as strict among-family selection (where $R_b = 2.15$; see Example 21.4). Likewise, the response under individual (i.e., mass) selection is $R_m = \bar{t}_m \sigma_A h = 2.36$. Because individual selection is a special case of the general index, we can always choose the index weights to give at least as large an expected response as individual selection. For example, placing twice the weight on family means relative to within-family deviations ($b_1 = 1$, $b_2 = 2$), returns an expected response of $R = 2.59$, which is 110% of the expected response under individual selection.

Lush's Optimal Index

As the previous example shows, by making the appropriate choice of index weights, we can always obtain a response at least as large as that expected under mass selection. Note from Equation 21.51 that σ_A and \bar{t}_I remain constant under different index weights, implying that the maximal response occurs if we choose the weights that maximize the correlation, $\rho(I, y)$, between the index and offspring value (Equation 21.5 shows that this is equivalent to maximizing the correlation, $\rho(I, A)$, between the index and breeding values of an individual). Lush (1947) showed that the resulting optimal index weights are

$$b_1 = \frac{1 - r}{1 - t} \quad \text{and} \quad b_2 = \frac{1 + (n - 1)r}{1 + (n - 1)t} \quad (21.54)$$

The formal derivation (which follows from a Smith-Hazel index; Example A6.8) is given in our general treatment of index selection in Volume 3. We refer to the family index using these weights as the **Lush index**. Note that the weight (b_1) on family deviations is independent of the family size (n), while the weight on the family mean (b_2) depends on n , approaching r/t for large families. Figure 21.7 plots the ratio of among- to within-family weights (b_2/b_1) for the Lush index as a function of t and n . For small between-sib correlations (t), more weight is placed on family mean, while more weight is placed on within-family deviation when the sib correlation is large.

We can rearrange the Lush index as $I_L = z_{ij} + B_L \bar{z}_i$, where substituting Equation 21.54 into Equation 21.50c returns

$$B_L = \frac{(r - t)n}{(1 - r)[1 + (n - 1)t]} \quad (21.55)$$

Using the optimal weights, Equation 21.53c simplifies to yield the response under Lush's index as

$$R_{LI} = \bar{t} \sigma_A h \sqrt{1 + \frac{(r - t)^2(n - 1)}{(1 - t)[1 + (n - 1)t]}} \quad (21.56a)$$

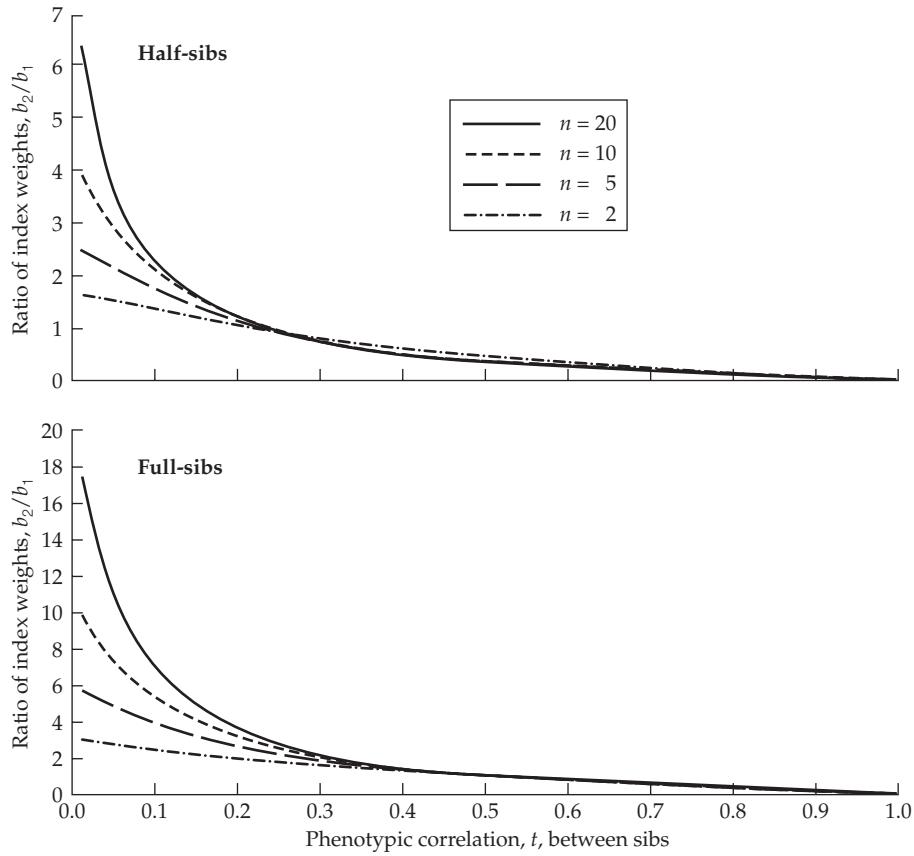

Figure 21.7 The ratio, b_2/b_1 , of the weights placed on the among- (b_2) relative to within- (b_1) family weights under the optimal Lush index (Equation 21.54). Individual selection corresponds to $b_2/b_1 = 1$. These optimal weights are a function of the phenotypic correlation, t , between sibs and the number, n , of sibs per family.

The resulting increase in response over that expected under individual selection ($R_m = \bar{r} \sigma_A h$; Equation 13.6b) is thus

$$\frac{R_{LI}}{R_m} = \sqrt{1 + \frac{(r-t)^2(n-1)}{(1-t)[1+(n-1)t]}} \geq 1 \quad (21.56b)$$

Figure 21.8 plots Equation 21.56b as a function of t and n for half- and full-sibs. Because the quantity in the square root exceeds one, the expected response under Lush's index exceeds the response under individual selection, except at $r = t$ (i.e., $t = 0.25$ for half-sibs, $t = 0.5$ for full-sibs), in which case the expected responses are equal. For large values of n , Equation 21.56b converges to

$$\frac{R_{LI}}{R_m} = \sqrt{1 + \frac{(r-t)^2}{(1-t)t}} \quad (21.56c)$$

which can take on large values for t near zero or one, as seen by the roughly U-shaped plots in Figure 21.8.

Example 21.12. Recalling (Example 21.4) that $t = 0.265$ and $r = 0.5$ for full-sibs in Clayton et al.'s (1957) bristle experiments, the resulting Lush weight on family deviations becomes

$$b_1 = \frac{1-r}{1-t} = \frac{1-0.5}{1-0.265} = 0.680$$

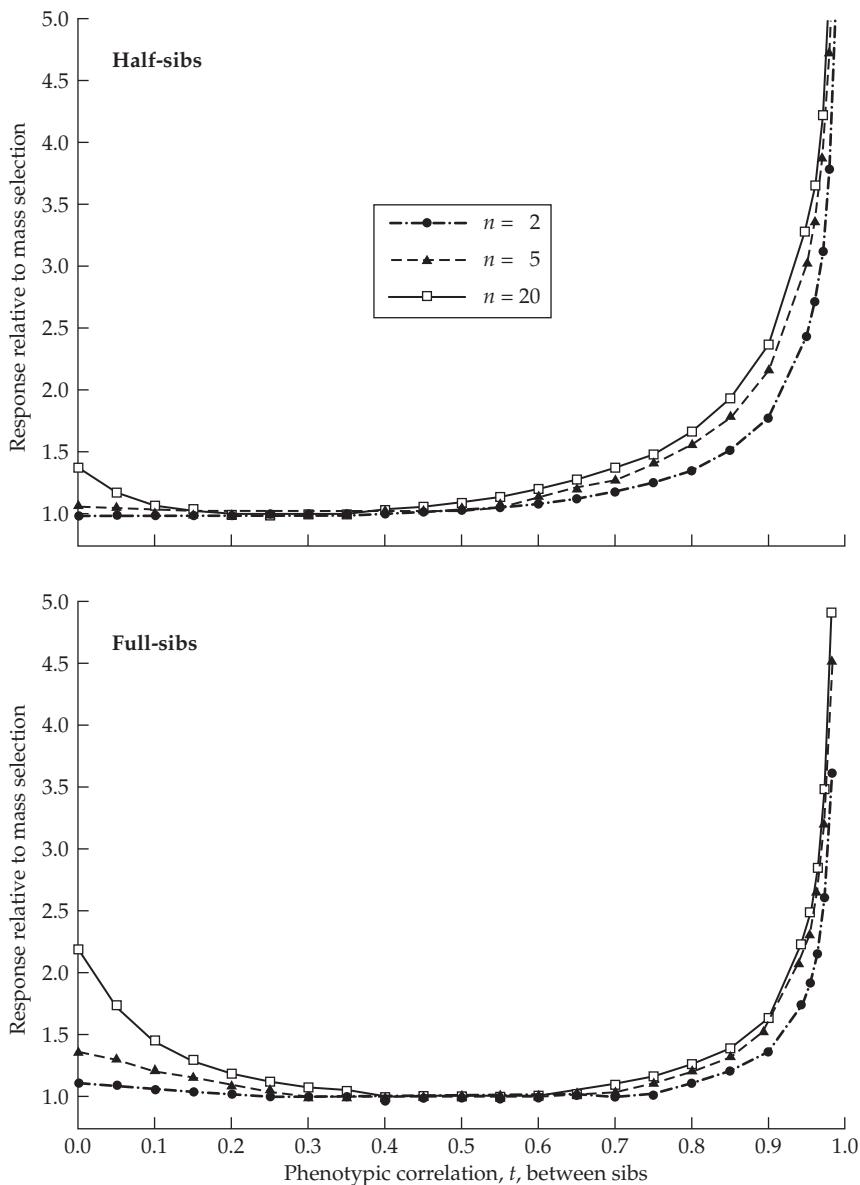

Figure 21.8 Response of Lush's index relative to individual selection, as a function of the number of sibs, n , for full-sibs ($r = 1/2$) and half-sibs ($r = 1/4$). Except at $r = t$ (where the expected responses are equal), Lush's index results in a larger expected response than individual selection.

If we further recall that the family size was $n = 12$, the optimal weight on family means becomes

$$b_2 = \frac{1 + (n - 1)r}{1 + (n - 1)t} = \frac{1 + (12 - 1)0.5}{1 + (12 - 1)0.265} = 1.66$$

We can rescale the weights as $b_1 = 1$ and $b_2 = 1.66/0.680 = 2.44$, with Equation 21.53c returning an expected response of

$$R_{LI} = \bar{\tau}_{LI} \sigma_A h \rho(I, y) = 1.39 \cdot 1.70 \cdot \left(\frac{1 + 0.542(2.44 - 1)}{\sqrt{1^2 + 0.326(2.44^2 - 1^2)}} \right) = 2.60$$

The expected response under individual selection was $R_m = 2.36$ (Example 21.11), so the

expected response under the Lush index is 10% greater than that of mass selection.

The Lush index weights change with t and r , and so may have to be periodically updated as changes in the genetic variance change t and as inbreeding changes r (Chapters 16, 23, and 24). In particular, both drift and gametic-phase disequilibrium can be important when several generations of selection are considered (Chapter 16). As selection proceeds, both these forces increase the relative importance of within-family selection over among-family selection (Chapters 16 and 24). This results in individual values given increased weight and family means given decreased weight.

Specifically, the amount of within-family additive variance (in the absence of drift or inbreeding) remains at $\sigma_a^2/2$ (half the genic variance, the value of σ_A^2 in the absence of LD), while the amount of among-family variance is $\sigma_a^2/2 + d$, where $d < 0$ (Chapter 16). Hence, LD has no impact on the within-family component of additive variance, but it decreases the among-family component. Wray and Hill (1989) noted that while the relative efficiency of index selection over individual selection may be greatly diminished by gametic-phase disequilibrium, the relative rankings of the methods still hold.

A concern with any index is that the population parameters have to be correctly estimated, otherwise the index constructed from these estimates will have incorrect weights and be less than optimal (Volume 3). Fortunately, only the intraclass correlation, t , must be estimated for the Lush index, and Sales and Hill (1976) showed that the efficiency of index selection is quite robust to estimation errors in t (as initially suggested by Lush 1947).

Nonetheless, given some of these concerns, it is not surprising that experimental verification of the advantage of the Lush index over individual or family selection is mixed. Further, the common problem of low statistical power in most selection experiments due to small sample sizes makes negative results difficult to interpret (Chapter 18). McBride and Robertson (1963) and Avalos and Hill (1981) found that index selection resulted in a larger response than individual selection for abdominal bristles in *Drosophila melanogaster*. More conclusive results, also on *Drosophila* bristle number, were those of James (cited in Frankham 1982), who found that the observed increase in response under index selection (relative to mass selection) was $133\% \pm 9.7\%$ and $111\% \pm 7\%$ in two replicates, consistent with the expected increase of 121%. Results for selection for egg production in poultry were less conclusive, and although Kinney et al. (1970) found that individual selection gave a larger (but not significant) response than family index selection, while Garwood and Lowe (1981) found that index selection gave a larger response (again not significant) than family selection. Work on larval and pupal weight in *Tribolium* showed similar mixed results, as Wilson (1974) found that individual selection gave the largest response, while Campo and Tagarro (1977) did not find any significant differences (index selection gave a larger response in a replicate with large family size, while individual selection showed the larger response in a replicate with small family size).

We note in passing that a more general family index was considered by Osborne (1957a, 1957b) for the nested-sib design, which separately weights information from full- and half-sib families. If z_{ijk} denotes the k th full-sib from dam j and sire i , an index weighting both half- and full-sib information is

$$I = b_1 (z_{ijk} - \bar{z}_{ij}) + b_2 (\bar{z}_{ij} - \bar{z}_{i\cdot}) + b_3 \bar{z}_{i\cdot}$$

where b_1 is the weight on the deviation within a full-sib family, b_2 is the weight on the deviation among dam-family means within a sire, and b_3 is the sire weight (half-sib means). Volume 3 examines this, and more general indices, in much greater detail.

Correcting the Selection Intensity for Correlated Variables

As mentioned previously, expressions for the selection intensity in finite populations make the assumption that the order statistics are uncorrelated. However, the selection of multiple

individuals from the same family results in correlations among the order statistics due to the correlation between sibs. Our treatment of this issue follows that of Hill (1976, 1977b).

Suppose the population from which individuals are drawn consists of m families, each with n sibs, for a total of $M = mn$ measured individuals. If phenotypic values are uncorrelated among all members of the sample (the sib correlation, t , is zero), Burrow's correction (Equation 14.4b) yields a finite population size-adjusted selection intensity of

$$\bar{\tau}_{(K,M)} = \bar{\tau}_p - \frac{1-p}{2\bar{\tau}_p p(M+1)}$$

where a fraction, $p = K/M$, of the population is saved and $\bar{\tau}_p$ is the infinite-population selection intensity associated with the fraction p saved (Equation 14.3a). When some members are correlated, this reduces the effective number of independent variables to some value below M . This value ranges from $mn = M$, with no correlation between sibs ($t = 0$), to m , with a perfect correlation between sibs ($t = 1$). Using this observation, Hill (1976) suggested a linear approximation for the effective number, M_e , of independent variables of

$$M_e = M(1-t) + mt \quad (21.57a)$$

Substituting into Burrow's correction gives an expected selection intensity adjusted for correlations of approximately

$$\bar{\tau}_{(K,M)}(t) = \bar{\tau}_p - \frac{1-p}{2\bar{\tau}_p p[M(1-t) + mt + 1]} \quad (21.57b)$$

Note that $\bar{\tau}$ decreases as t increases. Simulation studies by Hill showed that this is a reasonable approximation, and Hill (1976) provided tables of exact values (over a limited set of n and t values). An alternative approximation was offered by Rawlings (1976), while Tong (1982) and Meuwissen (1991), respectively, considered contributions from unequal family size and under a nested full-sib-half-sib design.

The effect of sib-correlations on the selection intensity for individual selection is generally small, as t is typically less than 0.5, and has only a modest effect on reducing $\bar{\tau}$. In contrast, the presence of the family mean, \bar{z}_i , in the index scores greatly inflates the correlation between the sib index values, I , over the correlation among phenotypic values, z . Hill (1976) showed that if selection occurs on the index $I = z_{ij} + B\bar{z}_i$ (Equation 21.50b), the intraclass correlation, τ , among the *index values* of sibs is given by

$$\tau = 1 - \frac{n(1-t)}{n + B(2+B)[1 + (n-1)t]} \quad (21.58a)$$

where t is the intraclass correlation of individual *phenotypic values* among sibs. Note that for large B , τ approaches 1.0. Hence, for schemes that place considerable weight on family means, the index scores for sibs within a family are almost perfectly corrected, and the effective number of independent order statistics approaches the number of families chosen. This is very reasonable, as I approaches \bar{z}_i for large B , which is equivalent to among-family selection, giving the number of independent order statistics as the number of families, m .

Using the value of B (from Equation 21.55) under Lush index weights, Hill (1976) showed (for large n) that

$$\tau \simeq \begin{cases} 1-t & \text{full-sibs} \\ \frac{1-t}{1+8t} \simeq \frac{1}{1+2h^2} & \text{half-sibs} \end{cases} \quad (21.58b)$$

Example 21.13. Once again, consider Clayton et al's (1957) experiment on *Drosophila* bristle number. From Example 21.12, the Lush index weights are $b_2/b_1 = 2.44$, with Equation 21.50c yielding $B = b_2/b_1 - 1 = 1.44$. Recalling that $t = 0.265$ and $n = 12$, Equation 21.58a returns the correlation, τ , among the index values of sibs as

$$\tau = 1 - \frac{12(1 - 0.265)}{12 + 1.44(2 + 1.44)[1 + (12 - 1)0.265]} = 0.72$$

which is 2.7 times the correlation, t , among sib phenotypic values. Note that under strict family selection ($\tau = 1$), the correlation among the index value increases to 3.8 times the sib phenotypic correlation.

Suppose we select on a Lush index using four families ($m = 4$). The resulting total number of individuals becomes $N = 12 \cdot 4 = 48$, while Equation 21.57a gives the effective number of independent variables as

$$M_e = 48(1 - 0.72) + 4 \cdot 0.72 = 16.3$$

which is just 34% of the actual number of total individuals. Because $p = 0.2$ (implying $\bar{\tau}_p = 1.40$), Equation 21.57b yields a corrected selection intensity of

$$\bar{\tau} = 1.40 - \frac{1 - 0.2}{2 \cdot 1.40 \cdot 0.2 \cdot (16.3 + 1)} = 1.32$$

or a reduction of $\sim 6\%$.

Associative Effects: Competition, Social Interactions, Group and Kin Selection

These findings . . . support the writer's view that competitive ability should be accepted as it stands as a genetic character, simple or aggregate, a view of great importance in the discussion to follow. Sakai (1955)

This chapter weaves together several seemingly unrelated, but nevertheless important, topics: competition; altruism and other social behaviors; traits defined by group, rather than individual, attributes; maternal effects; and group and kin selection. The connection between all of these topics is the notion that the genotype (and hence phenotype) of one individual may influence the trait value of another. In this sense, the “environmental” component of the phenotype of a focal individual may itself have some heritable component (based on the contribution from some other individual), allowing for some part of the environmental component to evolve along with the focal trait. In such settings, the phenotype of a focal individual consists of two components: **direct effects** from the focal individual and **associative effects** contributed from other individuals within the group. A critical implication of this distinction is that the breeding value of an individual contains a component for direct effects that appear in its own phenotype (and hence can be influenced by individual selection) and a component for associative effects that only appears in the phenotypes of *other* group members. The exploitation of associative effects by selection generally requires either interactions among kin (**kin selection**) or selection based on some combination of both individual and group values (**multilevel selection**). In the extreme, **group selection** occurs when all of the weight is placed on among-group differences. Note that multilevel selection is an extension of family-index selection (Chapter 21) to more general groups.

The framework for dealing with these issues was laid out in a series of classical, but largely ignored, papers by Griffing (1967, 1968a, 1968b, 1969, 1976a, 1976b, 1977), who introduced the notion of associative effects. There are also roots extending to classical work on maternal effects based on trait phenotype (Falconer 1965) or on an unmeasured maternal value (Willham 1963), as well as to the foundations of the study of social evolution (Hamilton 1963, 1964a, 1964b). There are two modeling approaches for dealing with associative effects: **trait-based** and **variance component-based**. Trait-based approaches (Moore et al. 1997) have their roots in univariate (Falconer 1965) and multivariate (Kirkpatrick and Lande 1989; Lande and Kirkpatrick 1990) models of selection response under maternal effects. As their name implies, trait-based approaches assume that we know the particular traits in group members that influence the phenotype of the focal individual. This approach is best handled in a multivariate framework, so we will delay its full discussion until Volume 3.

The variance-component approach also has roots in maternal-effects models (Willham 1963), wherein a general (but unmeasured, i.e., latent) **maternal performance value** influences the phenotype of the focal individual. Using BLUP, we can estimate the genetic variance of the associative effects (as well as its covariance with the direct effects). Somewhat counterintuitively, variance component-based methods (where the actual traits that generate the associative effects are unspecified) are empirically more powerful than trait-based methods. The reason is that we can estimate this unspecified total contribution directly, while if characters that influence associative effects are left out of a trait-based model, this can introduce errors. McGlothlin and Brodie (2009) and Bijma (2014) show the congruence between these methods, which is also examined in detail in Volume 3.

Traits whose phenotypes are determined, in part, by interactions with other individuals have important roles in both breeding and evolution. In breeding, we are often more interested in the performance of a group rather than that of an individual. For example, standard poultry husbandry is to keep several females together in a cage, with total egg production per cage being the key quantity of interest. In the extreme, an aggressive female may kill all her cage-mates, and, in less extreme cases, may largely dominate feeding, resulting in an individual benefit at the expense of the group. Hence, individual selection may result in a *decrease* in group performance, in which case the number of eggs per cage would decline.

The issue here is that *individual selection cannot effectively utilize the genetic variation in associative effects* to guarantee the response of the mean associative value in the direction favored by the breeder. The same concerns have long been raised in evolutionary biology, in particular to account for the evolution of **altruistic traits** (such as alarm calls in birds) that are expected to decrease individual fitness, yet still have evolved. There is a very rich, and stormy, evolutionary literature on the importance (or lack thereof) of selection based on group attributes. The general view in evolutionary biology has often been to invoke group selection arguments only as a last, desperate resort when all individual selection arguments fail (e.g., Williams 1966). As we will see, much of the debate regarding group versus kin selection is misplaced, as they are essentially manifestations of the same general process.

Our treatment starts with a formal definition of direct and associative effects, including the powerful concept of the total breeding value, A_T , of a trait (which requires measurements of group members). Next, we show how the presence of associative effects influences selection. One key result is that when the breeding values for direct and associative effects are negatively correlated, individual selection can result in a reversed response. Conversely, group selection (even when group members are unrelated) always results in an expected positive response, but it can be very ineffective when associative effects are small. We then examine selection based on an index of both individual and group information, including the optimal weighting for maximal response. A key innovation that we examine in detail is the use of BLUP/REML methodology (Chapters 19 and 20) to estimate the direct and associative effects of individuals, along with their variance components. We conclude by applying these results to some of the debates on group and kin selection in evolutionary biology. Our goal in this last section is not to extensively review this literature, which is often contradictory and, at times, was driven more by verbal models than detailed analyses. Rather, it is to show how the problem of selection based on group attributes can be easily placed in a quantitative-genetics framework.

For many readers, this may be one of the most important chapters in the book, as associative effects are potentially game-changing in the analysis of many traits. Evolutionary biologists, breeders, behavioral ecologists, and human geneticists all need to be aware of their importance and implications. They reshape many classic problems in evolutionary biology, such as Fisher's fundamental theorem (Chapter 6), inclusive fitness, and kin and group selection. Their presence fundamentally changes breeding strategies, as individual selection potentially leaves much of the usable genetic variation in a trait untapped and can result in reversed responses (Chapter 15). Most behavioral traits arise from interactions between individuals, which is exactly the framework for associative effects. Finally, their presence radically changes the way in which we analyze traits. An important example is disease resistance. As this is both a function of the susceptibility of an individual and the infectiousness of those around it, a full consideration requires a model with associative effects (Lipschutz-Powell et al. 2012a, 2012b; Costa e Silva et al. 2013). Partial reviews of some of the implications of associative effects are given by Griffing (1977), Moore et al. (1997), Wolf et al. (1998), Bijma and Wade (2008), McGlothlin et al. (2010), Wade et al. (2010), Wolf and Moore (2010), Bijma (2011, 2014), and Bailey (2012).

DIRECT VERSUS ASSOCIATIVE EFFECTS

All organisms interact with their external environment, and a very significant fraction of that

environment is biological. In particular, interactions with conspecifics through competition, cooperation, parental care, or other social interactions can constitute an important part of the environment that an individual experiences, which, in turn, can influence trait values. Further, this “environment” may contain heritable components and coevolve with the trait of interest. The classic example of this is competition, which we briefly consider first.

Early Models of Competition

It has long been appreciated by breeders that competition among plants within a plot has a significant impact on important agricultural traits such as yield. While a particular genotype may have high yield when grown in isolation, when grown in a group, its competitive effects on other members within its group could result in a lower plot yield. Yield (and other traits) of a particular plant in a plot is therefore a function of two components. First, an individual’s genotype has a direct influence on its ability to garner resources such as light, water, and nutrients. Second, that genotype influences others around it by competing for limiting resources. Other plants in the plot also compete, and these in turn influence the yield of the focal individual. One might expect that plants that are very successful at garnering resources have positive direct effects, but negative associative effects on nearby individuals. Thus, a plot of high-competing genotypes can have a low yield, as the positive direct effects for any particular plant are more than countered by negative associative effects from being surrounded by superior competitors.

A historically important paper on the evolution of competition is that by Sakai (1955), who noted that competition, like yield or height, is a genetic trait and hence can potentially evolve. Following Sakai, a number of workers developed single-locus population genetic models to examine the evolution of competition (Schutz et al. 1968; Allard and Adams 1969; Schutz and Usanis 1969; Cockerham and Burrows 1971; Cockerham et al. 1972). These studies all used simple ecological models of competition among a series of fixed types (here, all possible single-locus genotypes). While interesting, this class of models does not easily generalize beyond one locus. Griffing (1967) made the important extension of Sakai’s idea by replacing a single-locus genotype with direct and associative values that are quantitative traits, consisting of breeding and residual values. Placed in this framework, such traits can potentially evolve and can also have their variance components estimated, allowing associative effects to be exploited by using appropriate selection designs.

Example 22.1. The point that high-competing genotypes can reduce yield was made in a classic paper by Wiebe et al. (1963), who examined yield in mixed- versus single-genotype plots of barley. They observed that genotypes that yielded well in mixed stands had poorer yield when grown as pure stands, while those genotypes that did poorly in mixed stands had the highest yield in pure stands. In our framework, we could imagine that lines that do well in mixed stands have both high positive direct effects and high negative associative effects, suppressing the phenotypes of their neighbors. When grown in a pure stand, the high negative associative effects suppress plot yield. Conversely, lines that perform poorly in mixed stands might have low direct effects but high positive associative effects, and so the phenotypes of their neighbors are enhanced (or at least not hindered). When grown as a pure stand, these high positive associative effects more than compensate for the low direct effects, increasing plot yield.

Direct and Associative Effects

A simple example will introduce Griffing’s idea. As shown in Figure 22.1A, consider a group of four individuals. Our focal individual is 1, and its phenotype, z_1 (for the trait of interest), is determined by its own intrinsic value, $P_{d,1}$ (the subscript d indicating the direct effect), plus the associative effects, $P_{s,2}$, $P_{s,3}$, and $P_{s,4}$, contributed by other group members.

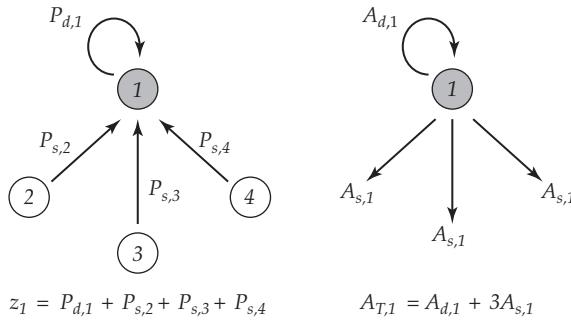

Figure 22.1 **Left:** The phenotypic value, z_1 , of the focal individual is the sum of its direct phenotypic effect, $P_{d,1}$, plus the associative effects, $P_{s,2}, P_{s,3}, P_{s,4}$, of the three other members in its group. **Right:** The total breeding value ($A_{T,1}$) of individual 1 is its direct breeding value, $A_{d,1}$, plus the total contribution of the associative-effect breeding value, $A_{s,1}$, to the three members of its group. A key concept is that *only part of A_T (namely A_d) is embedded within its own phenotypic value*. The remaining part of A_T , namely its associative component, $3A_s$, is only expressed in the phenotypes of *other* group members.

Associative effects are also referred to in the literature as **indirect genetic effects (IGEs)** (Moore et al. 1997; Wolf et al. 1998; McGlothlin et al. 2010), or **social effects** (Bijma et al. 2007a, 2007b), and we use the subscript s (indicating social effects) to denote them. In our discussion, we will use the terms *associative* and *social effects* interchangeably. Note that the values of $P_{s,i}$ do not necessarily correspond to the phenotypes for the trait of interest in the other group members, but rather represent the contribution from these members to the phenotype of the focal individual. This contribution from fellow group members is part of the environment experienced by the focal individual.

More generally, for a group containing n equally interacting individuals, the resulting phenotype (z_i) for individual i becomes

$$z_i = P_{d,i} + \sum_{j \neq i}^n P_{s,j} \quad (22.1a)$$

where the sum has $n - 1$ terms. Each of these components can be decomposed into a breeding value, A , plus a residual component, E (containing environmental effects plus any nonadditive genetic effects), yielding

$$z_i = \mu + (A_{d,i} + E_{d,i}) + \sum_{j \neq i}^n (A_{s,j} + E_{s,j}) \quad (22.1b)$$

We can write this more compactly as

$$z_i = \mu + A_{d,i} + \sum_{j \neq i}^n A_{s,j} + e_i, \quad \text{with } e_i = E_{d,i} + \sum_{j \neq i}^n E_{s,j} \quad (22.1c)$$

Because the environmental values have expected value of zero, the mean phenotypic value in the group is simply

$$\mu_z = \mu + \mu_{A_d} + (n - 1)\mu_{A_s} \quad (22.1d)$$

Further, the change in the mean trait value within a group following selection is

$$\Delta\mu_z = \Delta\mu_{A_d} + (n - 1)\Delta\mu_{A_s} = R_d + (n - 1)R_s \quad (22.1e)$$

which decomposes the change in trait value into contributions from responses, R_d and R_s , respectively, in the direct and social values.

This equation foreshadows individual versus group selection. Individual selection targets the direct effect and results in a favorable change in μ_{A_d} . If the direct and social breeding values are correlated within an individual, namely, $\sigma(A_d, A_s) \neq 0$, then individual selection can also change μ_{A_s} , but not necessarily in a favorable direction. Indeed, as Example 22.4 will show, an increase in μ_{A_d} under individual selection can be more than countered by an unfavorable change in μ_{A_s} , resulting in the mean phenotype changing in an unfavorable direction. Direct selection on μ_{A_s} requires either undergoing group selection or having relatives within the group. All of these points will be expanded upon below. Our focus is entirely on additive genetic effects, as most of the theory has been developed under this assumption. Attempts to include nonadditive variance were developed by Gallais (1976) and Wright (1986). Finally, one way to make the concept of associative effects a bit more concrete is to note that one can map associative-effect QTLs; see Mutic and Wolf (2007) and Wolf et al. (2011) for examples.

Animal Well-being and the Improvement of the Heritable Social Environment

In high-intensity agricultural systems, competition has a strong effect on yield and other traits. Animals in such environments face significant stress, which impacts both their production and their well-being. As reviewed by Muir and Craig (1998), animal well-being is becoming an increasingly important aspect of animal production. Muir suggests that social aspects such as aggression, fighting, and sharing of common resources are all potential targets of selection, and responses in these traits (for less aggression and more sharing) improves both animal welfare and production. Further, for a number of species (such as certain fishes), domestication has proved somewhat problematic due to the tendency for cannibalism (and lesser forms of aggression), when individuals are grown under production conditions. Muir suggested improving welfare by selecting for an improved mean social environment through selection of individuals with favorable A_s values for the traits of interest. Again, these are aspects of the group environment and can respond favorably to an appropriate selection design, provided there is a heritable component of P_s , namely, $\sigma^2(A_s) > 0$.

What Do We Mean by Group?

Given that we use the term *group* extensively in this chapter, a more formal definition is required. Our focus here is on traits whose values are influenced by interactions with others. The set of individuals that interacts with the focal individual constitutes the unit we will call a group. This may be straightforward in some breeding settings, such as the specific animals in a pen or cage. However, in other settings, such as cattle in a very large feedlot, only some subset of all the individuals likely interact with the focal individual. Hence, group size may be much smaller than the number of individuals physically confined to some space. Likewise, individuals may be part of different groups for different traits, especially if those traits are expressed at different times during development. The same is true on a grander scale in natural populations. The key issue with traits influenced by interactions is that phenotypes of the group members provide some information on part of the breeding value of the focal individual—the part dealing with its associative effect—that is simply not provided by the phenotype of the focal individual. To exploit this additional heritable variation (when it exists), interactions with relatives or selection that puts at least some weight on group value is essential.

The second feature about groups is their formation and reproduction, an issue that is especially important under differential propagation of groups (i.e., group selection). Here, we are assuming a situation akin to our analysis of family selection (Chapter 21), in that, while group information may be used to select individuals to form the next generation, these individuals are then mated at random. In the group-selection literature, this is referred to as a **migrant pool model** (Levins 1970; Wade 1978). Such a structure only allows changes in breeding values (as opposed to genotypic values) to propagate to the next generation. In settings where entire groups are propagated as a unit (the **propagule pool model**; Wade

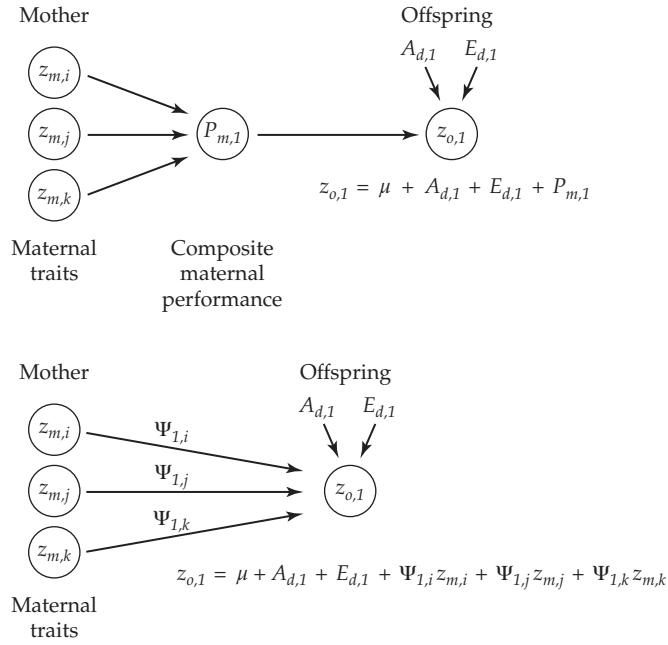

Figure 22.2 The difference between trait-based and variance-component based models. Here, the phenotypic value, $z_{o,1}$, of a trait (which we label 1) in an offspring is a function of maternal phenotype. We suppose that there are three maternal traits (i, j, k) whose phenotypes influence the offspring value. **Top:** Under a variance-component based approach, we ignore all the maternal trait values and simply estimate a single maternal performance value, $P_{m,1}$, that directly influences the trait value in the offspring. The resulting model becomes $z_{o,1} = \mu + A_{d,1} + E_{d,1} + P_{m,1}$, where $A_{d,1}$ is the trait breeding value in the offspring, $E_{d,1}$, its environmental value, and $P_{m,1} = A_{s,1} + E_{s,1}$ can be decomposed into the social breeding value on trait 1 plus a residual. **Bottom:** Under a trait-based model, provided we know all of the maternal traits whose phenotypes influence trait 1 in the offspring, then we directly incorporate these, along with their regression coefficients, $\Psi_{1,i}$, showing how these maternal phenotypes translate into offspring trait value. Here, $z_{o,1} = \mu + A_{d,1} + E_{d,1} + \Psi_{1,i}z_{m,i} + \Psi_{1,j}z_{m,j} + \Psi_{1,k}z_{m,k}$, where the last three terms together comprise $P_{m,1}$. Trait-based models are required if one wishes to consider the joint evolution of traits 1 and i, j, k . Their drawback is that one has to specify to all of the relevant maternal traits. Conversely, under a variance-component method, all of the maternal phenotypes are conveniently collapsed into a single value, whose breeding value can be estimated from an appropriate design (detailed below).

1978), the potential exists for nonadditive variance to contribute to the among-group variance.

Trait- vs. Variance Component-based Models

A brief comment is in order, expanding upon our earlier remarks on trait vs. variance-component based modeling (see Bijma 2014 for an extended discussion). The original trait-based model of associative effects was Falconer's (1965) model for litter size in mice (Equation 15.21), namely

$$z_i = G_i + e_i + (m \cdot z_{mo,i})$$

where G_i is the direct breeding value for litter size, while the associative effect is a function of the litter size of its mother ($z_{mo,i}$). Building on this idea, Moore et al. (1997) and Wolf et al. (1998) suggested a model wherein the value for trait i also depends upon the value, z'_j , of trait j (which may be a different trait from i) in an interacting individual,

$$z_i = A_i + e_i + \Psi_{ij}z'_j = A_i + e_i + \Psi_{ij}A'_j + \Psi_{ij}E'_j \quad (22.2)$$

where Ψ_{ij} (following Kirkpatrick and Lande 1989) is the multivariate extension of Falconer's m . This class of models can lead to some very interesting behavior, such as feedback loops that significantly modify Equation 22.2. Figure 22.2 illustrates this difference in modeling, while Volume 3 explores trait-based models in some detail.

Bijma (2014) noted that variance-component approaches are akin to using Robertson's secondary theorem, $R = \sigma(w, A)$ (Equation 6.25a), to predict response, which ignores any specific traits and simply considers the covariance between breeding value (which we generalize by calculating total breeding value, A_T , below) and relative fitness. In contrast, trait-based approaches are akin to using the multivariate Lande equation, $\mathbf{R} = \mathbf{G}\beta$ (Equation 13.26a), to predict response. The Lande equation returns the response in all traits of interest, but it requires that all relevant traits be included in the analysis and is potentially erroneous if they are not (Volume 3).

The Total Breeding Value (TBV) and T^2

Given that an individual contains breeding values for both direct and social effects, what is its contribution to the next generation? We can directly see this from Equation 22.1d, where it is shown as the contribution to the population mean from individual 1 from its direct breeding value (A_{d_1}) plus its contribution to the $(n - 1)$ other individuals in its group through its associative-effects breeding value, A_{s_1} (Figure 22.1b). Based on this observation, Bijma et al. (2007a) defined the **total breeding value (TBV)**, A_T , of a trait from an individual measured in a group of size n as the sum of its direct effect plus the total associative effects over all group members, or

$$A_{T_i} = A_{d_i} + (n - 1)A_{s_i} \quad (22.3)$$

Moore et al. (1997) introduced a similar measure for trait-based models. Noting that the mean of the population is simply the mean breeding value allows Equation 22.3 to recover Equation 22.1d. The critical observation is that when associative effects are present, the total breeding value of an individual contains components that are *not expressed in its own phenotype*, but rather, only in the phenotypes of other individuals with which it interacts.

Example 22.2. Consider a trait in a group of four (unrelated) individuals, where we assume there are no environmental effects, which means that $P_d = A_d$ and $P_s = A_s$. The population mean is 20, and the four group members have the following breeding values for direct, associative, and total effects:

Individual	A_d	A_s	A_T	$\sum_{j \neq i} A_{s_j}$	z
1	9	-4	-3	4	33
2	5	-1	2	1	26
3	-6	2	0	-2	12
4	-8	3	1	-3	9

Because $n = 4$, $A_T = A_d + 3 A_s$. The contribution of the associative effects of the other three group members to i 's phenotypic value is given by $\sum_{j \neq i} A_{s_j}$. For example, for individual 1, the contributions from individuals 2 through 4 is $-1 + 2 + 3 = 4$. Thus, from Equation 22.1c, the phenotypic value we would observe is

$$z_i = 20 + A_{d_i} + \sum_{j \neq i}^4 A_{s_j}$$

Individual 1 has the largest direct effect (9) and the largest observed trait value (33). This individual also has the most unfavorable associative value (-4), and the smallest total breeding value (-3). Conversely, it has the largest contribution (4) to its trait value from the associative effects of the other group members. Its high trait value is due to this combination of a high direct effect and a high contribution from the associative effects of the other group members.

Its unfavorable associative effects do not appear in its own phenotype, but rather are expressed in the trait values of the other group members. As a result, its own phenotypic value is a poor predictor of A_T .

If the next generation is formed by crossing the two individuals (1 and 2) with the largest trait values, the expected offspring mean will be $20 + (-3+2)/2 = 19.5$, which is the mean plus the average of the two individuals' total breeding values. Although the two largest individuals were chosen, the population mean *decreases*. Conversely, crossing the two smallest individuals gives an expected offspring mean of $20 + (0+1)/2 = 20.5$, increasing the mean. While the two smallest individuals have the smallest direct effects, they also have the most favorable associative effects, and hence result in a more favorable response. The greatest expected response occurs by crossing the two individuals with the largest total breeding values (2 and 4), for an expected mean of $20 + (2+1)/2 = 21.5$.

The covariance between an individual's phenotype and total breeding value is

$$\begin{aligned}\sigma(z_i, A_{T_i}) &= \sigma\left[\mu + A_{d_i} + \sum_{j \neq i}^n A_{s_j} + e_i, A_{d_i} + (n-1)A_{s_i}\right] \\ &= \sigma\left[A_{d_i}, A_{d_i} + (n-1)A_{s_i}\right] + \sum_{j \neq i}^n \sigma\left[A_{s_j}, A_{d_i} + (n-1)A_{s_i}\right]\end{aligned}\quad (22.4a)$$

For now, we assume group members are unrelated, in which case the covariances in the summation are all zero,

$$\sigma(z, A_T) = \sigma^2(A_d) + (n-1)\sigma(A_d, A_s) \quad (22.4b)$$

If the direct and associative effects are uncorrelated, this reduces to the standard result that the covariance between an individual's phenotype and breeding value is simply the additive genetic variance (in this case, of direct effects). By contrast, the variance of the total breeding value becomes

$$\begin{aligned}\sigma^2(A_T) &= \sigma^2[A_d + (n-1)A_s] \\ &= \sigma^2(A_d) + 2(n-1)\sigma(A_d, A_s) + (n-1)^2\sigma^2(A_s)\end{aligned}\quad (22.4c)$$

$$= \sigma(z, A_T) + (n-1)[\sigma(A_d, A_s) + (n-1)\sigma^2(A_s)] \quad (22.4d)$$

Equation 22.4d shows that the covariance between total breeding value and phenotype is different from the variance in total breeding value. This reflects the fact that the associative effects of an individual do not influence its own phenotype. Note from Equation 22.4c that $\sigma(A_d, A_s)$ and $\sigma^2(A_s)$ are scaled by $(n-1)$ and $(n-1)^2$, respectively, in $\sigma^2(A_T)$. Hence, with even modest group sizes, small values of $\sigma(A_d, A_s)$ and $\sigma^2(A_s)$ can still have a very significant impact. Some of the early papers reporting estimates of these two quantities ignored this scaling with n , and hence tended to downplay the importance of social interactions (Chen et al. 2006; Van Vleck et al. 2007).

Now consider the phenotypic variance,

$$\sigma_z^2 = \sigma^2\left(P_{d_i} + \sum_{j \neq i}^n P_{s_j}\right) \quad (22.5a)$$

If we assume (for now) that the group members are unrelated, then $\sigma(P_{d_i}, P_{s_j}) = 0$. For a group of size n , Equation 22.5a reduces to

$$\sigma_z^2 = \sigma^2(P_d) + (n-1)\sigma^2(P_s) \quad (22.5b)$$

$$= \sigma^2(A_d) + (n-1)\sigma^2(A_s) + \sigma^2(E_d) + (n-1)\sigma^2(E_s) \quad (22.5c)$$

$$= \sigma^2(A_d) + (n-1)\sigma^2(A_s) + \sigma^2(e) \quad (22.5d)$$

where e is given by Equation 22.1c. With the phenotypic variance in hand, we can define the heritability of the direct and associative effects, h_d^2 and h_s^2 , respectively, as

$$h_d^2 = \frac{\sigma^2(A_d)}{\sigma_z^2} \quad \text{and} \quad h_s^2 = \frac{\sigma^2(A_s)}{\sigma_z^2} \quad (22.6a)$$

The careful reader will note that there is a different, but perhaps more natural, definition of these two heritabilities. Equation 22.6a standardizes the genetic variances with respect to the total trait variance, but one could also standardize them with respect to the variance of direct and associative effects, for example,

$$h_{d'}^2 = \frac{\sigma^2(A_d)}{\sigma^2(P_d)} \quad \text{and} \quad h_{s'}^2 = \frac{\sigma^2(A_s)}{\sigma^2(P_s)} \quad (22.6b)$$

We use a prime to distinguish these from the heritabilities scaled to total trait variance ($\sigma^2(P_x)$ vs. σ_z^2). While heritabilities scaled by σ_z^2 (Equation 22.6a) are the most widespread in the literature, there are some advantages to scaling heritabilities by $\sigma^2(P_x)$ (where $x = d$ or s). On this scale, the heritabilities measure the fraction of additive genetic variation in the actual effect (direct or associative) itself, rather than in the trait value. Further, $h_{x'}^2$ is independent of the group size (provided that A_s does not change with group size), as $\sigma^2(P_x)$ is independent of n , while σ_z^2 is a function of n (Equation 22.5b).

In keeping with Equation 22.6a, we can similarly define the “heritability” of the total breeding value as

$$T^2 = \frac{\sigma^2(A_T)}{\sigma_z^2} \quad (22.7a)$$

as suggested by Bijma et al. (2007a). The reason we have used T^2 rather than h_T^2 is that, unlike heritabilities, T^2 can exceed one. This can happen because $\sigma^2(A_T)$ contains additional terms not found in σ_z^2 , as *the associative effect of an individual influences others in the group, rather than the individual in which it resides*.

To see this, first assume that the environmental effects are all zero ($\sigma^2(e) = 0$), so that we can focus on differences in the genetic variance components. From Equations 22.4c and 22.5c,

$$\begin{aligned} \sigma^2(A_T) - \sigma_z^2 &= 2(n-1)\sigma(A_d, A_s) + (n-1)^2\sigma^2(A_s) - (n-1)\sigma^2(A_s) \\ &= (n-1)[2\sigma(A_d, A_s) + (n-2)\sigma^2(A_s)] \end{aligned} \quad (22.7b)$$

If this difference exceeds the contribution (σ_e^2) from environmental effects, then $T^2 > 1$.

Bijma (2011, 2014) noted that $\sigma^2(A_T)$ provides the appropriate (and general) definition for the amount of heritable variation underlying the potential for response. Recalling Equations 22.1e and 22.3, the Robertson-Price identity (Equation 6.10) yields the expected response (change in mean breeding value) to selection as

$$R = \sigma(w, A_T) \quad (22.8a)$$

Because the linear regression of w on A_T has a slope of

$$\beta_{w|A_T} = \frac{\sigma(w, A_T)}{\sigma^2(A_T)} \quad (22.8b)$$

(LW Equation 3.14b), the general expression for response can be written as

$$R = \beta_{w|A_T} \sigma^2(A_T) \quad (22.8c)$$

The apparent simplicity of this expression is somewhat misleading, as $\beta_{w|A_T}$ can be a very complex function of the relationship among group members (see Bijma 2011 for examples).

Example 22.3. Consider a trait in a group of 10 unrelated individuals, with $\sigma^2(P_d) = 10$, $\sigma^2(P_s) = 1$, and both direct and associative effects having modest heritabilities on the scale of the effects themselves ($h_{d'}^2 = 0.4$, $h_{s'}^2 = 0.3$). To simplify matters, assume $\sigma(A_d, A_s) = 0$. Applying Equation 22.5b, the resulting phenotypic variance is

$$\sigma_z^2 = \sigma^2(P_d) + 9 \cdot \sigma^2(P_s) = 10 + 9 \cdot 1 = 19$$

From Equation 22.4c, the variance in total breeding value becomes

$$\sigma^2(A_T) = \sigma^2(A_d) + 9^2 \cdot \sigma^2(A_s) = h_{d'}^2 \sigma^2(P_d) + [9^2 \cdot h_{s'}^2 \sigma^2(P_s)] = 4 + (81 \cdot 0.3) = 28.3$$

yielding (from Equation 22.7a) $T^2 = 28.3/19 = 1.49$.

A real-world example of large potential differences in h_d^2 versus T^2 involves survival days in chickens (Bijma et al. 2007b). Ignoring associative effects yields a direct heritability of $h_d^2 = 0.07$, while a mixed model incorporating associative effects (detailed later in the chapter) yielded an estimate of $T^2 = 0.20$, a threefold increase. Hence, under the conditions of this study, roughly two-thirds of the heritable variation in the trait arises from interactions between individuals and is thus hidden from standard analyses that ignore them. As discussed below, this component is only fully accessible under individual selection if the group includes relatives.

A_s as a Function of Group Size

As the careful reader will have noted, the direct effect, A_d , is independent of group size, while the social effect, A_s , potentially changes with group size. Suppose a genotype has a breeding value for social effects of 10 when measured in groups of size four. Does this change with group size and, if so, how? This is an empirical issue, and one can frame it in a G × E setting. The environments here are different group size, and if A_s shows G × E, the value of A_s changes over n .

Two simple scenarios bracket the possible changes. First, suppose that an individual eats 500 grams of food daily. In a group with a fixed food supply, the associative effect of this individual is to remove 500 grams from the total food supply each day. Hence, in a group of size n , $P_{s_i} = -500/(n-1)$, while its *total* associative effect is the sum over all group members, $(n-1)P_{s_i} = -500$. Here, the total associative effect remains unchanged over group size, while the *individual* associative effect on any group member shows a **dilution** with increasing group size. Alternatively, consider a large tree whose associative effect results from shading individuals under its canopy. In such a case, its associative effect shows no dilution with group size. Similarly, Bijma et al. (2007a) noted that alarm calls are also expected to show no dilution with group size.

More generally, we have been assuming that all group members experience the same social effect from a conspecific (i.e., they all experience $P_{s,i}$ from individual i). However, one can imagine settings where $P_{s,i}$ is some base value, but its effect on specific individuals depends on their physical distance from individual i (e.g., Muir 2005; Cappa and Cantet 2008), or the total amount of time that they interact with each other (Cantet and Cappa 2008) (e.g., Example 22.11). Bijma (2014) presented a more general treatment of this issue. A second complication, wherein interactions may differ between kin and nonkin (e.g., Sherman 1977), was examined by Alemu et al. (2014).

A developing research area involves the further characterization of social effects and the degree to which they change over group size. Some initial insight was provided by Hadfield and Wilson (2007) and Bijma (2010b). Hadfield and Wilson assumed a simple regression model

$$P_{s_i,n} = P_{sb_i} + \frac{1}{n-1} P_{sr_i} \quad (22.9)$$

with the value for social effect in a group of size n being a function of two components: a base (or intercept) value, P_{sb_i} , and a linear dilution rate, P_{sr_i} . Note that the resulting total sum of associative effects from i over the $(n - 1)$ group members becomes $(n - 1)P_{sb_i} + P_{sr_i}$ meaning that P_{sr} is the constant contribution, while that from P_{sb} scales with group size.

Bijma (2010b) suggested a related model

$$P_{s_i,n} = \frac{1}{(n - 1)^d} P_{s_i,2} \quad (22.10a)$$

which expresses all group social values as a function of the value for a group of size two ($P_{s_i,2}$) weighted by a power function of the **dilution fraction**, d (assumed to be the same over all genotypes). As we will see in the models below, Bijma's model is a bit more tractable, while the Hadfield-Wilson model is more general. When $d = 1$ and $P_{sp_i} = 0$, the two models are equivalent. Under the Bijma model, substituting Equation 22.10a into Equation 22.5a gives the total phenotypic variance as

$$\sigma_{z,n}^2 = \sigma^2(P_d) + (n - 1)^{1-2d}\sigma^2(P_{s,2}) \quad (22.10b)$$

Phenotypic variance increases with n for $d < 1/2$, remains constant for $d = 1/2$, and decreases with n for $d > 1/2$. Assuming that breeding values are diluted in the same fashion as phenotypic effects, then under the Bijma model

$$A_{s,n} = \frac{A_{s,2}}{(n - 1)^d} \quad \text{and} \quad \sigma^2(A_{s,n}) = \frac{\sigma^2(A_{s,2})}{(n - 1)^{2d}} \quad (22.10c)$$

Hence, $\sigma(A_d, A_s) = \sigma(A_d, A_{s,2})/(n - 1)^d$, and substituting into Equation 22.4c gives the total additive-genetic variance for a group of size n as

$$\sigma^2(A_{T,n}) = \sigma^2(A_d) + (n - 1)^{1-d} [2\sigma(A_d, A_{s,2}) + (n - 1)^{1-d}\sigma^2(A_{s,2})] \quad (22.10d)$$

Hence, provided that $d < 1$, the additive total variance increases with n . Both Hadfield and Wilson (2007) and Bijma (2010b) have suggested methods to estimate the quantities in Equations 22.9 and 22.10a, respectively.

SELECTION IN THE PRESENCE OF ASSOCIATIVE EFFECTS

One of the key results when associative effects are present is that individual selection can result in a reversed response, while group selection always results in a positive response (although it may be far from optimal). These points were clearly made by Griffing (1967) for the simple case of two interacting, and unrelated, individuals within each group. For selection on individual phenotypes, the response becomes

$$R = \frac{\bar{t}}{\sigma(z)} [\sigma^2(A_d) + \sigma(A_d, A_s)] \quad (22.11a)$$

A negative covariance between direct and associative effects reduces the efficiency of selection, and if it is sufficiently negative, it gives a reversed response. This loss of efficiency occurs because the only information an individual's phenotype contains about its breeding value for associative effects is that provided by the covariance between the direct and associative breeding values (which can be negative). Conversely, if we select based on the mean of a group, we are selecting on both direct and associative effects to improve trait value. For the case of $n = 2$, Griffing obtained the expected response under group selection as

$$R = \frac{\bar{t}}{2\sigma(\bar{z})} [\sigma^2(A_d) + 2\sigma(A_d, A_s) + \sigma^2(A_s)] = \frac{\bar{t}}{2\sigma(\bar{z})} \sigma^2(A_T) \quad (22.11b)$$

While group selection always yields a nonnegative response, if the associative effects are weak, this approach will prove very inefficient relative to individual selection. For example, in the absence of associative effects, $\sigma^2(\bar{z}) = \sigma^2(z)/2$, and Equation 22.11b reduces to $\bar{z}\sigma(A_d)/[\sqrt{2}\sigma(z)]$, or $1/\sqrt{2} = 0.701$ of the response under individual selection.

Individual Selection: Theory

Consider individual selection in a group of size n , whose members are potentially related. Recalling Equation 22.4a, the correlation between phenotype and total breeding value is

$$\sigma(z_i, A_{T_i}) = \sigma^2(A_d) + (n - 1)\sigma(A_d, A_s) + \sum_{j \neq i} \sigma[A_{s_j}, A_{d_i} + (n - 1)A_{s_i}]$$

Let r_{ij} denotes the relationship between individuals i and j . When individuals within the group are related, then

$$\sigma(A_{s_j}, A_{s_i}) = r_{ij}\sigma^2(A_s)$$

Likewise if A_d and A_s are correlated, then for relatives we also have

$$\sigma(A_{d_j}, A_{s_i}) = r_{ij}\sigma(A_d, A_s)$$

Hence,

$$\begin{aligned} \sum_{j \neq i} \sigma[A_{s_j}, A_{d_i} + (n - 1)A_{s_i}] &= \sum_{j \neq i} \sigma(A_{s_j}, A_{d_i}) + (n - 1) \sum_{j \neq i} \sigma(A_{s_j}, A_{s_i}) \\ &= \sigma(A_d, A_s) \sum_{j \neq i} r_{ij} + (n - 1)\sigma^2(A_s) \sum_{j \neq i} r_{ij} \\ &= [\sigma(A_d, A_s) + (n - 1)\sigma^2(A_s)] \left[\sum_{j \neq i} r_{ij} \right] \end{aligned} \quad (22.12a)$$

When all of the group members have the same relatedness ($r_{ij} = r$), the sum becomes $(n - 1)r$, returning the result of Bijma et al. (2007a),

$$\sigma(z, A_T) = \sigma^2(A_d) + (n - 1)[\sigma(A_d, A_s) + r\sigma(A_s, A_d) + r(n - 1)\sigma^2(A_s)] \quad (22.12b)$$

$$= \sigma^2(A_d) + (n - 1)(1 + r)\sigma(A_d, A_s) + r(n - 1)^2\sigma^2(A_s) \quad (22.12c)$$

Equation 22.12c shows the impact of having relatives within the group, which is to shift some of the variance in social effects, $\sigma^2(A_s)$, into the covariance, $\sigma(z, A_T)$, between individual phenotype and total breeding value. The use of relatives in the group thus allows individual selection to access some of this otherwise untapped variance. This occurs because the breeding values for social effects of group members (which impacts the phenotypic value of the focal individual) are now correlated with an individual's own breeding value for social effects (where the latter has no direct impact on its phenotype).

A useful alternative expression is to partition $\sigma(z, A_T)$ into the contribution expected in unrelated groups (Equation 22.4b) plus the additional contribution due to individuals in the group being related, which yields

$$\sigma(z, A_T) = \sigma(z, A_T | r = 0) + (n - 1)r[\sigma(A_s, A_d) + (n - 1)\sigma^2(A_s)] \quad (22.12d)$$

Alternatively, this can be expressed as

$$\sigma(z, A_T) = r\sigma^2(A_T) + (1 - r)[\sigma^2(A_d) + (n - 1)\sigma(A_d, A_s)] \quad (22.12e)$$

showing that the more closely related group members are, the more weight individual selection puts on A_T . In the extreme, when groups are composed of clones, then $\sigma(z, A_T) =$

$\sigma^2(A_T)$. Plant breeding often selects among groups comprised of genetically identical individuals (i.e., inbred lines and clonally propagated lines), with such settings exploiting all of the heritable variation in both direct and associative effects without requiring any special design.

Similarly, when all members in the group have the same relatedness, r , the phenotypic variance becomes

$$\begin{aligned}\sigma^2(z) &= \sigma^2(A_d) + \sigma^2(E_d) + (n-1)[\sigma^2(A_s) + \sigma^2(E_s)] \\ &\quad + (n-1)r[2\sigma(A_s, A_d) + (n-2)\sigma^2(A_d)]\end{aligned}\quad (22.13a)$$

$$= \sigma^2(z | r = 0) + (n-1)r[2\sigma(A_s, A_d) + (n-2)\sigma^2(A_d)] \quad (22.13b)$$

where the phenotypic variance when all group members are unrelated, $\sigma^2(z | r = 0)$, is given by Equation 22.5c.

The response to selection is simply the change in the mean total breeding value, which (from Chapter 13) is the within-generation change in the phenotypic mean after selection (the selection differential, S) times the slope of the regression of A_T on phenotype z , yielding

$$R = \frac{\sigma(z, A_T)}{\sigma_z^2} S = \frac{\sigma(z, A_T)}{\sigma_z} \bar{r} \quad (22.14)$$

The second expression follows from the standard identity that $S = \sigma_z \bar{r}$ (Equation 13.6a). Substituting Equation 22.12c, with $n = 2$ and $r = 0$, into Equation 22.13 recovers Griffing's result (Equation 22.11a).

Example 22.4. Muir (2005) estimated variance components for six-week body weight in Japanese quail (*Coturnix coturnix japonica*) housed in groups of $n = 16$ per cage. REML estimates of the genetic variances were $\sigma^2(A_d) = 33.7$ and $\sigma^2(A_s) = 2.87$, while $\sigma(A_d, A_s) = -5.5$. Under these values, the predicted response to individual selection in a group of 16 unrelated individuals is

$$R = \frac{\bar{r}}{\sigma_z} [\sigma^2(A_d) + (n-1)\sigma(A_d, A_s)] = \frac{\bar{r}}{\sigma_z} [33.7 + 15 \cdot (-5.5)] = -48.8 \frac{\bar{r}}{\sigma_z}$$

The strong negative covariance between direct and social (competitive) effects results in an expected reversed selection response if individual selection is used, as the positive gain from the improvement of direct effects (33.7) is swamped by the negative effects from the correlated response in social values (-82.5).

The presence of relatives within the group results in some fraction of $\sigma^2(A_s)$ being incorporated into the response under individual selection. Suppose the group of 16 consists of two half-sib families. In this case, the average relationship is 0.125, and from Equation 22.12d, the resulting covariance between phenotype and total breeding values becomes

$$\begin{aligned}\sigma(z, A_T) &= \sigma(z, A_T | r = 0) + (n-1)r[\sigma(A_s, A_d) + (n-1)\sigma^2(A_s)] \\ &= -48.4 + 15 \cdot 0.125 (-5.5 + 15 \cdot 2.87) = 21.6\end{aligned}$$

and from Equation 22.14,

$$R = \frac{\bar{r}}{\sigma_z} \sigma(z, A_T) = 21.6 \frac{\bar{r}}{\sigma_z}$$

Hence, simply using groups of relatives (as opposed to groups of unrelated individuals) allows individual selection to give an expected positive response.

Example 22.5. Consider a trait with $\sigma^2(A_d) = 500$, $\sigma^2(A_s) = 50$, $\rho(A_d, A_s) = -0.25$, and $\sigma^2(E_d) = 400$. For ease of presentation, we assume that there are no social environmental

effects ($E_s = 0$) and that E_d is uncorrelated across family members (i.e., no common family environment and no dominance). Consider a group size of $n = 6$. Given a selection intensity of \bar{t} , what response is expected under individual selection when group members are unrelated? Here $\sigma(A_d, A_s) = -0.25 \sqrt{500 \cdot 50} = -39.5$. Substituting into Equation 22.4b gives the covariance as

$$\sigma(z, A_T) = \sigma^2(A_d) + (n - 1)\sigma(A_d, A_s) = 500 - (5 \cdot 39.5) = 302.5$$

Likewise, from Equation 22.5c, the phenotypic variance is

$$\begin{aligned}\sigma^2(z) &= \sigma^2(A_d) + \sigma^2(E_d) + (n - 1)[\sigma^2(A_s) + \sigma^2(E_s)] \\ &= 500 + 400 + 5 \cdot 50 = 1150\end{aligned}$$

Applying Equation 22.14, the resulting response becomes

$$R = \frac{\sigma(z, A_T)}{\sigma_z} \bar{t} = \frac{302.5}{\sqrt{1150}} \bar{t} = 8.92 \bar{t}$$

Now suppose that group members are half-sibs ($r = 0.25$). What is the expected response? Applying Equation 22.12d yields

$$\begin{aligned}\sigma(z, A_T) &= \sigma(z, A_T | r = 0) + (n - 1)r[\sigma(A_s, A_d) + (n - 1)\sigma^2(A_s)] \\ &= 302.5 + 5 \cdot 0.25(-39.5 + 5 \cdot 50) = 565.5\end{aligned}$$

while Equation 22.13b yields a phenotypic variance of

$$\begin{aligned}\sigma^2(z) &= \sigma^2(z | r = 0) + (n - 1)r[\sigma(A_s, A_d) + (n - 2)\sigma^2(A_d)] \\ &= 1150 + [5 \cdot 0.25(-39.5 + 4 \cdot 50)] = 1350.6\end{aligned}$$

resulting in a response of $R = 15.39 \bar{t}$. Likewise, if the group consists of full sibs ($r = 0.5$), the resulting covariance, variance, and response are, respectively, 828.5, 1551.2, and $21.04 \bar{t}$. Thus, the response to selection increases with the relatedness of group members, with a 1.7- and 2.4-fold increase when using groups of half- and full-sibs (respectively) relative to groups of unrelated individuals.

Individual Selection: Direct vs. Social Response

Recalling Equation 22.1e, the response in the trait has two components: that from direct effects, $R_d = \Delta\mu_{A_d}$, and that from social effects, $R_s = \Delta\mu_{A_s}$. The relative contribution of each to the total response easily follows by considering the covariance of an individual's phenotype value, z , with either its direct, A_d , or social, A_s , breeding values. Specifically,

$$R_z = R_d + (n - 1)R_s, \quad \text{where} \quad R_d = \frac{\sigma(A_d, z)}{\sigma_z} \bar{t} \quad \text{and} \quad R_s = \frac{\sigma(A_s, z)}{\sigma_z} \bar{t} \quad (22.15a)$$

Here

$$\sigma(A_d, z) = \sigma\left(A_d, A_d + \sum_{i \neq j} A_{s,i} + e\right) = \sigma^2(A_d) + r(n - 1)\sigma(A_d, A_s) \quad (22.15b)$$

while

$$\sigma(A_s, z) = \sigma\left(A_s, A_d + \sum_{i \neq j} A_{s,i} + e\right) = \sigma(A_d, A_s) + r(n - 1)\sigma^2(A_s) \quad (22.15c)$$

Equation 22.15b shows that the group must contain relatives ($r \neq 0$) in order for the covariance between direct and social values to impact the response in the direct value. Likewise, under individual selection, response in the social value only occurs if the direct and social values are correlated within individuals ($\sigma(A_d, A_s) \neq 0$) or if group members are related ($r \neq 0$), in which case the social value of the focal individual is correlated with the social values of those within its group.

Example 22.6. Consider the response in a family of half-sibs from Example 22.5, where the expected total response was $15.39\bar{t}$. What were the contributions from the direct and social responses? For the values used in that example,

$$\begin{aligned}\sigma(A_d, z) &= \sigma^2(A_d) + r(n-1)\sigma(A_d, A_s) = 500 + [0.25 \cdot 5 \cdot (-39.5)] = 450.63 \\ \sigma(A_s, z) &= \sigma(A_d, A_s) + r(n-1)\sigma^2(A_s) = -39.5 + [0.24 \cdot 5 \cdot 50] = 23.0\end{aligned}$$

Recalling from Example 22.5 that $\sigma_z^2 = 1350.6$ for half-sibs, Equations 22.15a and 22.15b return the two components of response as

$$R_d = \frac{450.63}{\sqrt{1350.6}}\bar{t} = 12.26\bar{t} \quad \text{and} \quad R_s = \frac{23}{\sqrt{1350.6}}\bar{t} = 0.63\bar{t}$$

Hence, 80% ($12.26/15.39$) of the total response was due to response in direct effects, while 20% was from the response in social effects ($5 \cdot 0.63/15.39$). Under individual selection with half-sib families, both the mean direct and mean social values improved. By contrast, if group members are unrelated, then (Example 22.5) $\sigma_z^2 = 1150$, while

$$\sigma(A_d, z) = \sigma^2(A_d) = 500 \quad \text{and} \quad \sigma(A_s, z) = \sigma(A_d, A_s) = -39.5$$

resulting in responses of

$$R_d = \frac{500}{\sqrt{1150}}\bar{t} = 14.74\bar{t} \quad \text{and} \quad R_s = \frac{-39.5}{\sqrt{1150}}\bar{t} = -1.165\bar{t}$$

In this case, while the total response was positive, the large direct response (14.74) was partly offset by a decrease in the mean social environment ($[n-1]R_s = 5 \cdot [-1.165] = -5.83$), yielding a total response of $(14.74 - 5.83)\bar{t} = 8.91\bar{t}$. The lack of relatedness implies no direct selection involving $\sigma^2(A_s)$, and hence the social breeding values only change through their correlation with the direct values, which in this example was negative.

Individual Selection: Maternal Effects

An important special case, and indeed the forerunners of more general models of associative effects, are models of direct and **maternal** effects (Dickerson 1947; Willham 1963, 1972; Cheverud 1984a). Here, the trait value of an individual is a function of its direct effect, P_{di} , and a **maternal performance trait**, P_m , contributed by its mother, meaning that if j is the mother of i , then

$$z_i = P_{di} + P_{mj} \tag{22.16a}$$

In the absence of inbreeding, $r = 1/2$ for this group (mother-offspring) with $n = 2$. From Equation 22.12c, the covariance between phenotype and total breeding value ($A_T = A_d + A_m$, with $A_s = A_m$) is

$$\sigma(z, A_T) = \sigma^2(A_d) + (3/2)\sigma(A_d, A_m) + (1/2)\sigma^2(A_m) \tag{22.16b}$$

while Equation 22.13a yields a phenotypic variance of

$$\sigma^2(z) = \sigma^2(A_d) + \sigma(A_d, A_m) + \sigma^2(A_m) + \sigma^2(e) \tag{22.16c}$$

making the resulting response to selection

$$R = \frac{\sigma(z, A_T)}{\sigma_z} \bar{z} = \frac{\sigma^2(A_d) + (3/2)\sigma(A_d, A_m) + (1/2)\sigma^2(A_m)}{\sqrt{\sigma^2(A_d) + \sigma(A_d, A_m) + \sigma^2(A_m) + \sigma^2(e)}} \bar{z} \quad (22.16d)$$

The total response can also be expressed in terms of the direct and maternal-effect response. From Equation 22.15,

$$R_d = \frac{\sigma(A_d, z)}{\sigma_z} \bar{z} = \frac{\sigma^2(A_d) + (1/2)\sigma(A_d, A_m)}{\sigma_z} \bar{z} \quad (22.17a)$$

and

$$R_m = \frac{\sigma(A_m, z)}{\sigma_z} \bar{z} = \frac{\sigma(A_d, A_m) + (1/2)\sigma^2(A_m)}{\sigma_z} \bar{z} \quad (22.17b)$$

with the response, R , in the trait mean being

$$R = R_d + (2 - 1)R_m = R_d + R_m \quad (22.17c)$$

Substitution of Equations 22.17a and 22.17b into Equation 22.17c recovers Equation 22.16d. As reviewed by Cheverud (1984a), most estimates of the direct-maternal covariance are negative. This raises the possibility of a reversed response due to a greater reduction in the maternal environment than improvement in the direct effect. It also allows for the trait to improve (via its direct value) at the expense of a declining maternal value.

The careful reader might recall from Chapter 15 that Falconer's trait-based model of a single maternal effect results in more complicated dynamics (such as time lags). Why do these not appear in this analysis? As noted by Bijma (2011), variance-component models essentially focus on the permanent component of response, ignoring transient contributions that can appear in a trait-based analysis. He showed that Equation 22.16d and Falconer's model both give the same value for the permanent response.

Group Selection: Theory

Under individual selection with unrelated group members, there is no contribution from $\sigma^2(A_s)$ to the response, and changes in A_s only enter as a correlated response to changes in A_d , which can be in an unfavorable direction when $\sigma(A_d, A_s) < 0$. As we will see, $\sigma^2(A_s)$ enters into the response under group selection even when there are no relatives in the group. The reason is that the group phenotype is a function of the distribution of A_s values.

Under strict group selection, selection is based on the group mean, \bar{z} , or equivalently the total value of the group, $n\bar{z} = \sum z$, and we will usually work with the latter. To obtain the covariance between the total value of a group and the total breeding value of one of its members, first note that

$$\begin{aligned} \sum_{j=1}^n z_j &= \sum_{j=1}^n \left[A_{d_j} + E_{d_j} + \sum_{k \neq j}^n (A_{s_k} + E_{s_k}) \right] = \sum_{j=1}^n A_{d_j} + \sum_{j=1}^n \sum_{k \neq j}^n A_{s_k} + \sum_{j=1}^n e_j \\ &= \sum_{j=1}^n A_{d_j} + (n-1) \sum_{j=1}^n A_{s_j} + \sum_{j=1}^n e_j \\ &= \sum_{j=1}^n A_{T_j} + \sum_{j=1}^n e_j \end{aligned} \quad (22.18)$$

where the residual values, e_i , sweep up a variety of environmental terms, and are given by Equation 22.1c. The residuals are assumed to be uncorrelated with any breeding values, but of course residuals can be (and usually are) correlated within a group (e.g., Equation

22.23a). If r_{ij} is the relationship between individuals i and j , the covariance between the group total and the total breeding value of a group member, i , is

$$\begin{aligned}\sigma\left(A_{T_i}, \sum_{j=1}^n z_j\right) &= \sigma\left(A_{T_i}, \sum_{j=1}^n [A_{T_j} + e_j]\right) = \sum_{j=1}^n \sigma(A_{T_i}, A_{T_j}) = \sigma^2(A_T) \sum_{j=1}^n r_{ij} \\ &= \sigma^2(A_T) \left(1 + \sum_{j \neq i} r_{ij}\right)\end{aligned}\quad (22.19a)$$

If the group members are unrelated, then

$$\sigma\left(A_{T_i}, \sum_{j=1}^n z_j\right) = \sigma^2(A_T) \quad (22.19b)$$

which implies that $\sigma(A_{T_i}, \bar{z}) = \sigma^2(A_T)/n$. Hence, group selection acts on the total breeding value of an individual, rather than on only part of A_T , as was the case with individual selection (e.g., Equation 22.12e). The contribution of associative effects to the total breeding value does not influence the phenotype of the focal individual, but *does* influence the phenotypes of other group members, and hence, \bar{z} . Group selection directly targets these effects. If all members have the same degree of relationship (r), then

$$\sigma\left(A_{T_i}, \sum_{j=1}^n z_j\right) = \sigma^2(A_T) [1 + (n - 1)r] \quad (22.19c)$$

Selection can act on associative effects even when none of the individuals in the group are related, but its efficiency is amplified when using relatives (compare Equations 22.19b and 22.19c). From Equation 22.19c, the covariance of the total breeding value, A_T , of a group member with its group mean, \bar{z} , is

$$\sigma(A_{T_i}, \bar{z}) = \frac{1}{n} \sigma^2(A_T) [1 + (n - 1)r] = \sigma^2(A_T) \left(r + \frac{1 - r}{n}\right) \quad (22.19d)$$

Turning to the phenotypic variance of the group total, $n\bar{z}$, a little bit of algebra is required. From Equation 22.18, we can decompose this group variance into additive-genetic and environmental components

$$\sigma^2\left(\sum_{j=1}^n A_{T_j} + \sum_{j=1}^n e_j\right) = \sigma\left(\sum_{j=1}^n A_{T_j}, \sum_{k=1}^n A_{T_k}\right) + \sigma\left(\sum_{j=1}^n e_j, \sum_{k=1}^n e_k\right) \quad (22.20)$$

Tackling the genetic component first yields

$$\sigma\left(\sum_{j=1}^n A_{T_j}, \sum_{k=1}^n A_{T_k}\right) = \sigma^2(A_T) \cdot \sum_{j=1}^n \sum_{k=1}^n r_{ij} \quad (22.21a)$$

When all group members have the same degree of relationship, r , this reduces to

$$\sigma\left(\sum_{j=1}^n A_{T_j}, \sum_{k=1}^n A_{T_k}\right) = \sigma^2(A_T) n [1 + (n - 1)r] \quad (22.21b)$$

Turning our attention to the residual terms, recall (Equation 22.1c) that the residual is a function of both direct and social environmental effects,

$$e_i = E_{d_i} + \sum_{k \neq i} E_{s_k}$$

Clearly, individuals within the same group are correlated because they share the E_s values from the other group members. Recalling that $\sigma(E_{d_i}, E_{s_k}) = 0$ for $i \neq k$, the residual variance becomes

$$\begin{aligned}\sigma^2(e) &= \sigma(e_i, e_i) = \sigma\left(E_{d_i} + \sum_{k \neq i} E_{s_k}, E_{d_i} + \sum_{k \neq i} E_{s_k}\right) = \sigma(E_{d_i}, E_{d_i}) + \sum_{k \neq i} \sigma(E_{s_k}, E_{s_k}) \\ &= \sigma^2(E_d) + (n - 1)\sigma^2(E_s)\end{aligned}\quad (22.22a)$$

For $i \neq j$ in the same group, the covariance among residuals is

$$\begin{aligned}\sigma(e_i, e_j) &= \sigma\left(E_{d_i} + E_{s_j} + \sum_{k \neq i, j} E_{s_k}, E_{d_j} + E_{s_i} + \sum_{k \neq i, j} E_{s_k}\right) \\ &= \sigma(E_{d_i}, E_{d_j}) + \sigma(E_{d_i}, E_{s_i}) + \sigma(E_{d_j}, E_{s_i}) + \sigma\left(\sum_{k \neq i, j} E_{s_k}, \sum_{k \neq i, j} E_{s_k}\right) \\ &= 0 + 2\sigma(E_d, E_s) + \sum_{k \neq i, j} \sigma(E_{s_k}, E_{s_k}) \\ &= 2\sigma(E_d, E_s) + (n - 2)\sigma^2(E_s)\end{aligned}\quad (22.22b)$$

The first term accounts for the fact that the direct and social environmental values can be correlated within the same individual, while the second term accounts for the shared environmental values contributed by the other $n - 2$ group members. Putting these together yields

$$\sigma(e_i, e_j) = \begin{cases} \sigma^2(e) & i = j \\ \rho \sigma^2(e) & i \neq j, i \text{ and } j \text{ in the same group} \\ 0 & i \neq j, i \text{ and } j \text{ in different groups} \end{cases}\quad (22.23a)$$

where

$$\sigma^2(e) = \sigma^2(E_d) + (n - 1)\sigma^2(E_s) \quad \text{and} \quad \rho = \frac{2\sigma(E_d, E_s) + (n - 2)\sigma^2(E_s)}{\sigma^2(e)}\quad (22.23b)$$

Here ρ is the correlation among environmental values within a group, and can be either positive or negative. For large values of n , we expect $\sigma^2(E_s)$ to dominate the covariance term, yielding $\rho > 0$. Equations 22.23a and 22.23b were first obtained by Bijma et al. (2007b). Correlations among environmental residuals are also generated by shared maternal effects and (for full-sibs) dominance. If all group members are the same type of relative, this is simply incorporated into ρ . However, when a group consists of two (or more) families, the additional residual covariance among sibs needs to be accounted for (Example 22.14, below, shows how this is accomplished in a BLUP framework).

Using these results, and following the same logic as with additive-genetic values, yields

$$\sigma\left(\sum_{j=1}^n e_j, \sum_{k=1}^n e_k\right) = n\sigma^2(e) + \sum_{j \neq k} \sigma(e_j, e_k) = n\sigma^2(e)[1 + (n - 1)\rho]\quad (22.24)$$

Substituting Equations 22.21b and 22.24 into Equation 22.20 returns the variance of the group total as

$$\sigma^2\left(\sum_{j=1}^n z_j\right) = n\sigma^2(A_T)[1 + (n - 1)r] + n\sigma^2(e)[1 + (n - 1)\rho]\quad (22.25a)$$

The variance of the group mean is simply $1/n^2$ of this value, or

$$\begin{aligned}\sigma^2(\bar{z}) &= \sigma^2(A_T)\left(\frac{1 + (n - 1)r}{n}\right) + \sigma^2(e)\left(\frac{1 + (n - 1)\rho}{n}\right) \\ &= \sigma^2(A_T)\left(r + \frac{1 - r}{n}\right) + \sigma^2(e)\left(\rho + \frac{1 - \rho}{n}\right)\end{aligned}\quad (22.25b)$$

Note the symmetric roles of the relatedness, r , of group members and the within-group correlation, ρ , of residuals with respect to, respectively, the variance in total breeding values and the residual variance.

Using the covariance between total breeding value and group mean (Equation 22.19d) and the variance of the group mean (Equation 22.25b), the resulting response to selection (i.e., the change in trait mean) follows from our general response expression (Equation 13.10b), and is

$$R = \frac{\sigma(A_T, \bar{z})}{\sigma^2(\bar{z})} S = \frac{\sigma^2(A_T)r_n}{\sigma^2(A_T)r_n + \sigma^2(e)\rho_n} S \quad (22.26a)$$

$$= \frac{\sigma(A_T, \bar{z})}{\sigma(\bar{z})} \bar{t} = \frac{\sigma^2(A_T)r_n}{\sqrt{\sigma^2(A_T)r_n + \sigma^2(e)\rho_n}} \bar{t} \quad (22.26b)$$

where

$$r_n = r + \frac{1-r}{n} \quad \text{and} \quad \rho_n = \rho + \frac{1-\rho}{n}$$

For $n = 2$ and $r = 0$, applying Equations 22.19b and 22.25a recovers Griffing's result (Equation 22.11b). As expected, in cases where there are only direct effects, Equations 22.26a and 22.26b reduce to our expressions for family selection (Chapter 21).

Example 22.7. Consider group selection using Muir's quail data from Example 22.4. Here $\sigma^2(A_d) = 33.7$, $\sigma^2(A_s) = 2.87$, $\sigma(A_d, A_s) = -5.5$, and $n = 16$. Muir estimated the residual variance as $\sigma^2(e) = 69.0$, while his model assumed $\rho = 0$, resulting $\rho_n = 1/n$, and hence $\sigma^2(e)\rho_n = 69.0/16 = 4.32$. Applying Equation 22.4e yields a total additive variance of

$$\begin{aligned} \sigma^2(A_T) &= \sigma^2(A_d) + 2(n-1)\sigma(A_d, A_s) + (n-1)^2\sigma^2(A_s) \\ &= 33.7 + [30 \cdot (-5.5)] + [30^2 \cdot 2.87] = 2451.7 \end{aligned}$$

while Equation 22.26b yields a response of

$$R = \frac{\sigma^2(A_T)r_n}{\sqrt{\sigma^2(A_T)r_n + \sigma^2(e)\rho_n}} \bar{t} = \frac{2451.7 \cdot r_n}{\sqrt{2451.7 \cdot r_n + 4.32}} \bar{t}$$

For groups of unrelated individuals, $r = 0$ and $r_n = 1/16 = 0.0625$, respectively, and the response becomes $R = 12.2\bar{t}$. For half- and full-sibs ($r = 0.25$ and 0.5), $r_n = 0.297$ and 0.531 , respectively, with responses of $26.9\bar{t}$ and $36.0\bar{t}$, twofold and threefold increases relative to that for a group of unrelated individuals.

While Equation 22.26a shows that group selection always results in an expected non-negative response (as $\sigma^2(A_T) \geq 0$), it may be less than optimal. If direct effects account for the majority of variance, group selection can be very inefficient relative to individual selection. To see this, consider groups of unrelated individuals and suppose the trait of interest has no associative effects, $\sigma^2(A_s) = 0$, so that $\sigma^2(A_T) = \sigma^2(A_d)$. Under individual (or mass) selection, the response is $R_m = h\sigma(A_d)\bar{t}$ (Equation 13.6b). Now consider the response, R_G , in the mean of trait z under group selection, where $\sigma(\bar{z}, A_T) = (1/n)\sigma^2(A_d)$ and $\sigma^2(\bar{z}) = \sigma_z^2/n$, giving the response (from Equation 22.26b) as

$$R_G = \frac{\sigma(\bar{z}, A_T)}{\sigma(\bar{z})} \bar{t} = \frac{(1/n)\sigma^2(A_d)}{\sigma_z/\sqrt{n}} \bar{t} = \frac{1}{\sqrt{n}} \frac{\sigma(A_d)}{\sigma_z} \sigma(A_d) \bar{t} = \frac{1}{\sqrt{n}} h\sigma(A_d) \bar{t} = \frac{1}{\sqrt{n}} R_m$$

Under these conditions, individual selection is always superior to group selection, with the superiority increasing with group size. For groups of 5, 10, and 25, group selection has only 44.7%, 31.6%, and 20% (respectively) of the expected response of individual selection.

Group Selection: Direct vs. Social Response

As was the case for individual selection, we can decompose the response under group selection into the responses from direct and social effects, $R_z = R_d + (n - 1)R_s$. Under group selection, these response components are given by

$$R_d = \frac{\sigma(A_d, \sum z)}{\sigma(\sum z)} \bar{r} \quad \text{and} \quad R_s = \frac{\sigma(A_s, \sum z)}{\sigma(\sum z)} \bar{r} \quad (22.27a)$$

The covariance between the direct breeding value of a group member and the group total becomes

$$\begin{aligned} \sigma\left(A_{d_i}, \sum_{j=1}^n z_j\right) &= \sigma\left(A_{d_i}, \sum_{j=1}^n A_{d_j} + (n-1) \sum_{j=1}^n A_{s_j} + \sum_{j=1}^n e_j\right) \\ &= \sigma^2(A_d) \sum_{j=1}^n r_{ij} + (n-1)\sigma(A_d, A_s) \sum_{j=1}^n r_{ij} \\ &= [\sigma^2(A_d) + (n-1)\sigma(A_d, A_s)] [1 + (n-1)\bar{r}] \end{aligned} \quad (22.27b)$$

Where $\bar{r} = \sum_{j \neq i} r_{ij}/(n-1)$ is the average degree of relationship (for i) among group members (assuming that $r_{ii} = 1$, i.e., i is not inbred), resulting in $\sum_j r_{ij} = 1 + (n-1)\bar{r}$. Similarly, for the social breeding value

$$\sigma\left(A_{s_i}, \sum_{j=1}^n z_j\right) = [\sigma(A_d, A_s) + (n-1)\sigma^2(A_s)] [1 + (n-1)\bar{r}] \quad (22.27c)$$

Increasing the relatedness, r , of group members increases the contributions from $\sigma(A_d, A_s)$ and $\sigma^2(A_s)$ by the same proportional amount, $[1 + (n-1)\bar{r}]$. Hence, the relative contribution of these two components is independent of the degree of relatedness within the group. By contrast, recall that under individual selection, the relative contributions of these two components changes (and potentially can change rather dramatically) with r (Equations 22.15b and 22.15c).

Group Selection: Experimental Evidence

How effective is group selection? As reviewed in Chapter 21, the special case of the group being a single family has a fairly robust experimental literature. What is seen in more general settings? Experiments in laboratory settings generally have proved effective in generating a positive response (Goodnight and Stevens 1997; Goodnight 2005). Especially telling are several reports of group selection yielding a positive response when individual selection either failed to do so or generated a negative response.

One of the first group-selection experiments was by Wade (1976, 1977), who found a rapid response to group selection for the (group-level) trait of population size in the flour beetle *Tribolium castaneum*. A series of 48 populations was founded, each with 16 unrelated individuals, and population size was measured at 37 days postfounding. Under the control (allowing for individual selection during the growout to 37 days), a group of 16 individuals was chosen at random from the 48 populations and used to found a new population, repeatedly (with the possibility of resampling from the same population), until 48 new populations were formed. Under group selection for increased population size, sets of 16 individuals were drawn from the largest population and used to found a new population, which was continued until the largest population was exhausted. When this happened, individuals were similarly used from the second largest population, and so

forth, to fill out the new array of 48 populations. The group-selected populations showed significantly larger population sizes relative to the control, and they also showed reduced levels of cannibalism. Laboratory populations of *Tribolium* were also used by Craig (1982), who found that group selection was very efficient in increasing (and decreasing) emigration rates. In both studies, some degree of relationship might be expected within groups, which would be small at first, with \bar{r} increasing under inbreeding as selection proceeds (albeit likely still remaining somewhat small at the end of the experiment).

Response under group selection is not limited to animals. Goodnight (1985) contrasted individual and group selection for leaf area in the mustard *Arabodopsis thaliana*. Plants were grown in groups of 16 unrelated individuals. Individual selection for increased leaf area actually resulted in a reversed response, with offspring showing smaller leaf area. In contrast, average leaf area per plant (i.e., a larger total leaf area for the group) increased under group selection.

Finally, dramatic responses with significant economic impact have occurred when using group selection in animal production settings. In chickens, high egg-production systems typically house several hens per cage. Aggressive behavior and mortality are common in such settings. Selection for improved individual production could result in increased aggression within the cage, and hence lower cage production (reviewed in Muir 1985). To assess whether group selection could improve performance, Muir (1996) made selections based on the mean value of nine-bird cages ($n = 9$). Eggs per hen per day, eggs per hen, and egg mass all increased dramatically. What was even more striking, was that annual percentage mortality declined from 68% to just under 9% at the end of generation 6, which is similar to the mortality in single-bird cages. Muir called the resulting selected strain KGB chickens (for Kinder, Gentler Birds). Selection based on the group (here, cage) mean improved total performance of the cage, in part by reducing the amount of aggression within the cage, as Craig and Muir (1996) found that KGB birds showed a significant reduction (relative to controls) in beak-inflicted injuries.

The benefits of group selection have often been framed in terms of exploiting non-additive variation that is not accessible by traditional individual selection (e.g., Goodnight and Stevens 1997). While we have focused here on genetic variation that is not directly accessible under individual selection when groups are unrelated ($\sigma^2[A_s]$), this variation is entirely *additive*. Specifically, when heritable associative effects are present, they can only be directly accessible through either group selection (with either related or unrelated members) or individual selection when interactions occur in groups of related individuals (as the appropriate covariances for response in either setting places nonzero weight on $\sigma[A_s]$). This is not to ignore the possibility of exploiting additional nonadditive variation under group selection, but rather to highlight the importance of associative effects.

INCORPORATING BOTH INDIVIDUAL AND GROUP INFORMATION

Given that group selection always results in an expected positive response, while individual selection can range from (at best) being far more efficient than group selection to (at worst) generating an expected reversed response, clearly the optimal approach is some combination of selection on both individual and group components. This is simply an extension of the concept of a family index introduced in Chapter 21, that combines both individual and family (now group) information.

Response on a Weighted Index

To combine both individual and group selection, consider the index, I , where the value of the index for the i th individual is given by

$$I_i = z_i + g \sum_{j \neq i} z_j \quad (22.28a)$$

This is a modification of the initial proposal by Griffing (1977). Letting \bar{z}_i denote the mean

of the group containing individual i , this index can also be written as

$$I_i = (1 - g)z_i + g \sum_{j=1}^n z_j = (1 - g)z_i + g n \bar{z}_i \quad (22.28b)$$

showing that individual selection corresponds to $g = 0$ and group selection to $g = 1$. Thus, the index given by Equation 22.28b includes both individual and group selection as special cases. Selection of individuals based on within-group deviations is also a special case of Equation 22.28a, as setting $g = -1/n$ yields

$$I_i = z_i - \frac{1}{n} \sum_{j=1}^n z_j = z_i - \bar{z} \quad (22.28c)$$

The response in the trait mean (μ_z) from selection on this index is

$$R = \frac{\sigma(I, A_T)}{\sigma(I)} \bar{\tau}_I \quad (22.28d)$$

This can also be written in terms of the **accuracy** of selection, a concept first introduced in Chapter 13 (Equation 13.11a), which is the correlation between the target of selection (here I) and the breeding objective (here the total breeding value, A_T). We can express the ratio in Equation 22.28d as

$$\frac{\sigma(I, A_T)}{\sigma(I)} = \frac{\sigma(I, A_T)}{\sigma(I)} \frac{\sigma(A_T)}{\sigma(A_T)} = \sigma(A_T) \frac{\sigma(I, A_T)}{\sigma(A_T) \sigma(I)} = \sigma(A_T) \rho(A_T, I) \quad (22.28e)$$

where the accuracy

$$\rho(A_T, I) = \frac{\sigma(I, A_T)}{\sigma(A_T) \sigma(I)} \quad (22.28f)$$

is the correlation between the index value of an individual and its breeding value. Using this result, Equation 22.28d becomes

$$R = \rho(A_T, I) \sigma(A_T) \bar{\tau}_I \quad (22.28g)$$

which is simply Equation 13.11c for the selection criteria $x = I$. This is a very useful expression for comparing different selection schemes, as $\sigma(A_T)$ remains unchanged (provided group size remains fixed), so the maximal response occurs by maximizing $\rho(A_T, I) \bar{\tau}_I$. Given that the fraction saved largely sets the selection intensity $\bar{\tau}_I$ (subject to minor variation due to finite populations; see Equation 14.4b), the optimal scheme (i.e., the optimal weight, g) is that which maximizes the accuracy, $\rho(A_T, I)$.

To obtain a general expression for response for any combination of group selection fraction (g) and average relatedness within groups (r), we first need the covariance of I and A_T within an individual. This is obtained as follows. First, note that

$$\sigma(A_T, I) = (1 - g)\sigma(A_T, z) + g\sigma\left(A_T, \sum_{j=1}^n z_j\right) \quad (22.29a)$$

When group members are unrelated, Equations 22.4b and 22.19b give

$$\sigma(A_T, I) = (1 - g) [\sigma^2(A_d) + (n - 1)\sigma(A_d, A_s)] + g\sigma^2(A_T) \quad (22.29b)$$

When group members all have the same relationship, Equations 22.12e and 22.19c yield

$$\begin{aligned} \sigma(A_T, I) &= (1 - g) \left(r\sigma^2(A_T) + (1 - r) [\sigma^2(A_d) + (n - 1)\sigma(A_d, A_s)] \right) \\ &\quad + g [1 + (n - 1)r] \sigma^2(A_T) \end{aligned} \quad (22.29c)$$

Collecting terms, Equation 22.29c reduces to

$$\sigma(A_T, I) = [g + r + (n - 2)gr] \sigma^2(A_T) + (1-g)(1-r) [\sigma^2(A_d) + (n - 1)\sigma(A_s, A_d)] \quad (22.29d)$$

While parts of this result (in a bit more cryptic form) appear in Griffing (1977), this, more general, version is due to Bijma et al. (2007a). Note that g and r have symmetric roles in the covariance between the index and the total breeding value. Thus, from the standpoint of this covariance, relatedness and group selection (r and g) are interchangeable. However, as we will soon demonstrate, g and r do not play symmetric roles in the variance, σ_I^2 , of the index, so interchanging r and g values results in a different variance, and hence a different selection response (see Equation 22.28d and Example 22.8).

Now consider the variance of the index, I . From Equation 22.28a,

$$\begin{aligned} \sigma_I^2 &= \sigma\left(z_i + g \sum_{j \neq i} z_j, z_i + g \sum_{j \neq i} z_j\right) \\ &= \sigma_z^2 + 2g\sigma\left(z_i, \sum_{j \neq i} z_j\right) + g^2\sigma^2\left(\sum_{j \neq i} z_j\right) \end{aligned} \quad (22.30a)$$

If all group members have the same relationship, then

$$\sigma\left(z_i, \sum_{j \neq i} z_j\right) = (n - 1)\sigma(z_i, z_j) \quad (22.30b)$$

and

$$\sigma^2\left(\sum_{j \neq i} z_j\right) = (n - 1) [\sigma_z^2 + (n - 2)\sigma(z_i, z_j)] \quad (22.30c)$$

Substituting these last two expressions into Equation 22.30a and collecting terms gives

$$\sigma_I^2 = \sigma_z^2 [1 + g^2(n - 1)] + \sigma(z_i, z_j) [g(n - 1)(2 + g\{n - 2\})] \quad (22.30d)$$

As a check of Equation 22.30d, note that (as expected) this reduces to σ_z^2 when $g = 0$ and to $n\sigma_z^2 + n(n - 1)\sigma(z_i, z_j)$ when $g = 1$. Equation 22.13a gives the expression for σ_z^2 when all relatives within the group are related by r . It remains to obtain $\sigma(z_i, z_j)$, the phenotypic covariance of group members, in order to apply Equation 22.30d. From Equation 22.1c, and ignoring the constant, μ ,

$$\sigma(z_i, z_j) = \sigma\left(A_{d_i} + \sum_{k \neq i} A_{s_k} + e_i, A_{d_j} + \sum_{k \neq j} A_{s_k} + e_j\right) \quad (22.31a)$$

$$= \sigma(A_{d_i}, A_{d_j}) + 2\sigma\left(A_{d_i}, \sum_{k \neq i} A_{s_k}\right) + \sigma\left(\sum_{k \neq i} A_{s_k}, \sum_{k \neq j} A_{s_k}\right) + \sigma(e_i, e_j) \quad (22.31b)$$

If we expand and evaluate these covariance terms and collect the common terms, Equation 22.31b ultimately reduces to

$$\begin{aligned} \sigma(z_i, z_j) &= 2\sigma(A_d, A_s) + (n - 2)\sigma^2(A_s) + \rho\sigma^2(e) \\ &\quad + r [\sigma^2(A_d) + 2(n - 2)\sigma(A_d, A_s) + \{(n - 1) + (n - 2)^2\} \sigma^2(A_s)] \end{aligned} \quad (22.31c)$$

Notice, by comparison to Equation 22.4c, that the term appearing when group members are related ($r \neq 0$) is the variance of A_T when the group size is $(n - 1)$ plus the correction $(n - 1)\sigma^2(A_s)$. Equations 22.29d and 22.30d are substituted into Equation 22.28d to obtain the response. The interplay of $\sigma(A_T, I)$ and σ_I^2 (as functions of g and r) determine the accuracy of any particular index (Figure 22.3).

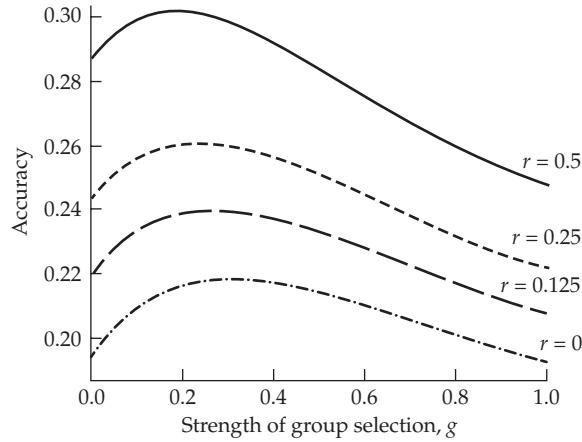

Figure 22.3 Accuracy of the index, I , as a function of the group weight, g , for groups of different types of relatives (the curves corresponding to different values of r). Accuracy was computed using Equation 22.28f, whose components are given by Equations 22.29d, 22.7b, and 22.30d. The variance components used were from Ellen et al. (2008) for survival days for chickens, and are given in Example 22.8, which also works through the calculations. Accuracy increases with r and is maximized at some intermediate strength of group selection, g .

Example 22.8. Ellen et al. (2008) estimated the following values for survival days in chickens raised in groups of $n = 4$: $\sigma^2(A_d) = 915$, $\sigma(A_d, A_d) = 62$, $\sigma^2(A_s) = 134$, $\sigma^2(e) = 11,500$, and $\rho = 0.08$. Applying Equation 22.4c yields

$$\begin{aligned}\sigma^2(A_T) &= \sigma^2(A_d) + 2(n-1)\sigma(A_d, A_s) + (n-1)^2\sigma^2(A_s) \\ &= 915 + (2 \cdot 3 \cdot 62) + (3^2 \cdot 134) = 2493\end{aligned}$$

while

$$\sigma^2(A_d) + (n-1)\sigma(A_s, A_d) = 915 + (3 \cdot 62) = 1101$$

Substituting these results into Equation 22.29d returns a covariance between I and total breeding value of

$$\sigma(A_T, I) = [(g + r + 2gr) \cdot 2493] + [(1 - g)(1 - r) \cdot 1101] \quad (22.32a)$$

To obtain the variance in I using Equation 22.30d, we first need expressions for $\sigma^2(z)$ and $\sigma(z_i, z_j)$. From Equation 22.5d, the phenotypic variance when the group contains unrelated individuals is

$$\sigma^2(z | r = 0) = \sigma^2(A_d) + (n-1)\sigma^2(A_s) + \sigma^2(e) = 915 + (3 \cdot 134) + 11,500 = 12,817$$

Noting that

$$(n-1) [2\sigma(A_s, A_d) + (n-2)\sigma^2(A_d)] = 3 \cdot [(2 \cdot 62) + (2 \cdot 915)] = 5862$$

Equation 22.13b shows the phenotypic variance for a group with relationship r as

$$\begin{aligned}\sigma^2(z) &= \sigma^2(z | r = 0) + (n-1)r [2\sigma(A_s, A_d) + (n-2)\sigma^2(A_d)] \\ &= 12,817 + (r \cdot 5862) \quad (22.32b)\end{aligned}$$

To obtain $\sigma(z_i, z_j)$, we first find that

$$2\sigma(A_d, A_s) + (n-2)\sigma^2(A_s) + \rho\sigma^2(e) = (2 \cdot 62) + (2 \cdot 134) + (0.08 \cdot 11,550) = 1312$$

and

$$\begin{aligned}\sigma^2(A_d) + 2(n-2)\sigma(A_d, A_s) + [(n-1) + (n-2)^2] \sigma^2(A_s) \\ = 915 + (2 \cdot 2 \cdot 62) + [(3+2^2) \cdot 134] = 2101\end{aligned}$$

Substituting into Equation 22.31c gives the general covariance between group members when all members are related by an amount, r , as

$$\sigma(z_i, z_j) = 1312 + r \cdot 2101 \quad (22.32c)$$

Finally, substituting Equations 22.32b and 22.32c into Equation 22.30d gives the variance in I as

$$\begin{aligned}\sigma_I^2 &= \sigma_z^2 [1 + g^2(n-1)] + \sigma(z_i, z_j)g(n-1)[2 + g(n-2)] \\ &= [12,817 + (r \cdot 5862)](1 + 3g^2) + [1312 + (r \cdot 2101)]6g(1+g) \quad (22.32d)\end{aligned}$$

Note from Equation 22.32a that the roles of relatedness (r) and amount of group selection (g) are fully interchangeable in the covariance between I and A_T . However, Equation 22.32d shows that this is *not* the case for σ_I^2 , and hence the expected responses when the values of r and g are swapped are not expected to be equal. For example, for $r = 0.5, g = 0$,

$$\sigma(I, A_T) = 1797, \quad \sigma_I^2 = 15,748, \quad \rho(A_T, I) = 0.287, \quad R = 14.32\bar{z}$$

where $\rho(A_T, I)$ is given by Equation 22.28f. For $r = 0, g = 0.5$,

$$\sigma(I, A_T) = 1797, \quad \sigma_I^2 = 28,334, \quad \rho(A_T, I) = 0.214, \quad R = 10.68\bar{z}$$

As points of reference, the accuracy and response under individual selection with no relatives in the group ($g = r = 0$) are $\rho(A_T, I) = 0.195$ and $R = 9.73\bar{z}$, while for group selection with unrelated individuals within the group ($g = 1, r = 0$), the accuracy and response become $\rho(A_T, I) = 0.193$ and $R = 9.63\bar{z}$.

Optimal Response

In the index shown by Equation 22.28a, g is the fraction of weight placed on a random individual from the group that interacts with the focal individual. If this weight is zero, the index reduces to individual selection, while if this weight is 1, all individuals in the group are weighted equally in the selection decision and there is group selection. An obvious question is to determine the optimal value for g that maximizes the selection response. From Equation 22.28g, we see that the optimal response occurs by using those weights in I that maximizes the correlation, $\rho(A_T, I)$, between I and A_T . To find these optimal weights, we start with the index

$$I = b_1 z + b_2 \sum_{j \neq i} z_j \quad (22.33a)$$

with no restrictions placed on the ranges of b_1 and b_2 . Selection on this index is equivalent to selection using the index

$$I = z + \frac{b_2}{b_1} \sum_{j \neq i} z_j \quad (22.33b)$$

Hence, the connection between Equations 22.28a and 22.33a is that $g = b_2/b_1$. The difference is that we no longer restrict consideration of g to between zero and one. All of the previous results for selection response on Equation 22.28a hold for any value of g , but we focused on the range of zero to one given the transition from individual to group selection. More generally, we could have negative weights, or a g value exceeding one. In the former case, negative g values correspond to a weighted within-group deviation (e.g., Equation 22.28c). In the latter case ($g > 1$), we place more weight on a random individual from the interacting

group than on the focal individual. This might occur when associative effects are much larger than direct effects, and hence group members provide more information than the focal individual about the value of A_T for that focal individual.

In Chapter 21, we were able to obtain straightforward expressions for optimal weights in a family index (Equation 21.54). Index selection theory (Volume 3) gives the optimal index weights in the form of a matrix expression (Equation 22.35a), which is greatly simplified under simple family selection (i.e., with no associative effects). Unfortunately, such is not the case here, and so we (very briefly) introduce the machinery for obtaining an optimal index, deferring the full development of the theory to Volume 3. The idea is that there are two potentially different indices: the index I , used for selection (i.e., to choose individuals to form the next generation), and the index H , whose response we wish to maximize. Specifically, we select on some index $I = \mathbf{b}^T \mathbf{x}$ where x_i is the value of trait i used to make selection decisions and b_i is the weight placed on that trait in the index. In keeping with Equation 22.33a, the vector of phenotypes for individual i is

$$\mathbf{x} = \begin{pmatrix} z_i \\ \sum_{j \neq i} z_j \end{pmatrix} \quad (22.34a)$$

Using this index to make selection decisions, we wish to find the weights, \mathbf{b} , that maximize the selection response for some weighted combination of variables, $H = \mathbf{c}^T \mathbf{a}$. Here the elements of \mathbf{c} are the weights and \mathbf{a} is the vector of breeding values for the traits of interest. In our case, we wish to maximize response in the total breeding value, which means that

$$H = A_T = A_d + (n - 1)A_s = \mathbf{c}^T \mathbf{a} \quad (22.34b)$$

where

$$\mathbf{a} = \begin{pmatrix} A_d \\ A_s \end{pmatrix} \quad \text{and} \quad \mathbf{c} = \begin{pmatrix} 1 \\ n - 1 \end{pmatrix} \quad (22.34c)$$

The optimal weights \mathbf{b}_s in I for maximizing response in H (i.e., to obtain the highest correlation between A_T and I) are given by the **Smith-Hazel index** (Smith 1936; Hazel 1943), which is derived in Example A6.8, where

$$\mathbf{b}_s = \mathbf{P}^{-1} \mathbf{G}^T \mathbf{c} \quad (22.35a)$$

\mathbf{P} is the phenotypic covariance matrix for the elements in \mathbf{x} , which in our case becomes

$$\mathbf{P} = \begin{pmatrix} \sigma^2(z) & \sigma(z_i, \sum_{j \neq i} z_j) \\ \sigma(z_i, \sum_{j \neq i} z_j) & \sigma(\sum_{j \neq i} z_j, \sum_{j \neq i} z_j) \end{pmatrix} \quad (22.36a)$$

$$= \begin{pmatrix} \sigma^2(z) & (n - 1)\sigma(z_i, z_j) \\ (n - 1)\sigma(z_i, z_j) & (n - 1)[\sigma_z^2 + (n - 2)\sigma(z_i, z_j)] \end{pmatrix} \quad (22.36b)$$

where we have used Equations 22.30b and 22.30c. \mathbf{G} is the matrix of covariances between the breeding values in the index H and the trait values in the index I , with $G_{ij} = \sigma(a_i, x_j)$. Because different traits can be involved in the two indices, \mathbf{G} need not be symmetric. For our case,

$$\mathbf{G}^T = \begin{pmatrix} \sigma(A_{d_i}, z_i) & \sigma(A_{s_i}, z_i) \\ \sigma(A_{d_i}, \sum_{j \neq i} z_j) & \sigma(A_{s_i}, \sum_{j \neq i} z_j) \end{pmatrix} \quad (22.37a)$$

where

$$\sigma(A_{d_i}, z_i) = \sigma^2(A_d) + r(n-1)\sigma(A_d, A_s) \quad (22.37b)$$

$$\sigma(A_{s_i}, z_i) = \sigma(A_d, A_s) + r(n-1)\sigma^2(A_s) \quad (22.37c)$$

$$\sigma\left(A_{d_i}, \sum_{j \neq i} z_j\right) = (n-1)\sigma(A_d, A_s) + r(n-1)[\sigma^2(A_d) + (n-2)\sigma(A_d, A_s)] \quad (22.37d)$$

$$\sigma\left(A_{s_i}, \sum_{j \neq i} z_j\right) = (n-1)\sigma^2(A_s) + r(n-1)[\sigma(A_d, A_s) + (n-2)\sigma^2(A_s)] \quad (22.37e)$$

Equations 22.37b through 22.37e follow from the approach used throughout this chapter of a term-by-term evaluation of the covariance. The use of index selection machinery to find the optimal value of g was initially outlined by Ellen et al. (2007).

Example 22.9. As an application of the previous theory, consider a trait where $\sigma(A_d, A_s) = 0$, and there are no correlations between environmental values within the group ($\rho = 0$) and no relatives in the group ($r = 0$). Equation 22.5d gives $\sigma^2(z) = \sigma^2(A_d) + (n-1)\sigma^2(A_s) + \sigma^2(e)$, while (with $\sigma(A_d, A_s) = r = \rho = 0$), Equation 22.31c reduces to $\sigma(z_i, z_j) = (n-2)\sigma^2(A_s)$. Hence, from Equation 22.36b,

$$\mathbf{P} = \begin{pmatrix} \sigma^2(z) & (n-1)(n-2)\sigma^2(A_s) \\ (n-1)(n-2)\sigma^2(A_s) & (n-1)[\sigma^2(z) + (n-2)^2\sigma^2(A_s)] \end{pmatrix}$$

Likewise, Equations 22.37b through 22.37e imply

$$\mathbf{G} = \begin{pmatrix} \sigma^2(A_d) & 0 \\ 0 & (n-1)\sigma^2(A_s) \end{pmatrix}$$

What are the optimal weight (g) for a trait with $\sigma^2(A_d) = 100$, $\sigma^2(A_s) = 9$, $\sigma^2(e) = 100$, and $n = 10$? For these values, Equation 22.35a yields

$$\mathbf{b}_s = \mathbf{P}^{-1}\mathbf{G}^T\mathbf{c} = \begin{pmatrix} 281 & 648 \\ 648 & 9090 \end{pmatrix}^{-1} \begin{pmatrix} 100 & 0 \\ 0 & 81 \end{pmatrix} \begin{pmatrix} 1 \\ 9 \end{pmatrix} = \begin{pmatrix} 0.2046 \\ 0.0656 \end{pmatrix}$$

The resulting index weight on group information is $0.0656/0.2046 = 0.32$, giving the index as

$$I_i = z_i + 0.32 \cdot \sum_{j \neq i} z_j$$

If we increase $\sigma^2(A_s)$ to 15, redoing the above calculations for the elements of \mathbf{P} and \mathbf{G} gives the optimal weights as

$$\mathbf{b}_s = \mathbf{P}^{-1}\mathbf{G}^T\mathbf{c} = \begin{pmatrix} 335 & 1080 \\ 1080 & 13,950 \end{pmatrix}^{-1} \begin{pmatrix} 100 & 0 \\ 0 & 136 \end{pmatrix} \begin{pmatrix} 1 \\ 9 \end{pmatrix} = \begin{pmatrix} 0.0236 \\ 0.0852 \end{pmatrix}$$

yielding a weight on the group sum of $0.0852/0.0236 = 3.6$, and an optimal index of

$$I_i = z_i + 3.6 \cdot \sum_{j \neq i} z_j$$

Hence, on average, the phenotypes of individuals with which a focal individual interacts are given almost four times the weight as the focal individual's own phenotype. Finally, suppose $\sigma^2(A_s) = 20$. In this case

$$\mathbf{b}_s = \mathbf{P}^{-1}\mathbf{G}^T\mathbf{c} = \begin{pmatrix} 380 & 1440 \\ 1440 & 18,000 \end{pmatrix}^{-1} \begin{pmatrix} 100 & 0 \\ 0 & 180 \end{pmatrix} \begin{pmatrix} 1 \\ 9 \end{pmatrix} = \begin{pmatrix} -0.1120 \\ 0.0989 \end{pmatrix}$$

making the optimal index

$$I_i = 0.0989 \cdot \left(\sum_{j \neq i} z_j \right) - 0.112 \cdot z_i$$

Expressing the summation as $n\bar{z} - z_i$, this is equivalent to selection on the index

$$I_i = 0.989\bar{z} - (0.0989 + 0.112)z_i = 0.989\bar{z} - 0.2109z_i$$

We can also rewrite this index as

$$I_i = (0.989 - 0.2109)\bar{z} - 0.2109(z_i - \bar{z}) = 0.7781\bar{z} - 0.2109(z_i - \bar{z})$$

which is equivalent to selecting using the index

$$I_i = \bar{z} - \frac{0.2109}{0.7781}(z_i - \bar{z}) = \bar{z} - 0.2710(z_i - \bar{z})$$

Hence, the optimal index in this case is the group mean minus a weighted within-group deviation.

BLUP ESTIMATION OF DIRECT AND ASSOCIATIVE EFFECTS

While Griffing developed many of the basic equations for selection response with associative effects, one reason for the initially low impact of his important work was that, at the time, there was no reliable way to estimate the key variance components, $\sigma^2(A_d)$, $\sigma^2(A_s)$, and $\sigma(A_d, A_s)$. These are required to compare h_d^2 with T^2 , and hence to judge the potential amount of additional genetic variation that cannot be exploited under individual selection. Further, reasonable estimates of these variance components are required to obtain the optimal index weights. Finally, without some tangible values, Griffing's work was, for some, a bit too abstract: the observed phenotype was decomposed as the sum of two unmeasured components, whose estimation was entirely unclear. The solution to these problems was suggested by Muir and Schinckel (2002) and detailed in the seminal paper of Muir (2005), who put these estimation problems into a standard BLUP/REML mixed-model framework (Chapters 19 and 20; LW Chapters 26 and 27).

Mixed-Model Estimation of Direct and Associative Effects

The general approach follows if we consider a standard animal model with additional random effects (Equations 19.20 and 19.21). Equation 22.1b shows how the phenotype of individual i is the sum of its direct breeding value, the social breeding values of its group members, and the environmental effects,

$$z_i = \mu + (A_{d_i} + E_{d_i}) + \sum_{j \neq i} (A_{s_j} + E_{s_j}) \quad (22.38a)$$

To start, we assume a very simple residual structure

$$z_i = \mu + A_{d_i} + \sum_{j \neq i} A_{s_j} + e_i \quad (22.38b)$$

where the e_i are uncorrelated and homoscedastic, so that $\mathbf{e} \sim (\mathbf{0}, \sigma^2(e) \mathbf{I})$. Letting \mathbf{a}_d denote the vector of **direct breeding values (DBVs)**, and \mathbf{a}_s be the vector of **social breeding values (SBVs)**, the resulting mixed model becomes

$$\mathbf{z} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}_d \mathbf{a}_d + \mathbf{Z}_s \mathbf{a}_s + \mathbf{e}, \quad \text{with } \mathbf{e} \sim (\mathbf{0}, \sigma^2(e) \mathbf{I}) \quad (22.38c)$$

Here β is the vector of fixed effects (which will be just the mean for our simple example) and \mathbf{X} is the design matrix associated with these fixed effects. Likewise, \mathbf{Z}_d and \mathbf{Z}_s are the corresponding incidence matrices for the direct and social effects, which follow logically upon considering the group members (Examples 22.10 and 22.11).

To complete the model, we need to specify the covariance structures of the three vectors of random effects. Our initial assumption on the residual errors implies that the covariance matrix for the residuals is $\sigma^2(e) \mathbf{I}$. The covariance structure for the two vectors of random effects is a function of the relationship matrix \mathbf{A} (Chapter 19) of the individuals in the study, which has block-matrix form

$$\text{Var} \begin{pmatrix} \mathbf{a}_d \\ \mathbf{a}_s \end{pmatrix} = \begin{pmatrix} \sigma^2(A_d)\mathbf{A} & \sigma(A_d, A_s)\mathbf{A} \\ \sigma(A_d, A_s)\mathbf{A} & \sigma^2(A_s)\mathbf{A} \end{pmatrix} \quad (22.39a)$$

This is often written more compactly using the **Kronecker** or **direct product** notation as $\mathbf{G} \otimes \mathbf{A}$, where

$$\mathbf{G} = \begin{pmatrix} \sigma^2(A_d) & \sigma(A_d, A_s) \\ \sigma(A_d, A_s) & \sigma^2(A_s) \end{pmatrix} \quad (22.39b)$$

Because the residuals are assumed to be uncorrelated with the other random effects, the full covariance structure for this model is

$$\text{Var} \begin{pmatrix} \mathbf{a}_d \\ \mathbf{a}_s \\ \mathbf{e} \end{pmatrix} = \begin{pmatrix} \sigma^2(A_d)\mathbf{A} & \sigma(A_d, A_s)\mathbf{A} & \mathbf{0} \\ \sigma(A_d, A_s)\mathbf{A} & \sigma^2(A_s)\mathbf{A} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \sigma^2(e)\mathbf{I} \end{pmatrix} \quad (22.39c)$$

Example 22.10. To introduce how a mixed-model with direct and social effects is constructed, consider the following toy example where eight individuals are measured. Individuals 1 through 4 are (noninbred) half-sibs, as are 5 through 8, but they are unrelated to the first family. The relationship matrix \mathbf{A} becomes

$$\mathbf{A} = \begin{pmatrix} 1 & 0.25 & 0.25 & 0.25 & 0 & 0 & 0 & 0 \\ 0.25 & 1 & 0.25 & 0.25 & 0 & 0 & 0 & 0 \\ 0.25 & 0.25 & 1 & 0.25 & 0 & 0 & 0 & 0 \\ 0.25 & 0.25 & 0.25 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0.25 & 0.25 & 0.25 \\ 0 & 0 & 0 & 0 & 0.25 & 1 & 0.25 & 0.25 \\ 0 & 0 & 0 & 0 & 0.25 & 0.25 & 1 & 0.25 \\ 0 & 0 & 0 & 0 & 0.25 & 0.25 & 0.25 & 1 \end{pmatrix}$$

These eight individuals are placed into two groups of size four. Group 1 contains individuals 1, 2, 5, and 6; while group 2 contains 3, 4, 7, and 8. For simplicity, the only assumed fixed effect is the mean, μ . The resulting matrices for the mixed-model equations become

$$\mathbf{z} = \begin{pmatrix} z_1 \\ z_2 \\ z_3 \\ z_4 \\ z_5 \\ z_6 \\ z_7 \\ z_8 \end{pmatrix} \quad \mathbf{X} = \begin{pmatrix} 1 \\ 1 \\ 1 \\ 1 \\ 1 \\ 1 \\ 1 \\ 1 \end{pmatrix} \quad \mathbf{a}_d = \begin{pmatrix} A_{d,1} \\ A_{d,2} \\ A_{d,3} \\ A_{d,4} \\ A_{d,5} \\ A_{d,6} \\ A_{d,7} \\ A_{d,8} \end{pmatrix} \quad \mathbf{Z}_d = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix} = \mathbf{I}_8$$

where $\beta = (\mu)$.

Turning now to the incidence matrix for social effects, \mathbf{Z}_s , note that its i th row has a 1 for each member in i 's group, and a 0 otherwise. For example, individual 1 is influenced by the

social breeding values of individuals 2, 5, and 6, which are assigned values of one in the first row of \mathbf{Z}_s , while all other elements in row one are zero. Likewise, individual 3 is influenced by the social breeding values of its group (individuals 4, 7 and 8), and so forth. Filling in the rest of the matrix yields

$$\mathbf{Z}_s = \begin{pmatrix} 0 & 1 & 0 & 0 & 1 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 & 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 1 & 1 \\ 0 & 0 & 1 & 0 & 0 & 0 & 1 & 1 \\ 1 & 1 & 0 & 0 & 0 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 1 & 0 & 0 & 1 & 0 \end{pmatrix} \quad \mathbf{a}_s = \begin{pmatrix} A_{s,1} \\ A_{s,2} \\ A_{s,3} \\ A_{s,4} \\ A_{s,5} \\ A_{s,6} \\ A_{s,7} \\ A_{s,8} \end{pmatrix}$$

The group effects are made more apparent (but \mathbf{A} is made more confusing) by reordering the individuals as $\mathbf{z}^T = (z_1, z_2, z_5, z_6, z_3, z_4, z_7, z_8)$, so that group members are clustered together. This gives

$$\mathbf{Z}_s = \begin{pmatrix} 0 & 1 & 1 & 1 & 0 & 0 & 0 & 0 \\ 1 & 0 & 1 & 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 & 0 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 0 \end{pmatrix}, \quad \mathbf{A} = 0.25 \cdot \begin{pmatrix} 4 & 1 & 0 & 0 & 1 & 1 & 0 & 0 \\ 1 & 4 & 0 & 0 & 1 & 1 & 0 & 0 \\ 0 & 0 & 4 & 1 & 0 & 0 & 1 & 1 \\ 0 & 0 & 1 & 4 & 0 & 0 & 1 & 1 \\ 1 & 1 & 0 & 0 & 4 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 & 1 & 4 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 & 0 & 4 & 1 \\ 0 & 0 & 1 & 1 & 0 & 0 & 1 & 4 \end{pmatrix}$$

Groups of different sizes are easily incorporated through the use of \mathbf{Z}_s .

Example 22.11. Assigning an element in \mathbf{Z}_s a value of one for each individual within a group weights all interactions equally. This need not be the case, however. For example, Muir (2005) noted that with plants (or other sessile organisms), the distance between two individuals likely influences their effects. In particular, he suggested that if trees are a distance d apart, a reasonable model for their associative interactions would be A_s/d^2 , where a tree has some intrinsic social breeding value (A_s) whose effect is diminished by distance. In a case of three trees, where d_{ij} is the distance between trees i and j , the resulting incidence matrix for social breeding values would be

$$\mathbf{Z}_s = \begin{pmatrix} 0 & 1/d_{12}^2 & 1/d_{13}^2 \\ 1/d_{21}^2 & 0 & 1/d_{23}^2 \\ 1/d_{31}^2 & 1/d_{32}^2 & 0 \end{pmatrix}$$

Cantet and Cappa (2008) suggested similar “intensity of competition” weights for individuals within groups of animals, such as the total contact time between two individuals. Other measures of interactions could be used and easily incorporated into \mathbf{Z}_s (e.g., Wey et al. 2007).

Because we allow for the possibility that the direct and social breeding values are correlated, the standard mixed-model equations for two vectors of random effects (Equation 19.21; LW Equations 26.19b and 26.30) must be slightly modified. They become

$$\begin{pmatrix} \mathbf{X}^T \mathbf{X} & \mathbf{X}^T \mathbf{Z}_d & \mathbf{X}^T \mathbf{Z}_s \\ \mathbf{Z}_d \mathbf{X}^T & \mathbf{Z}_d^T \mathbf{Z}_d + \lambda_1 \mathbf{A}^{-1} & \mathbf{Z}_d^T \mathbf{Z}_s + \lambda_2 \mathbf{A}^{-1} \\ \mathbf{Z}_s \mathbf{X}^T & \mathbf{Z}_s^T \mathbf{Z}_d + \lambda_2 \mathbf{A}^{-1} & \mathbf{Z}_s^T \mathbf{Z}_s + \lambda_3 \mathbf{A}^{-1} \end{pmatrix} \begin{pmatrix} \boldsymbol{\beta} \\ \mathbf{a}_d \\ \mathbf{a}_s \end{pmatrix} = \begin{pmatrix} \mathbf{X}^T \mathbf{X} \\ \mathbf{X}^T \mathbf{Z}_d \\ \mathbf{X}^T \mathbf{Z}_s \end{pmatrix} \quad (22.40a)$$

where the weights (λ_i) are related to elements in the inverse of \mathbf{G} , namely,

$$\begin{pmatrix} \lambda_1 & \lambda_2 \\ \lambda_2 & \lambda_3 \end{pmatrix} = \sigma^2(e) \mathbf{G}^{-1} = \sigma^2(e) \begin{pmatrix} \sigma^2(A_d) & \sigma(A_d, A_s) \\ \sigma(A_d, A_s) & \sigma^2(A_s) \end{pmatrix}^{-1} \quad (22.40b)$$

as obtained by Muir (2005) and Van Vleck and Cassady (2005).

In order to solve these equations, estimates of the variance components— $\sigma^2(e)$, $\sigma^2(A_d)$, $\sigma^2(A_s)$, and $\sigma(A_d, A_s)$ —are required, and within the mixed-model framework, these are obtained by REML (LW Chapter 27). Van Vleck and Cassady (2005) used simulated data to show that, under the appropriate design, REML does indeed provide separable estimates of the genetic variance components. However, two early applications to real data sets, weight gain in pigs within pens by Arango et al. (2005) and weight gain in Hereford cattle in feedlots by Van Vleck et al. (2007), found that the likelihood surface for $\sigma^2(A_s)$ was very flat, making model fitting challenging. We will examine such issues of identifiability shortly. While mixed-model methodology is very robust (for example, it easily handles missing data and variable group numbers), it can easily fail if the model is not correctly specified or the experimental design is such that random effects are not separable, points that we will address shortly.

Example 22.12. Using mixed-model methods, Bergsma et al. (2008) examined four traits (growth rate, feed intake, back-fat thickness, and muscle depth) in a sample of over 14,000 pigs with a known pedigree (from roughly 400 sires and 600 dams). The pigs were placed in pens of 6–12 animals and several different mixed models were fitted.

First, a mixed model allowing for only direct effects plus a separate vector for common litter effects, \mathbf{c} (which is fairly standard; Chapters 19 and 20), was fit. Here, the model was

$$\mathbf{z} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}_a\mathbf{a} + \mathbf{Z}_c\mathbf{c} + \mathbf{e}$$

where

$$\mathbf{a} \sim N(\mathbf{0}, \sigma^2(A) \cdot \mathbf{A}), \quad \mathbf{c} \sim N(\mathbf{0}, \sigma^2(c) \cdot \mathbf{I}), \quad \mathbf{e} \sim N(\mathbf{0}, \sigma^2(e) \cdot \mathbf{I})$$

The resulting estimates of additive variation and heritability for these traits were found to be

	Growth	Back fat	Muscle	Intake
$\sigma^2(A)$	2,583	2.83	7.94	41,275
h^2	0.37	0.36	0.25	0.41

Next, a model was fit that also included a random pen (group) effect, g_p , common to all members within the same group (but differing across groups). The model now becomes

$$\mathbf{z} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}_a\mathbf{a} + \mathbf{Z}_g\mathbf{g}_p + \mathbf{Z}_c\mathbf{c} + \mathbf{e}, \quad \text{where } \mathbf{g}_p \sim N(\mathbf{0}, \sigma^2(g_p) \cdot \mathbf{I})$$

Use of this model did not change the heritability estimates for back fat and muscle depth, but decreased the estimates for growth and feed intake

	Growth	Back fat	Muscle	Intake
$\sigma^2(A)$	1,780	2.79	7.69	17,678
h^2	0.25	0.36	0.24	0.18

Comparison with the previous table shows that failure to include a group effect (here, assumed to be entirely nonheritable, i.e., all environmental), resulted in some traits (growth and intake) having their heritabilities overestimated. Finally, a model was fit allowing for heritable social effects

$$\mathbf{z} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}_d\mathbf{a}_d + \mathbf{Z}_s\mathbf{a}_s + \mathbf{Z}_g\mathbf{g}_p + \mathbf{Z}_c\mathbf{c} + \mathbf{e}$$

which returned estimates of

	Growth	Back fat	Muscle	Intake
$\sigma^2(A_d)$	1,522	2.75	6.68	16,950
h_d^2	0.21	0.35	0.21	0.17
$\sigma^2(A_s)$	51	0.01	0.03	596
$\sigma^2(A_T)$	5,208	3.19	10.35	68,687
T^2	0.71	0.41	0.32	0.70

While both body-composition traits (back fat and muscle thickness) were largely unaffected by social effects, growth-related traits (growth and intake) were. Failure to incorporate group effects (either shared environmental, g_p , or genetic, A_s) resulted in an overestimation of the (direct) heritability for growth traits. The exploitable genetic variance (the total breeding value) for the two growth traits was about three times higher than suggested by the individual (direct) breeding values, and T^2 was about triple the value of h_d^2 . Hence, significant potential for improvement would remain untapped when using individual selection with groups of unrelated individuals for growth traits. Conversely, the incorporation of some group-selection would have little additional effect on the response of the two body-composition traits, as their h_d^2 and T^2 values are very close.

The results in the above example are fairly typical of the published results from the animal-breeding literature. Often the estimates of $\sigma(A_d, A_s)$ and $\sigma^2(A_s)$ are quite small relative to $\sigma^2(A_d)$, but because terms involving social effects are scaled by roughly n or n^2 (for the covariance and variance, respectively), their contributions can be considerable. For example, a series of eight (mostly growth) traits in cattle, pigs, and chicken, $(n-1)\sigma(A_d, A_s)$ was between 5 and 40% of $\sigma^2(A_d)$, with an average value of 24% (Van Vleck et al. 2007; Chen et al. 2008, 2009; Hsu et al. 2010).

As discussed in Chapter 19, one could use a Bayesian analysis of a mixed model instead of BLUP estimates of the random effects and REML estimates of the variance. Recall that a BLUP/REML analysis returns point estimates and associated confidence intervals for variables of interest, while a Bayesian analysis returns the whole posterior distribution of potential values given the data (Chapter 19; Appendices 2 and 3). Arora and Lahiri (1997) showed for mixed models that “empirical BLUP,” namely using REML estimates of variance components to solve the mixed-model equations, generally gives the same average value as a Bayesian analysis, but that the latter returns a smaller mean-squared error and hence offers more precision. Cappa and Cantet (2006, 2008) developed a Gibbs sampler (Appendix 3) for the mixed model with associative effects.

One of the strengths of mixed models is their flexibility. The basic model shown by Equation 22.38c, which allows for direct and associative effects, can easily be extended. For example, Bouwmann et al. (2010) included a separate maternal genetic effect, distinct from social effects, while Alemu et al. (2014) modified associative effects to allow kin and nonkin interactions to differ.

Muir’s Experiment: BLUP Selection for Quail Weight

In his classic paper, Muir (2005) not only laid out the approach for incorporating social effects into a mixed-model framework, but also directly tested this method by examining the response to selection based entirely on the estimated breeding values (EBVs) obtained from the model. Muir selected on six-week weight in Japanese quail (*Coturnix coturnix japonica*), which are aggressive and cannibalistic. Groups were formed with 16 birds per cage, with each group consisting of several half-sib families. Banding of the birds allowed the pedigree of individuals to be followed through the 23 hatches of the experiment. As Example 22.4 showed, due to a negative covariance between associative and direct effects, individual selection is expected to produce a reversed response when using a group of unrelated individuals.

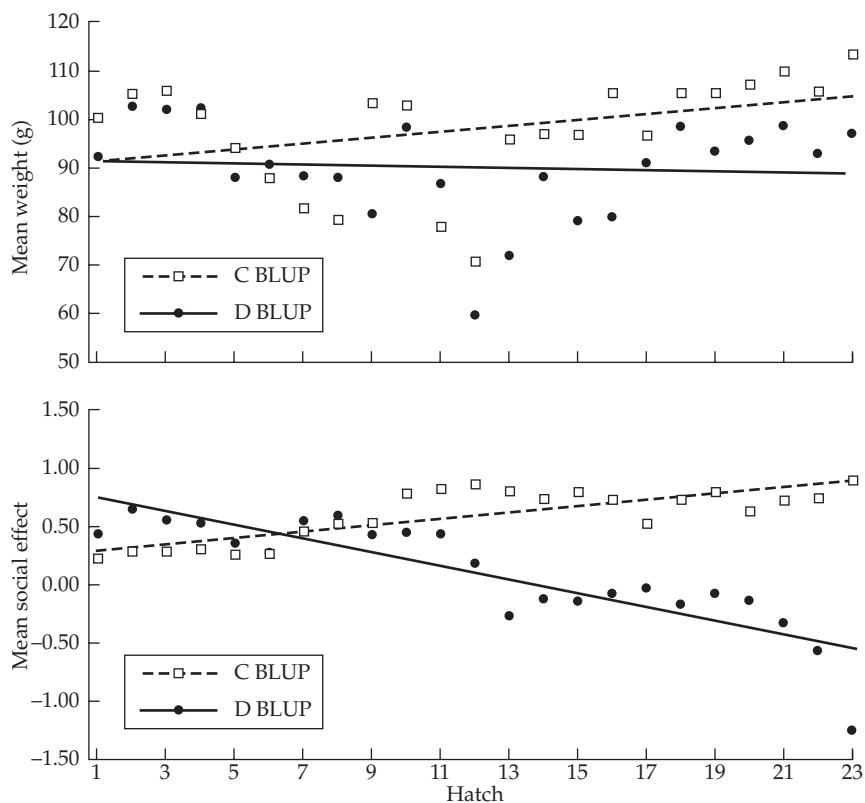

Figure 22.4 Selection response for two differentially selected lines of Japanese quail (Muir 2005). Both lines were selected for six-week weight using BLUP. Line D-BLUP selected individuals with the largest estimated direct breeding values, while line C-BLUP selected individuals with the largest estimated total breeding values. **A:** (Top) Mean response in six-week weight over 23 cycles of selection. The C-BLUP line showed a significant improvement, while the D-BLUP line showed a slight (but not significant) negative trend. **B:** (Bottom) The trend in mean social values showed an increase in the C-BLUP lines, and a decrease in D-BLUP lines. Hence, competition increased in lines strictly selected for direct breeding value, while it decreased in lines selected on an index of direct and associative effects.

Rather than select using individual phenotype or group means, Muir used BLUP selection (Chapters 13 and 19), wherein a mixed model is used to estimate the breeding values, and those individuals with the largest EBVs are chosen. Starting with the same base population, two lines were selected using different BLUP criteria. For both lines, the mixed model allowing for both direct and social effects was fitted, using REML estimates of the variances to obtain BLUPs for the desired breeding values. In the D-BLUP line, individuals with the largest EBVs of A_d (direct effects) were selected. In the C-BLUP line, those individuals with the largest EBVs of A_T , namely $\text{EBV}(A_d) + (16 - 1)\text{EBV}(A_s)$, were selected. Figure 22.4A shows the results through 23 hatches (cycles of selection). Under BLUP-D selection, the mean six-week weight decreased (slightly, but not significantly), while it significantly increased under C-BLUP. Both D-BLUP and C-BLUP increased the mean of direct effects, although the response under D-BLUP was about twice as great.

As further shown in Figure 22.4B, the reason for the decrease in mean weight in the D-BLUP line was that the mean associative effect increased under C-BLUP (i.e., became more favorable toward others in the group), but as expected given the negative correlation between A_d and A_s it decreased under D-BLUP (became less favorable). Two other improvements were observed in the C-BLUP line. Mortality increased significantly in the D-BLUP line, while it decreased slightly (but not significantly) in the C-BLUP line. Feed

conversion was also better in the C-BLUP line, requiring 6.65 grams of feed per gram of gain, versus 7.26 in the D-BLUP line. Clearly, selection based on the mixed-model estimates of total breeding value resulted in significantly better results than lines selected by a more conventional (i.e., D-BLUP) approach.

Details: Environmental Group Effects and the Covariance Structure of \mathbf{e}

Our simplifying assumption (Equation 22.28c), that the residuals, e_i , are homoscedastic and uncorrelated (meaning that $\sigma(\mathbf{e}) = \sigma^2(e) \mathbf{I}$), is generally incorrect. As Equation 22.23a shows, individuals within the same group are correlated because they share the E_s values from the other group members, and not correctly accounting for these shared environmental values results in an overestimation of the variance of the social breeding values (Van Vleck and Cassady 2005; Bijma et al. 2007b; Bergsma et al. 2008; Chen et al. 2009). Equation 22.23a returns the correct covariance matrix for the residuals as

$$\sigma(\mathbf{e}) = \sigma^2(e) \mathbf{R}, \quad \text{where } R_{ij} = \begin{cases} 0 & i \text{ and } j \text{ in different groups} \\ \rho & i \text{ and } j \text{ in the same group} \\ 1 & i = j \end{cases} \quad (22.41)$$

where $\sigma^2(e)$ and ρ are given by Equation 22.23b.

Example 22.13. For the design used in Example 22.10 with group members clustered, so that $\mathbf{z} = (z_1, z_2, z_5, z_6, z_3, z_4, z_7, z_8)^T$, the corresponding covariance matrix for the residuals becomes

$$\sigma(\mathbf{e}) = \sigma^2(e) \mathbf{R} = \sigma^2(e) \cdot \begin{pmatrix} 1 & \rho & \rho & \rho & 0 & 0 & 0 & 0 \\ \rho & 1 & \rho & \rho & 0 & 0 & 0 & 0 \\ \rho & \rho & 1 & \rho & 0 & 0 & 0 & 0 \\ \rho & \rho & \rho & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & \rho & \rho & \rho \\ 0 & 0 & 0 & 0 & \rho & 1 & \rho & \rho \\ 0 & 0 & 0 & 0 & \rho & \rho & 1 & \rho \\ 0 & 0 & 0 & 0 & \rho & \rho & \rho & 1 \end{pmatrix}$$

With the same number of individuals in all groups, the only two estimable parameters in the environmental covariance matrix are ρ and $\sigma^2(e)$. With groups of variable size (either by design or simply through the loss of data), the residual variances and covariances change with n (Equation 22.23b). In this case, the residual covariance matrix would be specified in terms of the three environmental variance/covariance terms, $\sigma^2(E_d)$, $\sigma^2(E_s)$, and $\sigma(E_d, E_s)$.

Provided $\rho > 0$, an equivalent approach is simply to fit a random group effect (Bergsma et al. 2008; Ellen et al. 2008). Example 22.14 works through an example. This approach is computationally less demanding than jointly estimating $\sigma^2(e)$ and ρ in an \mathbf{R} matrix. However, if the covariance, $\sigma(E_d, E_s)$, between environmental direct and social effects is sufficiently negative, ρ can be negative (Equation 22.23b) and the simple random group-effects model fails, as the group variance $\sigma^2(g_p)$ must be positive. As Equation 22.23b suggests, as group size increases, the contribution from $\sigma^2(E_s)$ eventually dominates ρ , making it positive. Thus, for a design with large group size, fitting a random group effect will often suffice.

Example 22.14. Suppose that instead of fully specifying the matrix \mathbf{R} (Equation 22.41), we instead simply fit a random group effect. Here, all individuals in group i share the common

random effect g_i , where we assume $g_i \sim N[0, \sigma^2(g_p)]$. The resulting mixed model becomes

$$\mathbf{z} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}_d\mathbf{a}_d + \mathbf{Z}_s\mathbf{a}_s + \mathbf{Z}_g\mathbf{g}_p + \mathbf{e}$$

where, for k groups, $\mathbf{g}_p^T = (g_1, g_2, \dots, g_k)$ is the vector of random group effects. The incidence matrix \mathbf{Z}_g has k columns, the i th of which (corresponding to membership in group i) has a one for each individual in group i and a zero elsewhere. For example, for the design in Example 22.13,

$$\mathbf{g} = \begin{pmatrix} g_1 \\ g_2 \end{pmatrix} \quad \text{and} \quad \mathbf{Z}_g = \begin{pmatrix} 1 & 0 \\ 1 & 0 \\ 1 & 0 \\ 1 & 0 \\ 0 & 1 \\ 0 & 1 \\ 0 & 1 \\ 0 & 1 \end{pmatrix}$$

If we assume a simple covariance for the residuals, so that $\boldsymbol{\sigma}(\mathbf{e}) = \sigma^2(\epsilon) \mathbf{I}$, the resulting contribution to the covariance matrix of \mathbf{z} from the group and residual terms becomes $\sigma^2(g_p) \mathbf{Z}_g \mathbf{Z}_g^T + \sigma^2(\epsilon) \mathbf{I}$, or

$$\sigma^2(g_p) \begin{pmatrix} 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \end{pmatrix} + \sigma^2(\epsilon) \mathbf{I} = \sigma^2(e) \begin{pmatrix} 1 & \alpha^2 & \alpha^2 & \alpha^2 & 0 & 0 & 0 & 0 \\ \alpha^2 & 1 & \alpha^2 & \alpha^2 & 0 & 0 & 0 & 0 \\ \alpha^2 & \alpha^2 & 1 & \alpha^2 & 0 & 0 & 0 & 0 \\ \alpha^2 & \alpha^2 & \alpha^2 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & \alpha^2 & \alpha^2 & \alpha^2 \\ 0 & 0 & 0 & 0 & \alpha^2 & 1 & \alpha^2 & \alpha^2 \\ 0 & 0 & 0 & 0 & \alpha^2 & \alpha^2 & 1 & \alpha^2 \\ 0 & 0 & 0 & 0 & \alpha^2 & \alpha^2 & \alpha^2 & 1 \end{pmatrix}$$

where

$$\sigma^2(e) = \sigma^2(\epsilon) + \sigma^2(g_p) \quad \text{and} \quad \alpha^2 = \frac{\sigma^2(g_p)}{\sigma^2(\epsilon) + \sigma^2(g_p)}$$

We use α^2 to remind the reader that (under this model), this is the ratio of two variances, and hence is always nonnegative. Comparison with Example 22.13 shows that adding a random effect for group corresponds to the more fully specified covariance residual model (Equation 22.41), with $\rho = \alpha^2$. When $\rho > 0$, both models are identical. However, if the within-group environmental correlations are negative ($\rho < 0$), then the simple group random-effects model fails.

Further, note that we can write the covariance matrix of group plus residual effects under this model as

$$\sigma^2(e) \cdot \left(\mathbf{I} + \alpha^2 [\mathbf{Z}_g \mathbf{Z}_g^T - \mathbf{I}] \right)$$

showing that the matrix \mathbf{R} in Equation 22.41 (provided $\rho > 0$) is given by

$$\mathbf{R} = \mathbf{I} + \alpha^2 [\mathbf{Z}_g \mathbf{Z}_g^T - \mathbf{I}]$$

Finally, a standard approach when families are in the analysis is to include a common-family effect, c , that is due to shared maternal effects and dominance (if full sibs are present). This is simply done by adding an additional vector of random effects, \mathbf{c} , for the family effects. Using this approach, the model starting this example now becomes

$$\mathbf{z} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}_d\mathbf{a}_d + \mathbf{Z}_s\mathbf{a}_s + \mathbf{Z}_g\mathbf{g}_p + \mathbf{Z}_c\mathbf{c} + \mathbf{e}$$

For example, suppose individuals 1, 2, 5, and 6 (in the ordering used in this example) are from one family, while the others are from a second then

$$\mathbf{c} = \begin{pmatrix} c_1 \\ c_2 \end{pmatrix} \quad \text{and} \quad \mathbf{Z}_c = \begin{pmatrix} 1 & 0 \\ 1 & 0 \\ 0 & 1 \\ 0 & 1 \\ 1 & 0 \\ 1 & 0 \\ 0 & 1 \\ 0 & 1 \end{pmatrix}$$

Note that if $\mathbf{Z}_g = \mathbf{Z}_c$, the group and family effects are *fully confounded* and cannot be separated (this point will be discussed in more detail shortly). This addition of a common family effect is easily incorporated into any of the above models.

Details: Ignoring Additive Social Values Introduces Bias

Before models directly accounting for social effects were developed, it was not unusual to add a fixed or random group effect to the standard animal model to account for common environments due to individuals being raised in the same pen, cage, or group. For example, if group effects are random, the corresponding animal model becomes

$$\mathbf{z} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{a} + \mathbf{Z}_g\mathbf{g}_p + \mathbf{e} \quad (22.42)$$

where we (initially) assume $\sigma(\mathbf{g}_p) = \sigma^2(g_p)\mathbf{I}$. In this model, \mathbf{a} would be the estimated vector of (direct) breeding values. As detailed above, \mathbf{g}_p can often account for any shared environmental social values (i.e., E_s). However, if *heritable* associative effects are present, simply adding a group effect is *insufficient*, as it results in overestimation of $\sigma^2(g_p)$ and often an overestimation of the (direct) additive variance (Example 22.12). Hence, an analysis that simply includes a group effect (but no \mathbf{a}_s vector) results in biased estimates of the direct breeding values when heritable associative effects are present.

Van Vleck and Cassady (2005) showed how the presence of additive associative effects inflates the estimate of group variance. Consider two members in the same group (with a common group effect, g_p),

$$\begin{aligned} z_1 &= A_{d_1} + A_{s_2} + \sum_{k=3}^n A_{s_k} + g_p + e_1 \\ z_2 &= A_{d_2} + A_{s_1} + \sum_{k=3}^n A_{s_k} + g_p + e_2 \end{aligned}$$

Using the standard ANOVA identity that the covariance within a group equals the variance among groups (LW Chapter 18), for unrelated individuals, $\sigma^2(g_p)$, is estimated from the within-group covariance, which reduces to

$$\begin{aligned} \sigma(z_1, z_2) &= \sigma(A_{d_1}, A_{s_1}) + \sigma(A_{d_2}, A_{s_2}) + (n-2)\sigma^2(A_s) + \sigma^2(g_p) + \sigma(e_1, e_2) \\ &= 2\sigma(A_d, A_s) + (n-2)\sigma^2(A_s) + \sigma^2(g_p) + \sigma(e_1, e_2) \end{aligned} \quad (22.43)$$

If the residuals are uncorrelated, the bias in the within-group covariance-based estimate of $\sigma^2(g_p)$ is $2\sigma(A_d, A_s) + (n-2)\sigma^2(A_s)$, which can be considerable. Hence, when additive (i.e., heritable) associative effects are present, the simple model given by Equation 22.42 is inappropriate. This model, however, can be useful in a preliminary analysis. Van Vleck and Cassady suggested that obtaining a large estimated group variance when using Equation

22.42 indicates that a more detailed model including additive associative effects should be fit to the data. Hence, one approach is to do a quick fit to Equation 22.42. If the group variance is sufficiently small, it is unlikely that additive associative effects are present. However, this approach is not always foolproof. Inspection of Equation 22.43 shows that a sufficiently negative covariance between direct and social breeding values may result in a small estimated group variance.

Details: Identifiability of Variance Components

Due to potential confounding of effects, any particular design might not allow for all variables of interest to be uniquely estimated. For the vector β of fixed effects, the uniqueness of an estimated variable is indicated the concept of **estimability** (LW Chapter 26). For $\mathbf{z} \sim (\mathbf{X}\beta, \mathbf{V})$, the vector of fixed effects is estimable (β has a unique value) if $(\mathbf{X}^T \mathbf{V}^{-1} \mathbf{X})^{-1}$ exists. Otherwise, some of the fixed effects are confounded and cannot be separated by the design (\mathbf{X}) being used. A similar concept, **identifiability**, exists for random effects and is based on whether variance components (often called the **dispersal parameters**) can be uniquely estimated. If variance components are not identifiable in the design, then BLUPs for their associated vectors of random effects do not exist, and the model will fail.

The lack of identifiability has been a problem in some attempts to estimate associative effects, with lack of convergence of REML estimates, convergence to multiple peaks in the likelihood surface (depending on starting conditions), and very flat likelihood surfaces all being seen (Arango et al. 2005; Van Vleck et al. 2007; Chen et al. 2008). Cantet and Cappa (2008) formally showed that using a *fixed* group effect results in a lack of identifiability when the design matrix, \mathbf{Z}_g , contains equal weights for all group members. Thus, treating group effects as fixed is not recommended, while treating them as random can often account for environmental correlations (as discussed above). Another common reason for lack of identifiability is the *composition of the group*. If all group members are from a single half-sib or full-sib family, the covariance of group members equals the covariance among family members within a group, confounding variance components and leading to a lack of identifiability (Cheng et al. 2009). Bijma et al. (2007b) noted that this problem plagued one of the early attempts to estimate social variance components (Wolf 2003). The important caveat is that lack of identifiability can easily arise in attempts to estimate social effects even when using seemingly innocent designs (such as a fixed group effect or having each group be a single family). One key is that family members must be spread over at least two groups, and each group should contain at least two different families. This avoids confounding within groups and allows A_s to be estimated by borrowing information (via relatives) across groups.

Conditions for identifiability of REML estimates of (co)variance components were given by Rothenberg (1971), Jiang (1996), and Cantet and Cappa (2008). Before presenting these conditions, we first review a few details about REML. Recall (LW Chapter 27) that REML estimates are those that maximize that part of the likelihood function independent of the fixed effects (this is often stated as being the **translation invariant** part of the likelihood). Let \mathbf{V} be the covariance matrix of \mathbf{z} , which is a function of its variance components. As detailed in LW Chapter 27, Harville (1977) showed that (if it exists) the transformation provided by the matrix

$$\mathbf{P} = \mathbf{V}^{-1} - \mathbf{V}^{-1} \mathbf{X} (\mathbf{X}^T \mathbf{V}^{-1} \mathbf{X})^{-1} \mathbf{X}^T \mathbf{V}^{-1} \quad (22.44a)$$

plays a critical role in REML estimates. (To be consistent with the literature, we use \mathbf{P} for this transformation matrix, despite our previous use of \mathbf{P} to indicate the phenotype variance-covariance matrix. The distinction between these two usages should be obvious given the context of the issue being discussed.)

That the matrix given by Equation 22.44a can remove fixed effects can be seen by recalling that (under GLS), $\hat{\beta} = (\mathbf{X}^T \mathbf{V}^{-1} \mathbf{X})^{-1} \mathbf{X}^T \mathbf{V}^{-1} \mathbf{z}$, and hence Equation 22.44a implies that

$$\mathbf{Pz} = \mathbf{V}^{-1} (\mathbf{z} - \mathbf{X}\hat{\beta}) \quad (22.44b)$$

where the vector \mathbf{Pz} is a function of the data \mathbf{z} adjusted by the estimated fixed effects, $\widehat{\mathbf{X}\beta}$ (i.e., centered to have a mean of zero). Now consider covariance structures of the form

$$\mathbf{V} = \sum_{i=1}^n \mathbf{V}_i \theta_i \quad (22.45a)$$

where \mathbf{V}_i is a matrix of known constants and the θ_i are unknown variances and covariances to be estimated. This is the structure for all of the \mathbf{V} matrices presented in this chapter. The equations to maximize the likelihood over the restricted space (the REML estimates) are given by LW Equations 27.18 and 27.19, and are solved iteratively. These equations involve the **trace** (the sum of the diagonal elements) of matrix products involving \mathbf{P} and the \mathbf{V}_i . Recall (LW Appendix 4) that for a vector Θ of n unknowns, the Fisher information matrix, \mathbf{F} (the matrix of second partial derivatives of the likelihood with respect to the parameters), can be used to provide large-sample standard errors. The resulting $n \times n$ information matrix for REML estimates of the unknown θ_i in Equation 22.45a has as its ij th element

$$F_{ij} = \text{trace}(\mathbf{PV}_i \mathbf{PV}_j) \quad (22.45b)$$

Much in the same fashion that the existence of $(\mathbf{X}^T \mathbf{V}^{-1} \mathbf{X})^{-1}$ informs us that all fixed effects are estimable in a given design, all variance components, θ_i , are identifiable if all of the eigenvalues of the matrix \mathbf{F} are positive, that is if \mathbf{F} is positive-definite (Rothenberg 1971; Jiang 1996). For the simplest associative-effects mixed model (Equation 22.38c), Equation 22.45a becomes

$$\mathbf{V} = \mathbf{V}_1 \sigma^2(A_d) + \mathbf{V}_2 \sigma(A_d, A_s) + \mathbf{V}_3 \sigma^2(A_s) + \mathbf{V}_4 \sigma^2(e) \quad (22.46a)$$

where

$$\mathbf{V}_1 = \mathbf{Z}_d \mathbf{A} \mathbf{Z}_d^T, \quad \mathbf{V}_2 = (\mathbf{Z}_d \mathbf{A} \mathbf{Z}_s^T + \mathbf{Z}_s \mathbf{A} \mathbf{Z}_d^T), \quad \mathbf{V}_3 = \mathbf{Z}_s \mathbf{A} \mathbf{Z}_s^T, \quad \mathbf{V}_4 = \mathbf{I} \quad (22.46b)$$

Substituting Equations 22.44a and 22.46b into Equation 22.45b fills out the \mathbf{F} matrix (which is only 4×4 in this case, given the four unknown variance components). For any particular design (the values of \mathbf{A} , \mathbf{Z}_d , and \mathbf{Z}_s), the eigenvalues of this matrix can be computed to determine if the variance components are all identifiable. Cheng et al. (2009) used this approach to show that two of the eigenvalues of their information matrix were zero for a design where groups consist entirely of single full-sib families, showing the lack of identifiability in such settings.

Appropriate Designs for Estimating Direct and Associative Effects

While most of the statistical power for detecting associative effects arises from the number of groups, not numbers of individuals (Bijma 2010c), the relationship structure within groups is also critical. In contrast to selection response, where there is a benefit from having all group members from the same family (and hence an increased r value), in a design to estimate direct and associative values and variance components, groups should be composed of at least two different families. If there is no within-group variation in relationships, direct and associative effects cannot be separated. Groups can also consist of unrelated individuals, but Bijma (2010c) showed that, in general, using groups with two (or more) different families offers more power than using unrelated individuals (also see Ødegård and Olesen 2011).

Using the appropriate mixed model is also critical. Initially, one might think that associative effects could be accommodated by simply adding a random effect for group to an otherwise standard animal model. As previously shown (Equation 22.43), however, this approach typically overestimates the direct effects, as well as inflating the group variance (which is a measure of the environmental social effects), when heritable associative effects are present, namely, $\sigma^2(A_s) > 0$. Conversely, ignoring any environmental associative effects also introduces bias. For example, a model fitting just a_d and a_s using the simple

error structure $\mathbf{e} \sim (0, \sigma^2(\mathbf{e}) \cdot \mathbf{I})$ also introduces bias by ignoring the correlation among environmental associative effects within a group. As mentioned above, the correct residual covariance structure can be accounted for by incorporating a random group effect into the model (which assumes a positive correlation between social environmental effects within a group), or by using a model with $\mathbf{e} \sim (0, \sigma^2(\mathbf{e}) \cdot \mathbf{R})$ where the elements of \mathbf{R} are given by 22.41, which allows for the within-group environmental correlations, ρ , to be negative.

Using Kin Groups: A Quick-and-dirty Way Around Associative Effects?

As the proceeding sections demonstrate, performing a Muir (2005)-style BLUP selection on total breeding value A_T (Figure 22.4) requires an appropriate design and care to ensure that groups contain a mixture of relatives and nonrelatives in order to provide separate estimates of A_d and A_s . Given this background, it may be counterintuitive that Muir et al. (2013) suggested that a quick-and-dirty way around dealing with associative effects is to ensure that groups are made up *entirely* of relatives. Their logic follows from Equation 22.12e, which shows that when the average relatedness within a group is r , selection based *entirely* on individual values still captures a fraction, r , of A_T . They suggested that in settings where individuals naturally interact in groups (such as caged birds), simply assigning relatives to groups provides a path for direct selection on A_T . As our above analysis suggests, such a setting may not allow for separate estimates of A_s and A_d (and hence a direct estimate of A_T), but it can provide a much simpler way to ensure at least some selection on A_T .

Their idea is that if relatives are assigned to the same groups, then standard BLUP selection based on individual phenotype and relatedness (Chapters 13 and 19) will capture part of A_T . While the accuracy will admittedly be lower than for a direct estimate from an appropriate design, it will still be far greater than when interacting groups are entirely comprised of nonrelatives (Equation 22.12e). To test this idea, Muir et al. (2013) essentially replicated Muir's classic (2005) experiment on weight gain in Japanese quail (Figure 22.4), but now using standard BLUP selection that completely ignores associative effects. They compared the response under two otherwise identical settings: one in which groups non-randomly consisted of half-sibs, and the second where groups were formed at random (and hence members were unrelated). The response using kin-groups was an order of magnitude greater than for the random groups. The beauty of this approach is that one simple action, ensuring interacting groups contain mostly relatives, allows individual selection to partially capture some of the variation in A_T without using all of the above extra machinery. However, one downside is that it may lead to increased inbreeding.

ASSOCIATIVE-EFFECTS, INCLUSIVE FITNESS, AND FISHER'S THEOREM

We conclude by examining some of the important implications for evolution when heritable associative effects ($\sigma^2(A_s) > 0$) are present. First and foremost, their presence has significant implications on the evolution of mean population fitness (Bijma 2010a), which forms the subject of this section.

Change in Mean Fitness When Associative Effects are Present

The most important trait in evolution is fitness, W (Chapters 6 and 29). Clearly, the fitness of any particular genotype is partly a function of the environment in which it finds itself. While we normally treat this environment as static, when conspecifics influence fitness (as is generally expected to be the case), part of this environment may also be evolving in response to selection (namely, conspecifics are constantly improving). In these settings, the use of models with associative effects is appropriate. Here, the individual fitness of a focal individual results from a direct fitness effect from its own genotype plus the associative effects on its fitness from the other genotypes with which it interacts. Competition, a detrimental fitness effect from other individuals, is one such associative effect, where the contribution from conspecifics is to lower fitness (e.g., Wilson et al. 2009, 2011). Conversely, with cooperation

or mutualism, associative effects increase the fitness of the focal individual.

Examining the expected change in mean fitness is straightforward. Using previous results, we simply take the trait being followed as individual fitness ($z = W$). From Equation 22.1c, the fitness of individual i becomes

$$W_i = \mu + A_{d_i} + \sum_{j \neq i} A_{s_j} + e_i \quad (22.47a)$$

A_d is the direct breeding value of fitness, while A_s is the social breeding value (how a focal individual influences the fitness of others in its group). As above, A_{s_i} does not contribute to W_i , while A_{s_j} for $j \neq i$ does. Likewise, the total breeding value for the fitness of an individual is simply

$$A_{T_i} = A_{d_i} + (n - 1)A_{s_i} \quad (22.47b)$$

with a variance of

$$\sigma^2(A_T) = \sigma^2(A_d) + 2(n - 1)\sigma(A_d, A_s) + (n - 1)^2\sigma^2(A_s) \quad (22.47c)$$

The first term, $\sigma^2(A_d)$, is the classical additive genetic variance in fitness in the absence of associative effects. When interactions are present, there is the potential for substantially more heritable variation in fitness. Indeed, the total genetic variance in fitness has the potential to exceed the actual variance in individual fitness, $\sigma^2(A_T) > \sigma^2_W$, as much of the variation is hidden in interactions with others, which do not appear in one's individual fitness.

When the trait is fitness itself, the response equation for individual selection (Equation 22.14) simplifies somewhat. Recall the Robertson-Price identity (Equation 6.10), $S = \sigma(z, w)$, where $w = W/\bar{W}$ is relative fitness. When $z = W$, the selection differential becomes

$$S_W = \sigma(W, w) = \frac{\sigma(W, W)}{\bar{W}} = \frac{\sigma^2(W)}{\bar{W}} \quad (22.48a)$$

Equation 22.14 expresses the response in terms of \bar{w}/σ . When the trait is fitness itself, Equation 22.48a shows that this simplifies to

$$\frac{\bar{w}}{\sigma(W)} = \frac{S_W / \sigma(W)}{\sigma(W)} = \frac{\sigma^2(W) / \bar{W}}{\sigma^2(W)} = \frac{1}{\bar{W}} \quad (22.48b)$$

Substituting Equation 22.48b into Equation 22.14 gives the response (the change in mean population fitness) as

$$R_W = \frac{\sigma(W, A_T)}{\sigma(W)} \bar{w} = \frac{1}{\bar{W}} \sigma(W, A_T) = \sigma(w, A_T) \quad (22.48c)$$

This is simply Price's equation (Equation 6.6), where we have restricted our discussion to cases where the transmission is such that mean breeding values of offspring equals the mean breeding values of their parents (and hence the correction term in Equation 6.6 for changes induced solely by transmission disappears). Such is expected to be the case for the infinitesimal model under random mating.

Applying Equation 22.12c gives the response in terms of the variance components as

$$R_W = \frac{1}{\bar{W}} [\sigma^2(A_d) + (n - 1)(1 + r)\sigma(A_d, A_s) + r(n - 1)^2\sigma^2(A_s)] \quad (22.48d)$$

As we saw for other traits, when $r = 0$, the possibility of a reversed response occurs if the breeding values for direct and social effects on fitness are sufficiently negatively correlated. Hence, under rather realistic conditions, individual selection can result in a *decrease* (and a potentially rather significant one) in mean fitness.

Ironically, even though a negative response can occur in the presence of associative effects, there is actually more total additive-genetic variance in fitness available when such effects are present, as $\sigma^2(A_T) > \sigma^2(A_d)$. However, only a fraction of this variance may be accessible to *individual* selection, and this fraction (being a covariance rather than a variance) can be negative (Equation 22.4b).

The key for exploiting the available variance is either selection among groups or the presence of relatives in one's group of interacting individuals. To see this last point, note from Equation 22.12e that we can express Equation 22.48d as

$$R_W = \frac{1}{\bar{W}} \left(r\sigma^2(A_T) + (1-r) [\sigma^2(A_d) + (n-1)\sigma(A_d, A_s)] \right) \quad (22.48e)$$

The term in square brackets represents the response in a group of nonrelatives. When interactions occur among kin ($r > 0$), then for sufficiently close relatives, the response becomes positive (mean fitness increases), even if the response is negative when $r = 0$. At the extreme, when $r = 1$ (all interactions are among clonemates), the response in mean fitness is simply $\sigma^2(A_T)/\bar{W}$ and all of the heritable variance in fitness is utilized. Conversely, when interactions occur among unrelated individuals, only a fraction of this additive-genetic potential for fitness, $\sigma^2(A_T)$, is exploited. This observation led Bijma (2010a) to suggest that when heritable fitness interactions are present, the key to evolutionary success is interacting with relatives. The reason for this is clear from our previous discussion. With interactions among unrelated individuals, one's phenotype (here fitness) provides very little information about one's own social breeding value for fitness. With interacting kin, the breeding values of the kin's social effects influence one's fitness, and these effects are positively correlated (via kinship) with one's own breeding value for social effects, as $\sigma(A_{s_i}, A_{s_j}) = r_{ij}\sigma^2(A_s)$. Hence, even under individual selection, there is correlated selection on an individual's social value when some of its group members are relatives ($r_{ij} > 0$).

Finally, we can decompose the total response in fitness into response from changes in the mean of the direct effects and response from changes in the mean of the social effects. Equation 22.15a gives

$$R_W = R_{W,d} + (n-1)R_{W,s} \quad (22.49a)$$

Recalling Equation 22.48b, Equations 22.15a through 22.15c give these response components as

$$R_{W,d} = \frac{\sigma^2(A_d) + r(n-1)\sigma(A_d, A_s)}{\bar{W}} \quad (22.49b)$$

and

$$R_{W,s} = \frac{\sigma(A_d, A_s) + r(n-1)\sigma^2(A_s)}{\bar{W}} \quad (22.49c)$$

Example 22.15. As Equation 22.48d shows, a reversed response in mean population fitness can occur, in the extreme driving a population to extinction. A potential example of this was provided by Dawson (1969), who studied competition between two species of flour beetles (*Tribolium castaneum* and *T. confusum*). He found that *castaneum* won (driving the other species to extinction) in nine of ten replicates. In the remaining replicate, *castaneum* again appeared to be winning (with a frequency of over 90% by generation 4 from a starting frequency of 50%) when an eye color mutation allelic to *chestnut* spontaneously appeared. From that generation onward, the frequency of this allele increased while the *castaneum* population itself was driven to extinction. One explanation for such a **Trojan gene**—a gene driving the population to extinction (Muir and Howard 1999)—is a strong positive direct fitness effect (increasing the frequency of the allele), but with a strong negative associative value on conspecifics (decreasing mean population fitness).

Example 22.16. Haldane (1932a) coined the term **altruistic trait** to denote a behavior (or trait) that harms an individual, but benefits others. The classic example is an alarm call: others in a group are warned (increasing their fitness), but at some expense to the individual making the call (a direct effect decreasing fitness). Note that the increase in an altruistic trait is an example of a reversed response, as the trait lowers the fitness of the individual that bears it. What are the conditions for such traits to spread? In terms of our fitness model with associative effects (Equation 22.47a), we can rephrase this as the conditions for the mean value of A_s to increase, which are given by Equation 22.49c. From the definition of altruism, $\sigma(A_d, A_s) < 0$, as performing an altruistic act decreases direct fitness while increasing the fitness of those in the group. Equation 22.49c shows that a necessary (but not sufficient) condition for altruism to evolve ($R_{W,s} > 0$) under individual selection is that $r > 0$, namely, that individuals interact in groups of relatives.

As pointed out by Bijma and Wade (2008), we can view $\sigma(A_d, A_s)$ as the **cost** ($-c < 0$) for performing an altruistic act for others in a group. Conversely, the altruistic contribution from others in one's group is $(n - 1)\sigma^2(A_s) \geq 0$, which we denote as the **benefit**, b . With these definitions, from Equation 22.49c, the condition for altruism to evolve under individual selection is

$$-c + rb > 0, \quad \text{or} \quad r > b/c \quad (22.50a)$$

This is the classic **Hamilton's rule** (Hamilton 1963, 1964a, 1964b), which is discussed shortly. For an altruistic trait to evolve under individual selection, individuals must interact in groups of relatives. If groups consist of unrelated individuals ($r = 0$), individual selection is not sufficient for altruism, and some component of group selection is required. Note from Equation 22.49c that a more general version of Hamilton's rule is

$$\sigma(A_d, A_s) + r(n - 1)\sigma^2(A_s) > 0 \quad (22.50b)$$

which shows that the benefit scales with group size, provided $\sigma^2(A_s)$ is independent of n . In contrast, under Bijma's dilution model for social effects (Equation 22.10a), the variance in social effects is a function of n , and (applying Equation 22.10c) Hamilton's rule becomes

$$\sigma(A_d, A_s) + r(n - 1)^{1-2d}\sigma^2(A_{s,2}) > 0 \quad (22.50c)$$

with benefit increasing with group size only when the dilution fraction $d < 1/2$.

The same logic extends to the evolution of altruism under group selection. From Equation 22.27a, the response in the mean social value to group selection depends on the covariance of A_s and the group total (here, the sum of the fitnesses of all group members). From Equation 22.27c,

$$\begin{aligned} \sigma\left(A_{s_i}, \sum_{j=1}^n W_j\right) &= [\sigma(A_d, A_s) + (n - 1)\sigma^2(A_s)] [1 + (n - 1)r] \\ &= (-c + b) [1 + (n - 1)r] \end{aligned} \quad (22.50d)$$

As long as $b > c$ (the benefit exceeds the cost), altruism can evolve under group selection, even in groups of *unrelated* individuals. When individuals within the group are related ($r > 0$), this covariance is significantly larger, and hence the response to selection for altruism is greater.

Lynch (1987) showed that this simple expression for Hamilton's rule breaks down under more complex settings, such as multiple relatives with different levels of interactions between them and allowing for ontological changes in behavior, for example, an individual may act as an offspring early in life and as a parent later in life

Inclusive Fitness

As Equation 22.47a illustrates, when heritable interactions are present, the fitness of an individual depends on both its own genes as well as the genes in others. Hamilton (1964a, 1964b) suggested that evolutionary focus should shift from individual fitness to what he called **inclusive fitness**: that component of fitness influenced only by the alleles carried

by the focal individual. Hamilton argued that evolution strives to increase inclusive, as opposed to individual, fitness (also see Michod and Abugov 1980; Grafen 2006; Akçay and Van Cleve 2016).

Formally, the inclusive fitness of an individual is context specific, and is defined as individual fitness plus the effect of that individual on the fitness of others (weighted by the relatedness to these others) minus any contribution to that fitness from the group environment. While sounding rather abstract, when placed in an associative-effect framework, this definition is quite clear. From Equation 22.47a, for individual i , A_{d_i} is the heritable component of individual fitness (W_i) remaining when the social contributions from others have been removed. The focal individual's social breeding value (A_{s_i}) does not influence its own fitness, but the social effects of other group members do, with the (heritable) contribution to individual i 's fitness from individual j being A_{s_j} . The correlation between the breeding value A_{s_i} carried by i and the contribution to i 's fitness from j is the relatedness r_{ij} , so that $r_{ij}A_{s_i}$ is the predicted value of A_{s_j} given A_{s_i} . Putting these together gives the heritable component (i.e., breeding value) of i 's inclusive fitness as

$$A_{incf,i} = A_{d_i} + A_{s_i} \sum_{j \neq i}^n r_{ij} = A_{d_i} + r(n-1)A_{s_i} \quad (22.51a)$$

where the last equality makes our standard assumption that all group members are equally related (which is easily relaxed). Note that the presence of r makes a genotype's inclusive fitness context specific: if the same genotype interacts with two different groups (even when both have identical allele frequencies), it may have different inclusive fitnesses.

The resulting variance in the breeding value for inclusive fitness becomes

$$\sigma^2(A_{incf}) = \sigma^2(A_d) + 2r(n-1)\sigma(A_d, A_s) + r^2(n-1)^2\sigma^2(A_s) \quad (22.51b)$$

In the absence of heritable associative effects, $\sigma^2(A_s) = 0$, this reduces to the additive variance in direct fitness, as is also the case when $r = 0$. It is important to note that the heritable component of inclusive fitness is not the same as the total breeding value, A_T , for fitness, as a comparison of Equation 22.51a to Equation 22.3 shows that

$$A_{T_i} = A_{incf,i} + (1-r)(n-1)A_{s_i} \quad (22.51c)$$

Just as Equation 22.49a decomposed the total response into components from direct and associative effects, we can similarly decompose the change in mean individual fitness, R_W , into change in mean inclusive fitness, $R_{W,incf}$, plus a residual response. From Equation 22.51c

$$R_W = R_{W,incf} + (1-r)(n-1)R_{W,s} \quad (22.52a)$$

showing that the total response in fitness is the change in inclusive fitness plus any response in the residual of the mean social value (after the effects of group relatives are absorbed into inclusive fitness). Using the same logic leading to Equation 22.48c, the response in the mean inclusive fitness is given by

$$R_{W,incf} = \frac{1}{\overline{W}} \sigma(W, A_{incf}) \quad (22.52b)$$

where, from Equations 22.47a and 22.51a, we have

$$\begin{aligned} \sigma(W, A_{incf}) &= \sigma\left(\mu + A_{d_i} + \sum_{j \neq i} A_{s_j} + e_i, A_{d_i} + r(n-1)A_{s_i}\right) \\ &= \sigma^2(A_d) + 2r(n-1)\sigma(A_d, A_s) + r^2(n-1)^2\sigma^2(A_s) \end{aligned} \quad (22.52c)$$

The last line follows by evaluating the covariance in a similar fashion as done throughout this chapter. Note by comparison with Equation 22.51b that Equation 22.52c is simply $\sigma^2(A_{incf})$, yielding

$$R_{W,incf} = \frac{\sigma^2(A_{incf})}{\overline{W}} \quad (22.52d)$$

Hence (under our simple model), the response in mean inclusive fitness is proportional to the additive variance in inclusive fitness, so that mean inclusive fitness is nondecreasing.

Why, then, can the mean of *individual* fitness decline despite the continual increase in mean inclusive fitness? The reason is a decline in the mean (residual) social value. Recalling Equation 22.49c, Equation 22.52a becomes

$$R_W - R_{W,incf} = \frac{(1-r)(n-1)}{\bar{W}} \left(\sigma(A_d, A_s) + r(n-1)\sigma^2(A_s) \right) \quad (22.52e)$$

Hence, if the covariance between direct and associative effects is sufficiently negative, any increase in inclusive fitness is more than countered by the decline in the mean social environment. When $r = 0$,

$$R_W - R_{W,incf} = \frac{(n-1)\sigma(A_d, A_s)}{\bar{W}} \quad (22.52f)$$

which can be positive or negative, depending on the sign of the covariance. Note, from Equation 22.52e, that increasing the relatedness, r , of group members decreases the residual response between mean individual and inclusive fitness, which in turn increases the chances that individual mean fitness increases.

Bijma's Theorem: Inclusive Fitness and Fisher's Fundamental Theorem

As we have seen, when heritable associative effects are present, individual selection can cause mean individual fitness to decrease. Further, while mean *individual* fitness can decrease, mean *inclusive fitness* is nondecreasing, as the response in inclusive fitness is proportional to its additive variance (Equation 22.52d). Comparing these results with those from Chapter 6, we have an apparent conflict. For the simple model of additive fitness effects and random mating, the classical interpretation of Fisher's fundamental theorem (FFT) holds, with the change in mean individual fitness being proportional to the additive variance in individual fitness, so that (under these conditions) mean individual fitness is nondecreasing. Further, the Price-Ewens exact version of the FFT (Chapter 6) states that the partial increase in mean individual fitness (the change that occurs when set in a constant environment) is nondecreasing. Bijma (2010a) reconciled these results, showing that the Price-Ewens FFT corresponds to statements about inclusive fitness (which reduces to individual fitness in the absence of associative effects).

Recall from Chapter 6 that Price (1972b) and Ewens (1989, 1992) showed that Fisher appeared not to be concerned about the *total* change in individual fitness, but rather about only *one component* of that change, namely that caused by changes in the allele frequencies of genes under selection, when all other factors (such as change in the environment) are held constant. Bijma (2010a) made the important distinction between what we have been calling the total breeding value, A_T , and the traditional breeding value, which we here denote by BV , computed by considering only the effects of the alleles in the focal individual on its own phenotype. The later (BV) is the more traditional definition of breeding value and (LW Chapter 4) is simply the regression of fitness on the direct and social breeding values of individual i ,

$$W_i = BV_i + e = \beta_{i,d}A_{d_i} + \beta_{i,s}A_{s_i} + e \quad (22.53a)$$

To compute these regression slopes, first note that the individual fitness of i is a function of its direct value plus the associative effects for every group member except i ,

$$W_i = \mu + A_{d_i} + \sum_{j \neq i} A_{s_j} + e_i$$

Recalling that $\sigma(A_{s_i}, A_{s_j}) = r_{ij}\sigma^2(A_s)$, the traditional breeding value for individual fitness for i reduces to

$$BV_i = A_{d_i} + A_{s_i} \sum_{j \neq i} r_{ij} \quad (22.53b)$$

as obtained by Bijma (2010a). For the case of all relatives being equally related, this reduces to

$$BV_i = A_{di} + r(n - 1)A_{si} \quad (22.53c)$$

Comparing this to Equation 22.51a shows that the traditional breeding value (BV) equals the breeding value for inclusive fitness. Thus, we have **Bijma's theorem:**

The traditional breeding value for individual fitness is equivalent to the breeding value for inclusive fitness.

From Equation 22.52d, it immediately follows that the response in inclusive fitness is proportional to the traditional additive variance in fitness (which, in this case, is the variance in inclusive fitness). Hence, inclusive fitness provides the bridge between the FFT and response when associative effects are present.

HAMILTON'S RULE

Example 22.16 briefly introduced Hamilton's classic result: the condition for an altruistic trait to spread is $br - c > 0$, where c is the fitness cost to the individual (or **actor**) performing the altruistic act, b is the benefit to individuals with which it interacts (the **recipients**), and r is the relationship between the actor and the recipient (Hamilton 1963, 1964a, 1964b). Hamilton's original result followed upon consideration of an altruistic trait determined by a single locus with additive fitness effects in an outbred population. In this setting, $-c + rb$ is the inclusive fitness of the altruistic allele, whose frequency increases when its inclusive fitness is positive. He further showed (again under this simple model) that inclusive, rather than individual, fitness is maximized by selection. The roots of Hamilton's result, that for altruism to spread under individual selection requires interactions occur among sufficiently related individuals, dates back to a widely attributed quote by Haldane: “Would I lay down my life to save my brother? No, but I would to save two brothers or eight cousins.” (As an aside, this is often cited as Haldane 1955, but this quote does not appear in that paper). Hamilton's contribution was to generalize Haldane's intuition and to introduce the important concept of inclusive fitness.

How General Is Hamilton's Rule?

Hamilton's rule is a bit like the breeder's equation: it provides a simple expression that conveys the nature of interactions between the key quantities of interest, but it can fail (at least as an exact expression) under a variety of conditions. Given that Hamilton assumed a single additive locus under weak selection in an outbred population, just how general is his result? Assuming weak selection, a number of studies have shown that altruistic traits with a polygenic basis also generally satisfy Hamilton's rule (e.g., Yokoyama and Felsenstein 1978; Boyd and Richerson 1980; Aoki 1982; Engels 1983). Conversely, Cavalli-Sforza and Feldman (1978) found that it can fail for even a single locus. When fitnesses are no longer additive (i.e., the fitness of the heterozygote is no longer the average of the two homozygotes), then comparing r to c/b may not be sufficient to predict spread or loss, as the actual value of b (in addition to the ratio c/b) can also matter.

Starting with Hamilton (1970), attempts for a more general version of Hamilton's rule were built around the Price Equation. Recall from Equation 6.6 that Price's (1970, 1972a) theorem states that the response in any quantity, G , can be expressed as

$$\Delta G = \sigma(G, w) + E[w \delta_G] \quad (22.54)$$

where w is relative fitness and δ_G is any transmission bias, namely, the average deviation between the value of G in an ancestor and its mean value in their descendants. Typically, we can treat G as either the frequency of an allele (for a single-locus analysis) or as the breeding value of a trait (for a quantitative-genetic analysis). In the absence of drift and under normal Mendelian segregation (i.e., no meiotic drive), the allele frequencies in the

offspring match the allele frequencies in their parents. Likewise, under the infinitesimal model (in an outbred population) the expected breeding value of an offspring equals the mean breeding value of its parents, and hence the second term in Price's equation is usually ignored (see Chapter 6 for a more detailed discussion).

One way to obtain Hamilton's result is to assume what is typically called **neighbor-modulated fitness** (Hamilton 1964a, 1964b), wherein the phenotypes of neighbors influences one's fitness (this has also been referred to as a **direct fitnesses** model, e.g., Taylor and Frank 1996; Taylor et al. 2007). Following Queller (1992a), we let the relative fitness of some focal individual, i , interacting with its neighbor, j , be

$$w_i = w_0 + w_{d,i} + w_{s,j} \quad (22.55a)$$

w_0 is a component independent of social interactions, $w_{d,i}$ is the direct effect of i on its own fitness, and $w_{s,j}$ is the (social) effect of the neighbor j on i 's fitness. Now, use a linear regression to quantify the effects of phenotypes z_i on fitness, with

$$w_i = a + \beta_{w_d|z} z_i + \beta_{w_s|z} z_j + e_i \quad (22.55b)$$

Ignoring the transmission bias term in Equation 22.54, Price's theorem yields an expected response in the mean breeding value, μ_A , of the trait as

$$\begin{aligned} \Delta\mu_A &= \sigma(w_i, A_i) = \sigma(\beta_{w_d|z} z_i + \beta_{w_s|z} z_j + e_i, A_i) \\ &= \beta_{w_d|z} \sigma(z_i, A_i) + \beta_{w_s|z} \sigma(z_j, A_i) + \sigma(e_i, A_i) \end{aligned} \quad (22.55c)$$

Here, we have used the fact that $\sigma(a, A_i) = 0$ for the constant a . Note that, to this point, Equation 22.55c is exact. If the residual, e_i , from the regression of fitness on phenotype (Equation 22.55b) is uncorrelated with the breeding value, A_i , the result is exactly

$$\Delta\mu_A = \beta_{w_d|z} \sigma(z_i, A_i) + \beta_{w_s|z} \sigma(z_j, A_i) \quad (22.56a)$$

The residual condition, $\sigma(e_i, A_i) = 0$, is satisfied when w is entirely determined by the phenotypes z_i and z_j plus any additional components, *provided* the latter are uncorrelated with A_i (see Chapter 6). The mean value of the trait increases when $\Delta\mu_A > 0$. Dividing both sides of Equation 22.56a by $\sigma(z_i, A_i)$, this occurs when

$$\beta_{w_d|z} + \beta_{w_s|z} \frac{\sigma(z_j, A_i)}{\sigma(z_i, A_i)} > 0 \quad (22.56b)$$

where $\beta_{w_d|z}$ is the cost (c) of the trait, $\beta_{w_s|z}$ is the benefit (b), and the ratio is a generalized measure of relatedness. Given that the phenotypic fitness regression residuals are uncorrelated with breeding values (and that we can safely ignore the transmission bias term), then Equation 22.56b is a general version of Hamilton's rule.

Under the infinitesimal model assumptions in an noninbred population, the regression term (a covariance divided by a variance) quantifying relatedness reduces to

$$\frac{\sigma(z_j, A_i)}{\sigma(z_i, A_i)} = \frac{\sigma(A_j, A_i)}{\sigma(A_i, A_i)} = \frac{r_{ij} \sigma(A_i, A_i)}{\sigma(A_i, A_i)} = r_{ij}$$

and we recover the standard version of Hamilton's rule. However, when inbreeding is present or the infinitesimal model assumptions are not valid (i.e., significant allele-frequency change can occur within a generation), Price's equation shows that a more general definition of relatedness may be required. There is a detailed literature on the appropriate measure of relatedness to use; see Hamilton (1970), Orlove and Wood (1978), Michod and Hamilton (1980), Aoki (1981), Seger (1981), Uyenoyama and Feldman (1981), Pepper (2000), Goodnight (2005), Smith et al. (2015), and references therein. For single-locus models, relatedness measures attempt to account for the difference in the frequency of an altruistic allele in

recipients versus the general population, and hence can depend on genotypic frequencies and other details of the assumed model. See Toro et al. (1982) and Michod (1982) for a more detailed discussion of these population-genetic models. There are a very large number of models for altruism and cooperation built around Hamilton's rule; see Lehmann and Keller (2006a, 2006b and references therein) for an overview, and McGlothlin et al. (2014) for a recent review of quantitative-genetic versions of Hamilton's rule.

Queller's Generalization of Hamilton's Rule

Equation 22.56b follows by considering fitness regressed on *phenotype*. This makes sense, as quantitative genetics tries to work with measurable quantities, such as the effect of phenotype on fitness and the correlation between breeding and phenotypic values. However, Queller (1992b) noted that by considering the regression of fitness directly on the *breeding values* of the selected traits, an exact expression for Hamilton's rule can be obtained. The key is that, by construction (e.g., LW Chapter 3), the residuals are uncorrelated with the predictor variables in the regression. Hence, writing fitness as a multiple regression on the breeding values of the actor (i) and recipient (j),

$$w_i = a + \beta_{w_d|A} A_i + \beta_{w_s|A} A_j + e_i \quad (22.57a)$$

we always have $\sigma(e_i, A_i) = 0$, and (assuming no transmission bias so that we can ignore the second term in 22.54), Price's equation yields

$$\begin{aligned} \Delta\mu_A &= \sigma(w_i, A_i) = \sigma(a + \beta_{w_d|A} A_i + \beta_{w_s|A} A_j + e_i, A_i) \\ &= \beta_{w_d|A} \sigma(A_i, A_i) + \beta_{w_s|A} \sigma(A_j, A_i) \end{aligned} \quad (22.57b)$$

Dividing both sides by $\sigma(A_i, A_i)$ gives Queller's generalization of Hamilton's rule as

$$\beta_{w_d|A} + \beta_{w_s|A} \frac{\sigma(A_j, A_i)}{\sigma(A_i, A_i)} > 0 \quad (22.58a)$$

Recalling the definition of a regression slope (the covariance divided by the variance of the predictor, e.g., LW Chapter 3), Queller's exact result reduces to the very satisfying form of

$$\beta_{w_d|A} + \beta_{w_s|A} \cdot \beta_{A_j|A_i} > 0 \quad (22.58b)$$

where $\beta_{w_d|A}$ is the cost, $\beta_{w_s|A}$ the benefit, and $\beta_{A_j|A_i}$ is a generalized measure of relatedness between i and j . Gardner et al. (2007) cautioned that while Equation 22.56b is rather general and Equation 22.58b completely general (both under the assumption of no biased transmission term), that “the cost of this generality is that it hides a lot of detail, and so naive application of Hamilton's rule may lead to mistakes.” See Frank (1998) for a detailed discussion of potential pitfalls.

GROUP SELECTION, KIN SELECTION, AND ASSOCIATIVE EFFECTS

Kin, Group, and Multilevel Selection

There is a vast (and often heated) literature in evolutionary genetics and social evolution dealing with kin selection, group selection, and inclusive fitness (selected works include Wynne-Edwards 1962, 1986; Maynard Smith 1964, 1976; Williams 1966; Wade 1978; Wilson 1983; Frank 1998; Lehmann and Keller 2006a; Lehmann et al. 2007; West et al. 2006, 2008; Wilson and Wilson 2007; Bijma and Wade 2008; Nowak et al. 2010; Abbot et al. 2011; Van Veelen et al. 2012; Goodnight 2013, 2015; West and Gardner 2013; Birch 2014; Birch and Okasha 2015; Gardner 2015; Lehtonen 2016). Much of the debate has revolved around the evolutionary mechanism(s) needed to account for traits that reduce the fitness of an individual but increase the fitness of a group. As we have seen, Hamilton's rule gives the

condition (a sufficiently high degree of relatedness among the interacting individuals) for such an allele to spread under individual selection. This is a **kin selection** model (Maynard-Smith 1964), whereby interactions among kin (i.e., $r > 0$) generate an inclusive fitness that can allow an allele, potentially harmful to the individual, but helpful to a group, to spread.

An alternative school of thought, **group selection**, which was proposed by Wynne-Edwards (1962, 1963), states that traits favoring a group spread via selection at the level of groups—those carrying alleles for beneficial group behavior tend to leave more groups than those that lack them (the roots of this idea trace back to Darwin 1871). In animal and plant breeding this is not at all controversial, as family selection (choosing only those individuals from the best families) is widely practiced (Chapter 21). In its most extreme form (e.g., Wynne-Edwards 1962, 1963), group selection is envisioned to occur through isolated demes that undergo differential extinction and propagation. Quantitative-genetic models of response to group selection due to population structure have been examined by Slaktin and Wade (1978), Slaktin (1981a), Crow and Aoki (1982), and Tanaka (1996a).

A less restricted form of group selection is the **levels-of-selection** (or **multilevel selection**) argument, where the fitness of an individual is influenced by those individuals with which it interacts, so that fitness is a function of the collection of interacting individuals, rather than a single individual. Family index selection (Chapter 21), wherein both within- and among-family information is used, is an example of a levels-of-selection approach. Levels-of-selection does not require isolated units, and groups (here, simply sets of interacting individuals) can form anew each generation even in a panmixtic population.

In evolutionary biology, the debate over the relative importance of kin vs. group selection has, at times, had the feeling of a holy war. One argument against group selection involves concerns about the formation and subsequent propagation of groups, as well as the generation of among-group variation upon which selection can act. The heavy hand of parsimony (running the risk of getting oneself cut with Occam's razor) is also raised against group selection—why invoke it if individual selection will do (Williams 1966)? Of course, one could argue this is entirely the wrong prior. Most biologists would not disagree with the idea that an individual's fitness is influenced by those with whom it interacts, in which case levels-of-selection would be the more reasonable default, especially because it includes individual selection as a special case. The issue then becomes an empirical one, namely, the relative fitness weights on group versus individual components. Estimation of levels-of-selection components is examined in Chapter 30.

Much Ado About Nothing?

The reader who is unfamiliar with the evolutionary literature might be a bit perplexed about this controversy, as when placed in a framework of associative effects, both group- and kin-selection components arise and have symmetric roles (e.g., Equation 22.29d). Indeed, a number of workers have suggested group and kin selection are simply two extremes on the continuum of potential interactions and hence closely related (Wade 1980; Queller 1991; Lehmann et al. 2007). Bijma and Wade (2008) succinctly make the point that

the ongoing debate on equivalence of kin and levels-of-selection models is partly caused by the fact that levels-of-selection models tend to hide the relatedness component of response to selection, whereas kin selection models tend to hide the multilevel selection component of response to selection . . . the response to selection is naturally described by the combination of relatedness and the degree of multilevel selection, rather than by focusing on one or the other of the two factors.

As we will see, in the absence of associative effects influencing a trait value ($\sigma^2(A_s) = 0$), both kin ($r \neq 0$) and multilevel (group weight $g \neq 0$, see Equation 22.28a) selection are required for social selection to have a response that differs from the breeder's equation. When associative effects influence trait values, kin and multilevel selection appear as symmetric roles, and even in the absence of these latter two factors (namely, $r = g = 0$), the selection response can still differ from the breeder's equation. These results were first clearly stated by Bijma and Wade (2008), and we closely follow their development below.

Group and Kin Selection: Models Without Trait Associative Effects

Most models of kin and group selection assume that the trait of interest is not influenced by associative effects, so that we can decompose the phenotypic value of individual i as

$$z_i = A_i + E_i$$

where A_i denotes i 's breeding value (we use A rather than A_d to stress that this model assumes *no* associative effects, so that no A_s terms appear). While no associative effects influence the *phenotypic value* of the trait of interest, we do assume that the fitness of an individual is influenced by the phenotypes of its neighbors. This results in *fitness* showing both direct and associative effects. This distinction between models where the trait does not show associative effects while fitnesses do, versus models where *both* the trait and fitness show associative effects is subtle, but rather important, as the resulting model behavior is quite different (Bijma and Wade 2008).

In particular, Bijma and Wade show that when traits lack associative effects, the response under either kin or group selection deviates from the breeder's equation only when *both* relatedness and multilevel selection occur. A slightly more general development of their result proceeds as follows.

First, consider a classical kin selection model, where the fitness of individual i is a function of its phenotypic value plus contributions that depend on the phenotypic values (for the same trait) of the $n - 1$ individuals with which it interacts. Generalizing Equation 22.55b, we can express i 's fitness as the multiple regression

$$w_i = a + \beta_{w_d|z} z_i + \beta_{w_s|z} \left(\sum_{j \neq i}^n z_j \right) + \epsilon_i \quad (22.59a)$$

where $\beta_{w_d|z}$ is the direct effect on fitness and $\beta_{w_s|z}$ the indirect (or social) effect on i 's fitness given the phenotypes of its conspecifics. Assuming the residual (ϵ_i) is uncorrelated with i 's breeding value (A_i) for the trait under selection, Equation 22.56a generalizes to give the selection response in the trait mean as

$$R = \Delta\mu_A = \beta_{w_d|z} \sigma(z_i, A_i) + \beta_{w_s|z} \left(\sum_{j \neq i}^n \sigma(z_j, A_i) \right) \quad (22.59b)$$

As mentioned previously, we can think of $\beta_{w_d|z} = c$ as the cost and $\beta_{w_s|z} = b$ as the benefit, so that for altruistic traits $\beta_{w_d|z} < 0$ and $\beta_{w_s|z} > 0$. For the infinitesimal model under random mating,

$$\sigma(z_i, A_i) = \sigma(A_i, A_i) = \sigma_A^2 \quad \text{and} \quad \sigma(z_j, A_i) = \sigma(A_j, A_i) = r_{ij} \sigma_A^2$$

If we assume that all interacting pairs have the same relationship (so that $r_{ij} = r$), Equation 22.59b reduces to

$$R = \Delta\mu_A = \sigma_A^2 \left(\beta_{w_d|z} + r(n-1)\beta_{w_s|z} \right) \quad (22.59c)$$

Hence, the trait increases when $\beta_{w_d|z} + r(n-1)\beta_{w_s|z} > 0$ (Hamilton's rule).

The multilevel selection connection that appears in kin selection models is seen by defining

$$g = \frac{\beta_{w_s|z}}{\beta_{w_d|z}} \quad (22.60a)$$

Using this definition, we can rewrite Equation 22.59a as

$$w_i = a + \beta_{w_d|z} \left(z_i + g \sum_{j \neq i} z_j \right) + \epsilon_i = a + \beta_{w_d|z} I_i + \epsilon_i \quad (22.60b)$$

where

$$I_i = z_i + g \sum_{j \neq i} z_j$$

is the index given by Equation 22.28a. Individual selection corresponds to $g = 0$, as $I_i = z_i$. Likewise, $g = 1$ corresponds to group selection, as

$$I_i = \sum_{j=1}^n z_j = n\bar{z}$$

so that fitness is entirely a function of group mean. As above, g need not be restricted to between zero and one. For example, negative values of g correspond to selection based on deviation within a group (see Example 22.9).

Expressed in terms of g , the expected response under kin selection (Equation 22.59c) becomes

$$\Delta\mu_A = \beta_{w_d|z} \sigma_A^2 \left(1 + (n-1)gr \right) \quad (22.61a)$$

This equation makes Bijma and Wade's main point: The response is a function of the *product* of relatedness (r) and levels-of-selection (g). If either is zero, Equation 22.61a reduces to

$$\Delta\mu_A = \beta_{w_d|z} \sigma_A^2 = \frac{\sigma(w_d, z_i)}{\sigma_z^2} \sigma_A^2 = S \frac{\sigma_A^2}{\sigma_z^2} = h^2 S \quad (22.61b)$$

where we have used the Robertson-Price identity (Equation 6.10), $\sigma(w_d, z_i) = S$. Hence, for the selection response to differ from the standard breeder's equation requires *both* relatedness ($r > 0$) and multilevel selection ($g \neq 0$). While the relatedness is obvious in kin-selection formulations, the levels-of-selection component historically has been a bit less transparent, being "hidden" in the costs and benefits, $\beta_{w_s|z}$ and $\beta_{w_d|z}$ (Bijma and Wade 2008).

Now consider the response under multilevel selection. Here, fitness is a function of both individual and group value, usually expressed as the components of fitness due to within-group deviation ($\Delta z_i = z_i - \bar{z}$) and to the group mean ($\bar{z} = \sum z_i/n$). As above, the fitness of i can be expressed as the regression

$$w_i = a + \beta_{w|\bar{z}} \bar{z} + \beta_{w|\Delta z} \Delta z_i + e_i \quad (22.62a)$$

Individual selection occurs when $\beta_{w|\bar{z}} = \beta_{w|\Delta z} = \beta$, as Equation 22.62a reduces to $w_i = a + \beta z_i + e_i$. Again assuming that e_i is uncorrelated with A_i , Price's theorem gives the response as $\Delta\mu_A = \sigma(w_i, A_i)$, which from Equation 22.62a becomes

$$R = \Delta\mu_A = \beta_{w|\bar{z}} \sigma(\bar{z}, A_i) + \beta_{w|\Delta z} \sigma(\Delta z_i, A_i) \quad (22.62b)$$

The first covariance term is given by

$$\sigma(\bar{z}, A_i) = \frac{1}{n} \sigma \left(\sum_{j=1}^n z_j, A_i \right) = \frac{\sigma(z_i, A_i) + \sum_{j \neq i} \sigma(z_j, A_i)}{n} = r_n \sigma_A^2 \quad (22.62c)$$

where $r_n = r + (1-r)/n$ (Equation 21.6b). This is just the among-group genetic variance (Chapter 21). Likewise,

$$\sigma(\Delta z_i, A_i) = \sigma(z_i - \bar{z}, A_i) = \sigma_A^2 (1 - r_n) \quad (22.62d)$$

which is the within-group genetic variance (Chapter 21). Substitution of Equations 22.62c and 22.62d into Equation 22.62b gives the expected response to multilevel selection as

$$\Delta\mu_A = \sigma_A^2 \left(r_n \beta_{w|\bar{z}} + (1 - r_n) \beta_{w|\Delta z} \right) \quad (22.62e)$$

As noted by Wade (1980) and Cheverud (1985), total response is the sum of the among-group response, $r_n \sigma_A^2 \beta_{w|\bar{z}}$, plus the within-group response, $(1 - r_n) \sigma_A^2 \beta_{w|\Delta z}$. Relatedness enters into multilevel selection models because r influences the relative amounts of within- versus among-group variance. Increasing r increases the among-group variation, $r_n \sigma_A^2$, while decreasing the within-group variation, $(1 - r_n) \sigma_A^2$. With increasing relatedness, more of the response comes from among-group (as opposed to within-group) selection. In the absence of relatives within the group ($r = 0$, so that $r_n = 1/n$), Equation 22.62e becomes

$$\Delta\mu_A = \sigma_A^2 \left(\frac{1}{n} \beta_{w|\bar{z}} + \left[1 - \frac{1}{n} \right] \beta_{w|\Delta z} \right) \quad (22.62f)$$

Example 22.17 shows that the term in the parentheses reduces to $\beta_{w_d|z}$, and hence in the absence of relatives the response reduces to Equation 22.61b, namely the breeder's equation. Relatedness of group members is thus required for the response under the multilevel fitness model (Equation 22.62a) to depart from the breeder's equation.

As mentioned, although these models have no associative effects when *trait* values are considered, their fitness functions (Equation 22.59a and 22.62a) generate direct and associative effects in *fitness*. It will prove useful (especially when contrasting the above results with models that do allow traits to have associative effects) to consider the direct and associative components of fitness as they relate to the breeding value, A_i , of the focal individual. Write the index I_i as

$$I_i = z_i + g \sum_{j \neq i}^n z_j = A_i + g \sum_{j \neq i}^n A_j + e_i^* \quad (22.63a)$$

where we have swept all of the terms not involving breeding values into the residual, e_i^* . Substitution into Equation 22.60b gives the fitness of i in terms of the breeding values A_i and A_j as

$$w_i = \beta_{w_d|z} A_{d,i} + g \beta_{w_d|z} \sum_{j \neq i}^n A_{d,j} + \epsilon_i^* = w_{d,i} + \sum_{j \neq i}^n w_{s,j} + \epsilon_i^* \quad (22.63a)$$

where we have used ϵ_i^* as the residual in the fitness regression to distinguish it from the residual (e_i^*) in our expression for the index I_i . We have now reverted to the A_d notation for the breeding values (of direct effects), as we will shortly expand this result to allow for breeding values of associative effects (A_s). The right side of Equation 22.63a decomposes the fitness into direct and associative components, with

$$w_{d,i} = \beta_{w_d|z} A_{d,i} \quad \text{and} \quad w_{s,j} = g \beta_{w_d|z} A_{d,j} \quad (22.63b)$$

The direct component ($w_{d,i}$) is the contribution from genes in the focal individual i toward its fitness, while the associative component ($w_{s,j}$) is the contribution from genes in j toward i 's fitness. From Price's equation, we have the response as the sum of direct and associative contributions, where

$$R_{i,d} = \sigma(w_{d,i}, A_i) = \beta_{w_d|z} \sigma(A_{d,i}, A_i) = \beta_{w_d|z} \sigma^2(A_d) \quad (22.63c)$$

which is the breeder's equation, while any additional contribution from i due to genes in j is given by

$$R_{i,j} = \sigma(w_{s,j}, A_i) = g \beta_{w_d|z} \sigma(A_{d,j}, A_i) = rg \beta_{w_d|z} \sigma^2(A_d) \quad (22.63d)$$

Thus, two factors are required for genes in j to influence the response based on selecting i . First, multilevel selection ($g \neq 0$) is required in order for there to be an effect of genes in j on the *fitness* of i ($g \beta_{w_d|z} A_{d,j}$). Second, the genes in i and j must be correlated ($r > 0$). Only when both $g \neq 0$ and $r \neq 0$ is there an additional increment in the selection response

from the genes in j , and only in this case do we see departures from the breeder's equation. Summing over all $n - 1$ of i 's interacting neighbors recovers Equation 22.61a.

Example 22.17. Following Bijma and Wade, we can formally show the connections between the fitness models given by Equation 22.59a (kin selection) and Equation 22.62a (multilevel selection). Expanding \bar{z} and Δz_i to express them in terms of z_i and $\sum_{j \neq i} z_j$, we have that

$$\begin{aligned}\beta_{w|\bar{z}}\bar{z} + \beta_{w|\Delta z}(z_i - \bar{z}) &= \beta_{w|\Delta z}z_i + (\beta_{w|\bar{z}} - \beta_{w|\Delta z})\bar{z} \\ &= \beta_{w|\Delta z}z_i + \frac{1}{n}\left(\beta_{w|\bar{z}} - \beta_{w|\Delta z}\right)\left(z_i + \sum_{j \neq i} z_j\right) \\ &= \frac{1}{n}\left(\beta_{w|\bar{z}} + [n - 1]\beta_{w|\Delta z}\right)z_i + \frac{1}{n}\left(\beta_{w|\bar{z}} - \beta_{w|\Delta z}\right)\sum_{j \neq i} z_j\end{aligned}\quad (22.64a)$$

Matching terms with Equation 22.59a, the regression slopes for fitness in these two model are related as follows:

$$\beta_{w_d|z} = \frac{\beta_{w|\bar{z}} + (n - 1)\beta_{w|\Delta z}}{n} \quad \text{and} \quad \beta_{w_s|z} = \frac{\beta_{w|\bar{z}} - \beta_{w|\Delta z}}{n} \quad (22.64b)$$

Similarly, we can show that

$$\beta_{w_d|z}z_i + \beta_{w_s|z}\sum_{j \neq i} z_j = (\beta_{w_d|z} - \beta_{w_s|z})\Delta z_i + (\beta_{w_d|z} + (n - 1)\beta_{w_s|z})\bar{z} \quad (22.65a)$$

implying

$$\beta_{w|\Delta z} = \beta_{w_d|z} - \beta_{w_s|z} \quad \text{and} \quad \beta_{w|\bar{z}} = \beta_{w_d|z} + (n - 1)\beta_{w_s|z} \quad (22.65b)$$

Thus, in the absence of trait associative effects ($\sigma^2(A_s) = 0$, and hence $\beta_{w_s|z} = 0$), $\beta_{w|\Delta z}$ and $\beta_{w|\bar{z}}$ are equivalent and simply differ by shifting focus over individual versus group values.

Finally, we can rearrange the left identity in Equation 22.64b to

$$\frac{1}{n}\beta_{w|\bar{z}} + \left(\frac{n - 1}{n}\right)\beta_{w|\Delta z} = \beta_{w_d|z}$$

Using Equation 22.65b to substitute for $\beta_{w|\bar{z}}$ and $\beta_{w|\Delta z}$ yields

$$\frac{\beta_{w_d|z} + (n - 1)\beta_{w_s|z}}{n} + \left(\frac{n - 1}{n}\right)(\beta_{w_d|z} - \beta_{w_s|z}) = \beta_{w_d|z}$$

showing that the response to multilevel selection when group members are unrelated ($r = 0$) reduces to the breeder's equation,

$$\Delta\mu_A = \sigma_A^2 \left(\frac{1}{n}\beta_{w|\bar{z}} + \left(\frac{n - 1}{n}\right)\beta_{w|\Delta z} \right) = \sigma_A^2 \beta_{w_d|z} = h^2 S$$

Hence, relatedness is required for the response under multilevel selection to deviate from the breeder's equation (Bijma and Wade 2008).

Group and Kin Selection in the Associative-effects Framework

The class of models just considered assumes that trait values are not influenced by associative effects (i.e., no $A_{s,j}$ terms appear in expression for z_i), but does allow for fitnesses to be influenced by the trait values of group members (Equations 22.59a and 22.62a). Under this assumption, the response to social selection only deviates from the breeder's equation when the product gr is nonzero. When associative effects are present in the trait ($\sigma^2(A_s) > 0$), both the trait value and fitness of the focal individual may be functions of the genotypes in the group. In this case, kin and group selection (r and g) play symmetric roles, and when either is nonzero, response can deviate from the breeder's equation. Indeed, even when $r = g = 0$, response can still deviate from the breeder's equation (e.g., Equation 22.11a). Hence, the addition of trait associative effects introduces a profound change in the behavior of the selection-response model. We first formally present the expected response to selection and then explore the source of this rather different behavior in the presence of trait associative effects by considering the contributions to response from direct and associative fitnesses.

When associative effects are present (A_s terms appear), from Equation 22.1b the index I becomes

$$\begin{aligned} I_i &= z_i + g \sum_{j \neq i}^n z_j = \left(A_{d_i} + \sum_{j \neq i} A_{s_j} \right) + g \sum_{j \neq i}^n \left(A_{d_j} + \sum_{k \neq j} A_{s_k} \right) + e_i \\ &= \left(A_{d_i} + g(n-1)A_{s_i} \right) + \sum_{j \neq i} \left(A_{s_j} + g \left[A_{d_j} + (n-2)A_{s_j} \right] \right) + e_i \end{aligned} \quad (22.66)$$

When associative effects are present, Equation 22.1e shows that the expected response is the change in the mean of total breeding value, $A_T = A_d + (n-1)A_s$, where A_d and A_s are the direct and social breeding values. Recalling Equation 22.60b ($w_i = \beta_{w_d|z}I_i + \epsilon_i$), applying the Price Equation, assuming that $\sigma(\epsilon_i, A_{T_i}) = 0$ and no transmission bias, we obtain

$$R = \Delta\mu_{A_T} = \sigma(w_i, A_{T_i}) = \beta_{w_d|z}\sigma(I_i, A_{T_i}) + \sigma(\epsilon_i, A_{T_i}) = \beta_{w_d|z}\sigma(I_i, A_{T_i}) \quad (22.67a)$$

Substituting the expression for $\sigma(A_{T_i}, I_i)$ given by Equation 22.29d into Equation 22.67a yields

$$R = \beta_{w_d|z} \left([g + r + (n-2)gr] \sigma^2(A_T) + (1-g)(1-r) [\sigma^2(A_d) + (n-1)\sigma(A_d, A_s)] \right) \quad (22.67b)$$

Equivalently, we could have used a breeder's equation framework (Equation 22.28d) by recalling that for $w_i = \beta_{w_d|z}I_i + \epsilon_i$ (Equation 22.60b), the regression slope can be expressed as

$$\beta_{w_d|z} = \frac{\sigma(w, I)}{\sigma^2(I)} = \frac{S_I}{\sigma(I)} \frac{1}{\sigma(I)} = \frac{\bar{I}_I}{\sigma(I)}$$

recovering Equation 22.28d.

Note the completely symmetric roles of relatedness (r) and levels-of-selection (g) in Equation 22.67b. The term in the second set of square brackets can be negative, resulting in R and β potentially having opposite signs (and hence a maladaptive response). Increasing either relatedness, r , or the amount of weight, g , on the other individuals within the group results in increased weight on the $\sigma^2(A_T)$ term, which is always nonnegative, increasing the chance of congruence between the signs of R and β . Finally, there is a synergistic effect between r and g in groups of size greater than two, in that the product $(n-2)gr$ weights $\sigma^2(A_T)$. Bijma and Wade note that this occurs because $n-2$ is the number of group members that two individuals have in common.

Let's now examine Equation 22.67b for a couple of special cases. First (as expected) in the absence of heritable social effects ($\sigma^2(A_s) = 0$), then $\sigma^2(A_T) = \sigma^2(A_d)$ and $\sigma(A_d, A_s) = 0$, with Equation 22.67b reducing to

$$R = \beta_{w_d|z}\sigma^2(A_d) [1 + (n-1)gr]$$

which recovers Equation 22.61a, showing that (in this case) *both* relatedness *and* multilevel selection are required for the response to deviate from the breeder's equation.

Now suppose that heritable social effects are present, but interacting group members are unrelated. Here $r = 0$ and Equation 22.67b reduces to

$$R = \beta_{w_d|z} \left(g\sigma^2(A_T) + (1-g) [\sigma^2(A_d) + (n-1)\sigma(A_d, A_s)] \right) \quad (22.67c)$$

Hence, when associative effects on the phenotype occur ($\sigma^2(A_s) > 0$), relatedness is not required for traits with social effects to show a deviation in response from that predicted from the breeder's equation. Likewise, if $g = 0$ and $r > 0$, we see from Equation 22.67b that Equation 22.67c applies, provided that g is now replaced by r . Hence, when relatedness among group members is present ($r \neq 0$), multilevel selection is not needed ($g = 0$) for deviation from the breeder's equation.

Finally, in the absence of both kin and group selection ($g = r = 0$), Equation 22.67b reduces to

$$R = \beta_{w_d|z} \left(\sigma^2(A_d) + (n-1)\sigma(A_d, A_s) \right) = \beta_{w_d|z}\sigma^2(A_d) + (n-1)\beta_{w_d|z}\sigma(A_d, A_s) \quad (22.67d)$$

where the first term in the last equality is the standard breeder's equation (in Lande equation form; Equation 13.8c). Hence, the presence of associative effects, by themselves, are sufficient to produce deviations from the breeder's equation even in the absence of kin or group selection, provided the direct and social breeding values are correlated. This point was highlighted earlier in the chapter.

Another point stressed earlier is that if $\sigma(A_d, A_s)$ is sufficiently negative, the direction of response, R , in the trait may be different from the direction of direct selection, $\beta_{w_d|z}$, on that trait, producing a reversed response. Bijma and Wade (2008) took this point further, and noted that (by definition), selection for an altruistic trait results in a decrease in individual fitness when the mean trait value increases. Hence, spread of an altruistic trait is an example of a reversed response, and we see that if the direct and social breeding values are sufficiently negative correlated within an individual that this can happen *even in the absence of* kin or group selection. The careful reader might be concerned that this result appears to be at odds with Example 22.16, wherein we showed that relatedness was required for individual selection ($g = 0$) to spread an altruistic trait. The difference is in the models. Example 22.16 assumed associative effects only in fitness, but Equation 22.67d assumes associative effects on the *trait itself*. This means that the social breeding value in individual i influences not just the fitness of a group member j , but also j 's *trait value*. Under this setting, altruism can evolve in the absence of either group selection or relatedness.

What is the basis of these rather dramatic differences in the behavior between models with and without associative *trait* effects? The key is to consider the direct and associative components of individual fitness, w_i , as we did in Equation 22.63b. From Equations 22.60b and 22.66, these are given by

$$w_{d,i} = \beta_{w_d|z}(A_{d,i} + g(n-1)A_{s,i}) \quad \text{and} \quad w_{s,j} = \beta_{w_d|z}(A_{s,j} + g[A_{d,j} + (n-2)A_{s,j}]) \quad (22.68)$$

as obtained by Bijma and Wade (2008). These equations generalize Equation 22.63b, reducing to it when associative trait effects are absent ($A_s = 0$). Careful inspection of these components show the sources and targets of selection, and the implications for response. For example, i 's social breeding value ($A_{s,i}$) only enters the direct component of individual fitness ($w_{d,i}$) when $g \neq 0$ (i.e., multilevel selection of occurring). The same is true for the direct breeding value ($A_{d,i}$) to influence the associative component of individual fitness ($w_{s,i}$).

Likewise, to see the role of relatedness, the generalization of the predicted response given by Equation 22.67a to include the direct and associative components of fitness becomes

$$\Delta\mu_{A_T} = \sigma(w_i, A_{T,i}) = \sigma(w_{d,i}, A_{T,i}) + \sum_{j \neq i} \sigma(w_{s,j}, A_{T,i}) \quad (22.69a)$$

No relatedness is required to have $\sigma(w_{d,i}, A_{T_i}) \neq 0$, and hence contribute to the selection response. Conversely, i and j must be related ($r_{ij} > 0$) for $\sigma(w_{s,j}, A_{T_i})$ to be nonzero. This last point follows because $w_{s,j}$ is a function of j 's direct and associative breeding values (A_{d_j} and A_{s_j} ; Equation 22.68), and

$$\sigma(A_{d_j}, A_{T_i}) = r_{ij}\sigma(A_{d_i}, A_{T_i}) \quad \text{and} \quad \sigma(A_{s_j}, A_{T_i}) = r_{ij}\sigma(A_{s_i}, A_{T_i}) \quad (22.69b)$$

both of which are zero if i and j are unrelated.

Equations 22.68 and 22.69b show the roles played multilevel selection (g) and relatedness (r) when associative effects are present for the trait. Multilevel selection determines how the associative and direct breeding values of i and j are distributed over the direct and associative components of fitness (Equation 22.68), while relatedness allows the associative component of fitness to contribute to response (Equation 22.69b). For example, in the absence of multilevel selection ($g = 0$), Equation 22.68 reduces to

$$w_{d,i} = \beta_{w_d|z}A_{d_i} \quad \text{and} \quad w_{s,j} = \beta_{w_d|z}A_{s_j} \quad (22.70a)$$

In this setting, selection response can only utilize $\sigma^2(A_s)$ when $\sigma(w_{s,j}, A_{T_i}) \neq 0$, which requires that i and j are related (Equation 22.69b).

Conversely, in the absence of any relatives within a group, $w_{s,j}$ does not contribute to the selection response, which from Equation 22.68 is entirely determined by

$$w_{d,i} = \beta_{w_d|z}[A_{d_i} + g(n-1)A_{s_i}] \quad (22.70b)$$

Multilevel selection ($g \neq 0$) allows for A_{s_i} to be included in $w_{d,i}$, and hence $\sigma^2(A_s)$ is incorporated into the response.

Finally, if both r and g are zero, then only $w_{d,i} = \beta_{w_d|z}A_{d_i}$ enters into the response, giving (from Equation 22.69d)

$$R = \Delta\mu_{A_T} = \beta_{w_d|z}\sigma(A_{d_i}, A_{T_i}) = \beta_{w_d|z}[\sigma^2(A_d) + (n-1)\sigma(A_d, A_s)] \quad (22.70c)$$

which shows a departure from the breeder's equation when direct and social breeding values are correlated. Because A_s only enters through its covariance with A_d , we are not directly accessing $\sigma^2(A_s)$, so that no direct selection on social values occurs.

Closing Comments

In the absence of associative effects influencing the trait value of interest, both relatedness and multilevel selection are required for the expected selection response to deviate from that predicted from the breeder's equation. Hence, when $\sigma^2(A_s) = 0$ and r or g is zero, the standard breeder's equation holds. When $\sigma^2(A_s) > 0$ (the trait value of a group member depends in part on the genotypes of other group members), the selection response typically deviates from the breeder's equation. The only general setting where this is not true is when the direct and social breeding values are uncorrelated and there is no group or kin selection, $\sigma(A_s, A_d) = g = r = 0$.

It must be emphasized that any departure of the response from that predicted from the breeder's equation does not (by itself) imply that social (i.e., group-level) trait mean will evolve in a favorable direction. When the departure is entirely due to a correlation between social and direct breeding values, $\sigma(A_s, A_d) \neq 0$, the result can be a social response in an unfavorable direction when this correlation is negative. In order for selection to directly access social breeding values, $\sigma^2(A_s)$ must appear in the response equation, and when trait associative effects are present this only occurs when either r or g is nonzero. Hence, in the evolution of social traits, three different components are important to consider: the presence or absence of (i) associative effects influencing trait value ($\sigma^2(A_s) > 0$); (ii) kin selection ($r \neq 0$); and (iii) multilevel selection ($g \neq 0$). In the presence of associative effects on the trait value, beneficial changes in the mean social value typically requires either

kin or multilevel selection. In the absence of associative effects ($\sigma^2(A_s) = 0$), both kin and multilevel selection are required for beneficial changes in the mean social value.

The associative effects framework is very powerful, as it brings the full machinery of quantitative genetics to bear to the evolution of group-level traits. One immediate advantage is conceptual, in that quantitative-trait models provide a more realistic description of complex traits (be they behavioral or morphological) than do the single-locus models upon which much of the earlier work on social selection is built. The other advantage is empirical: BLUP can be used to estimate the breeding values, and REML used to estimate the associated variances and covariances, of the direct and associative effects and hence model the transmission of a particular trait. The complementary empirical issue of estimating selection on different levels (e.g., individuals vs. groups) is developed in Chapter 30.

23

Selection Under Inbreeding

Either inbreeding or selection, never both at the same time. R. A. Fisher

There are several reasons for jointly considering inbreeding and selection. First, one may have little choice. For many species, such as the autogamous crops that provide much of our food, the extra work required to ensure outcrossing is often considerable. Second, in many cases, the creative use of inbreeding can increase selection response. Third, the development of elite pure lines starts with a cross between two (often inbred) lines, with the breeder then selfing the resulting progeny to fixation. Under such development schemes, selection can occur in the early generations of selfing (this chapter) and/or among the completely selfed lines (Volume 3). Finally, many wild populations undergoing natural selection have mating systems that result in offspring that are partly to highly inbred.

As we have seen, selection changes genotypic frequencies by changing allelic frequencies and creating gametic-phase disequilibrium (Chapters 5, 16, and 24). Under random mating, departures from generalized Hardy-Weinberg (such as those induced by gametic-phase disequilibrium) are reduced each generation. This erodes any transient contributions from nonadditive variances to the selection response, leaving only allele-frequency change (accomplished via σ_A^2) as the permanent component of response (Chapter 15). When inbreeding occurs, departures from generalized Hardy-Weinberg are *created*, rather than *destroyed*, by the mating system. By increasing the frequency of homozygotes, inbreeding redistributes the genetic variance in a population, reducing or removing it within a line undergoing inbreeding and increasing it among a collection of such lines (Chapter 11). Inbreeding also generally increases the covariance between relatives, as they become increasingly more genetically similar (Chapter 11). Finally, the reduction in the frequency of heterozygotes under inbreeding results in a corresponding reduction in the effective recombination rate, retarding the decay of multilocus departures from generalized Hardy-Weinberg. As we will see, all these of factors have important consequences for selection response.

When inbreeding occurs and nonadditive genetic action (dominance and/or epistasis) is present, the standard genetic variance components (σ_A^2 , σ_D^2 , and σ_{AD}^2) are no longer sufficient to predict response. As was discussed in Chapter 11, when dominance is present, at least three additional components (ι^* , σ_{DI}^2 , and σ_{ADI} ; see Table 11.1) are required to describe the covariance between inbred relatives, and hence to predict the short-term selection response. A further complication is inbreeding depression (LW Chapter 10), which can change the mean even in the absence of selection. Unless otherwise mentioned, we assume throughout this chapter that there is gametic-phase equilibrium and no epistasis. The complications these conditions introduce for selection response with inbreeding remain largely unexplored, but are potentially quite important. For example, directional selection creates negative disequilibrium (Chapter 16), which is reduced in each generation by recombination between heterozygotes. By reducing (and ultimately removing) heterozygotes, inbreeding can significantly retard the decay of any selection-induced disequilibrium, thus magnifying its impact relative to random mating (Allard 1975; Hayashi and Ukai 1994; Shaw et al. 1998; Kelly 1999a; Kelly and Williamson 2000).

Our examination of the selection response under inbreeding begins with a general overview of the machinery and concepts for treating the joint action of inbreeding and selection. This is followed by a discussion of family selection when the parents and/or scored progeny are inbred, which extends the results of Chapter 21. These first two sections

form the basics of the selection response under inbreeding. The remainder of the chapter examines a number of special (but important) cases, such as selfing and partial selfing, in more detail. Additional aspects of selection and inbreeding are covered elsewhere, with the interaction between selection and drift examined in Chapter 26, and the generation and selection among pure lines examined more extensively in Volume 3. We conclude by examining the evolution of the selfing rate. We caution the reader that while most of the topics here are not conceptually challenging, the bookkeeping can be demanding.

BASIC ISSUES IN SELECTION RESPONSE UNDER INBREEDING

Animal and plant breeders generally treat inbreeding very differently and inbreed to very different levels. For animal breeders (and others dealing with species that mainly outcross, such as many trees), inbreeding is an undesirable complication that is a by-product of selection tending to promote related individuals. This inflates the level of inbreeding beyond that expected under drift, thus increasing any inbreeding depression (LW Chapter 10), which can offset gains from selection. In addition to any effect on the artificially selected trait, inbreeding depression also lowers overall fitness, with more inbred individuals displaying poorer performance, especially in survival and reproductive traits. Because levels of inbreeding tend to be modest in their breeding schemes, animal breeders generally approximate the selection response under inbreeding by using the breeder's equation as adjusted for inbreeding depression (Uimari and Kennedy 1990; de Boer and van Arendonk 1992; Shaw et al. 1998).

Conversely, plant breeders (and others dealing with species that mainly self) often *exploit* inbreeding through selection schemes whose endproducts are pure lines. As a result, selected individuals can be highly inbred, and a more proper accounting of their covariances requires the machinery of Chapter 11. A rough rule of thumb (examined in greater detail at the end of the chapter) is that outcrossing species can display significant inbreeding depression (so that even a modest change in the level of inbreeding, f , can have substantial consequences for the wellbeing of the organism), while species with high levels of natural selfing often show little inbreeding depression (LW Chapter 10). As a consequence, we deal with two settings in this chapter. The first (which derives largely from animal breeding) involves the impact of small to modest amounts of inbreeding, which mainly occurs through inbreeding depression. The second (which derives largely from plant breeding) concerns selection on lines undergoing selfing or some other regular system of inbreeding.

Accounting for Inbreeding Depression

Even in the absence of selection, changes in the population level of inbreeding, f , can induce changes in the mean due to inbreeding depression (LW Chapter 10). Let ΔI denote the change in mean from inbreeding depression (the difference between the mean of a randomly mated population versus its value under the current level of inbreeding). If dominance is the only nonadditive genetic effect, the change from inbreeding in generation t , $\Delta I_t = Bf_t$, is a linear function of the inbreeding coefficient. The parameter B is the difference in trait mean between a completely inbred ($f = 1$) and fully outbred ($f = 0$) population, and it can be estimated by regressing the trait mean on f under the assumption that allele frequencies have not dramatically changed during the inbreeding process, namely, that lines are not lost under inbreeding (LW Chapter 10). If higher-order epistasis is present, then $\Delta I = Bf + Cf^2 + \dots$, where the order of polynomial in f depends on the type of dominant epistatic interactions present, e.g., order two for $D \times D$ (LW Chapter 10).

The genetic underpinnings of the inbreeding parameter B are as follows: if n diallelic loci underlie the trait, the i th of which has genotypic values of $0 : a_i + d_i : 2a_i$ with allele frequency p_i , then LW Equation 10.3 yields

$$B = -2 \sum_{i=1}^n d_i p_i (1 - p_i) \quad (23.1a)$$

demonstrating that B changes as allele frequencies change. Inbreeding depression occurs when the values of d_i tend to be positive (**directional dominance**), implying that an average heterozygote has a genotypic value closer to that of the larger-valued homozygote. More generally (Table 11.1), with n_k alleles at locus k ,

$$B = \sum_{k=1}^n \sum_{i=1}^{n_k} \delta_{kii} p_{ki} \quad (23.1b)$$

where δ_{kii} (which is a function of the base-population allele frequencies; LW Chapter 4) is the dominance deviation for the homozygote of allele i at locus k . Equation 23.1b follows because the expected value of the dominance deviations, $E[\delta_{ij}]$, is zero under random mating (LW Chapter 4), but nonzero under inbreeding. With probability f , the two alleles at a locus are IBD, with p_i being the frequency of $A_i A_i$ homozygotes in such cases. Hence, the expected value of $E[\delta_{ij}] = (1-f)E[\delta_{ij} | \text{not inbred}] + fE[\delta_{ii}] = fE[\delta_{ii}]$. Summing over all alleles recovers Equation 23.1b. A bit of algebra (using results from LW Table 4.1) shows that Equation 23.1b reduces to Equation 23.1a for diallelic loci.

To distinguish between the change due to inbreeding depression and the response due to selection, we decompose the total change in the population mean after t generations as

$$\Delta_\mu(t) = \mu_t - \mu_0 = R(t) + \Delta I_t \quad (23.1c)$$

where typically, $\Delta I_t < 0$. When computing the response to selection, we ignore the change from inbreeding depression, so

$$R(t) = \Delta_\mu(t) - \Delta I_t \quad (23.1d)$$

If the selected population is subsequently randomly mated, the inbreeding depression term disappears, revealing the true genetic response, $R(t)$.

Equations 23.1a and 23.1b show that the importance of our standard assumption of very little allele-frequency change (i.e., the infinitesimal model) is magnified when predicting short-term selection response under inbreeding. In addition to concerns about changes in the genetic variances as allele frequencies change, when inbreeding is present, we are additionally concerned with changes in the composite inbreeding depression parameter, B , which is also a function of the allele frequencies in the base population. If these frequencies significantly change under selection, the impact from inbreeding depression will become increasingly unpredictable, reflecting (in part) the unpredictability in the change in B . Note from Equation 23.1a that as one drives alleles toward fixation, B decreases in magnitude, as $p(1-p)$, which is maximized at $p = 1/2$, approaches zero.

Response Under Small Amounts of Inbreeding

When the amount of inbreeding is small enough that changes in the covariances between relatives are negligible relative to their random-mating counterparts, its main effect is through inbreeding depression. Consider a population of modest size undergoing random mating, where the amount of inbreeding generated by genetic drift at generation t is $f_t \simeq t/(2N_e)$, provided $t \ll N_e$ and $f_0 = 0$. If no epistasis is present, then

$$\Delta I_t = -B f_t \simeq -\frac{B t}{2N_e} \quad (23.2a)$$

An important, but subtle, correction is that the act of selection on a heritable trait further increases the level of inbreeding relative to a finite population of the same size (due to a tendency to select related individuals; Chapters 3 and 26). Hence, the appropriate value of N_e for Equation 23.2a starts with the pure-drift value, given the sample size and sex ratio (Chapter 3), which serves as the base value of N_e for the corrections given by Equations 26.6–26.8, which account for this further reduction in N_e according to the strength of selection and

heritability of the trait. The expected selection response with a small amount of inbreeding is the response from the breeder's equation (13.6b) plus a correction for any inbreeding depression,

$$\Delta_\mu(t) = R(t) + \Delta I_t \simeq t \bar{t} h^2 \sigma_z - \frac{B t}{2N_e} = t \bar{t} \left(h^2 \sigma_z - \frac{B}{2N_e \bar{t}} \right) \quad (23.2b)$$

(Nordskog and Hardiman 1980; Hill 1986). This is not an unreasonable approximation for $f = t/(2N_e) < 0.1$. For $f > 0.1$, inbreeding significantly alters the genetic variances from their base population values, and this must be taken into account (Chapter 26).

Using these corrections, one can then apply the standard breeder's equation or its extensions (Chapter 13), adjusted for inbreeding depression, to predict the net selection response (Equation 23.2b). De Boer and van Arendonk (1992) found that this approach (over a few generations) is accurate even at intermediate levels of inbreeding ($f \leq 0.35$), while simulations by Shaw et al. (1998) suggested that this approach may generally be fairly accurate, provided the magnitude of σ_{ADI} is small. When this covariance is negative, alleles with positive average effects tend to have negative dominant deviations as homozygotes, which accentuates the effects of inbreeding depression.

In a BLUP-selection framework (choosing individuals based on their mixed-model predicted breeding values; Chapters 13, 19, and 20) with inbreeding, it is often sufficient to simply include inbreeding depression as a cofactor, for example, the phenotypic value, y_i , of individual i can be decomposed as

$$y_i = \mu + A_i + B f_i + e_i \quad (23.2c)$$

Otherwise, it suffices to use a standard additive model (Uimari and Kennedy 1990; de Boer and van Arendonk 1992). Recall that the amount of inbreeding for individual i is calculated by $f_i = A_{ii} - 1$, where A_{ii} is the associated diagonal element for that individual in the relationship matrix, \mathbf{A} (Chapter 19). As detailed in Chapter 19, the use of mixed models accounts (through \mathbf{A}) for both gametic-phase disequilibrium (among unlinked loci) and the reduction in values of N_e from choosing relatives.

All of these approaches assume that B is relatively constant, but as mentioned, this parameter can change under selection. Indeed, as discussed in Chapter 28, Kelly (1999c) proposed a test for the presence of rare recessives by contrasting the relative change in two population parameters following selection: the trait mean and the value of B for that trait. Thus, the standard caveat for the breeder's equation, that it applies to a single generation of selection, also applies here, with the accuracy of this approximation breaking down as allele frequencies change, due to changes in either σ_A^2 or B .

A key point in species showing inbreeding depression is that even if the target of artificial selection is not significantly affected ($B \simeq 0$), the overall fitness (performance) of the individual generally declines as f increases (LW Chapter 10). As a result, significant attention in the animal breeding literature has focused on maximizing selection response under either constrained levels of inbreeding or under the minimization of inbreeding, especially for BLUP selection (Toro and Pérez-Enciso 1990; Quinton et al. 1992; Grundy et al. 1994, 1998, 2000; Meuwissen and Woolliams 1994; Villanueva et al. 1994; Brisbane and Gibson 1995; Luo et al. 1995; Quinton and Smith 1995; Meuwissen 1997; Meuwissen and Sonesson 1998; Meszaros et al. 1999; Sonesson and Meuwissen 2000; Sonesson et al. 2000). We return to this topic in Volume 3.

Using Ancestral Regressions to Predict Response

The simplicity of Equation 23.2b follows from the assumption that a small amount of inbreeding does not greatly change genetic variances. With larger amounts of inbreeding, variances and covariances can change in each generation, which can depend on additional terms such as σ_{DI}^2 and σ_{ADI} . Fortunately, the expected covariances between relatives under regular systems of inbreeding in the absence of selection are predictable (Chapter 11).

Motivated by this predictability, we make the key approximation throughout much of this chapter that selection does not substantially alter these covariances from their expected values in the absence of selection. *Provided* this assumption holds and all regressions are linear and homoscedastic, the method of ancestral regressions (Chapter 15) offers a powerful approach for predicting short-term selection response when inbreeding occurs.

Recall that under ancestral regression, the cumulative response can be expressed as a series of regression coefficients (a covariance divided by a variance) of the contribution to the current total response from selection in a previous generation, t , yielding an expected response after T generations of selection and inbreeding of

$$R(T) = \sum_{t=0}^{T-1} S_t \frac{\sigma_G(T, t)}{\sigma^2(z_t)} = \sum_{t=0}^{T-1} \bar{t}_t \frac{\sigma_G(T, t)}{\sigma(z_t)} \quad (23.3)$$

Here $\sigma_G(T, t)$ is the covariance (in genotypic values) between a relative in generation t and one in the current generation ($T > t$), while $\sigma^2(z_t)$ is the phenotypic variance in generation t . Note that the coefficients in Equation 23.3 are simply the regressions of z_T on z_t , which has a slope of $\sigma_z(T, t)/\sigma^2(z_t) = \sigma_G(T, t)/\sigma^2(z_t)$ in the absence of environmental correlations between generations T and t . The t th term in the sum in Equation 23.3 corresponds to the response from selection in generation t that remains in generation $T > t$. As we will see later in this chapter, under complicated systems of inbreeding, a number of relatives with different degrees of inbreeding must be simultaneously followed, leading to additional indices in the covariance, such as $\sigma_G(T, \tau, t)$ or $\sigma_G(T, \tau, t, k)$, where the additional indices τ and k indicate the generation of founding relatives (see Figure 23.2). Equation 23.3 is a generalization of the breeder's equation to settings where the genetic variances change in predictable ways under the mating system, making the assumption that these inbreeding-induced changes are much more significant than any changes in these parameters from selection.

Equation 23.3 is based on the infinitesimal model, it assumes that selection-induced changes in allele frequencies are negligible. While *genotypic* frequencies change due to inbreeding (with homozygotes increasing and heterozygotes decreasing), we assume that there is no significant change in *allele* frequencies. Hence, if p_i is the frequency of allele A_i in the base population, the frequency of lines eventually fixed for the $A_i A_i$ genotype is assumed to essentially remain as p_i , despite selection. Formally, it is changed to $p_i + \epsilon_i$, where ϵ_i is a very small amount. With a very large number of loci, all of these very small values of ϵ_i can add up to a considerable change in the mean, while still resulting in little change in genetic variances (Chapter 24). While allele-frequency change is negligible under the infinitesimal assumption, gametic-phase disequilibrium can be considerable (the Bulmer effect; Chapters 16 and 24), which can significantly alter the genetic variance without any allele-frequency change. For now, we make the approximation of ignoring any such disequilibrium-based change, a point addressed later in this chapter.

Because the covariance function also gives the genetic variance in generation t , as $\sigma_G^2(t) = \sigma_G(t, t)$, with the covariance function for our particular system of inbreeding in hand (a point we address shortly), we can immediately write the selection response as

$$R(T) = \sum_{t=0}^{T-1} S_t \frac{\sigma_G(T, t)}{\sigma_G(t, t) + \sigma_e^2} = \sum_{t=0}^{T-1} \bar{t}_t \frac{\sigma_G(T, t)}{\sqrt{\sigma_G(t, t) + \sigma_e^2}} \quad (23.4)$$

For example, the response after two generations of inbreeding and selection is

$$R(2) = \bar{t}_0 \frac{\sigma_G(2, 0)}{\sigma(z_0)} + \bar{t}_1 \frac{\sigma_G(2, 1)}{\sigma(z_1)} \quad (23.5a)$$

The first term represents the response from selection in generation zero that carries over to the second generation, while the second term is the response to selection from generation

one. If we stop selection after two generations but continue to inbreed the population to complete homozygosity, the permanent response (after correcting for any inbreeding depression) is

$$R_\infty(2) = \bar{\iota}_0 \frac{\sigma_G(\infty, 0)}{\sigma(z_0)} + \bar{\iota}_1 \frac{\sigma_G(\infty, 1)}{\sigma(z_1)} \quad (23.5b)$$

Inspection of Equation 23.5a and 23.5b highlights a key feature of response with inbreeding. In most cases, these covariances change, so that it is generally the case that $\sigma_G(i, t) \neq \sigma_G(j, t)$ for $i \neq j$. The relative contribution to response from selection in any particular generation t can thus change over time, meaning that there is both a transient and permanent component to response (Chapter 15).

The Covariance Between Inbred Relatives

To apply ancestral regressions, we must obtain the covariance between relatives under the particular inbreeding scheme of interest. Such covariances were discussed in detail in Chapter 11, and here we remind the reader of a few key concepts, which are summarized in Figure 23.1. Equation 11.13 gives the genetic covariance between individuals x and y under general inbreeding, but it assumes that there are no linkage effects or epistasis, as

$$\begin{aligned} \sigma_G(x, y) = & 2\Theta_{xy}\sigma_A^2 + \Delta_{xy,7}\sigma_D^2 + \Delta_{xy,1}\sigma_{DI}^2 \\ & + (2\Delta_{xy,1} + \Delta_{xy,3} + \Delta_{xy,5})\sigma_{ADI} + (\Delta_{xy,2} - f_x f_y)\iota^* \end{aligned} \quad (23.6a)$$

where

$$2\Theta_{xy} = 2\Delta_{xy,1} + \Delta_{xy,3} + \Delta_{xy,5} + \Delta_{xy,7} + \frac{1}{2}\Delta_{xy,8} \quad (23.6b)$$

To aid in reading, we suppress the xy subscript on Δ for those cases where the two relatives being considered are obvious.

The nine possible Δ_i coefficients of relatedness between two (diploid) individuals are defined in Figure 11.5 (and summarized in Figure 23.1), while the composite genetic parameters (the familiar additive and dominance variances, σ_A^2 and σ_D^2 , and the less-familiar quadratic components, σ_{DI}^2 and ι^* , and the covariance, σ_{ADI}) are defined from the standpoint of the noninbred base population (Table 11.1). While σ_{DI}^2 and ι^* are nonnegative (by construction), σ_{ADI} is a covariance and hence can be either positive or negative.

The nature of the identity-by-descent (IBD) measures, Δ_i , provides some insight into which components contribute to the transient, as opposed to the permanent, component of response. If we inbreed to complete homozygosity, then both alleles in an individual y are identical by descent (indicated in Figure 23.1 by a horizontal line between its two alleles). Only three of the Δ_i measures in Figure 23.1 correspond to this condition (Δ_1 , Δ_2 , and Δ_5). Note that under IBD state 2, although x and y are both inbred (both have horizontal lines), they are also *unrelated* (there are no vertical lines between them), and hence this condition generally does not enter into discussions of selection response. When either Δ_1 or Δ_5 are nonzero, σ_{DI}^2 and σ_{ADI} can contribute to the permanent response, while σ_D^2 cannot (as it enters only through Δ_7). When $\Delta_1 = \Delta_3 = \Delta_5 = 0$, then σ_A^2 and σ_D^2 are sufficient to describe the covariance between relatives. As mentioned in Chapter 11, the literature on covariances under general inbreeding can be a bit daunting and requires care when reading, as there is no consistent notation for these additional genetic components (Table 11.2).

Limitations

The major limitation with the ancestral regression approach is the assumption that selection does not significantly alter the covariances between relatives over what is expected under the system of inbreeding (in the absence of selection). Clearly, if there are favorable major alleles, selection will favor individuals carrying them, thus further increasing the amount of inbreeding in the population. As a result, this general approach is best thought of as a weak selection approximation, that is, it assumes that selection is weak on any underlying *locus*,

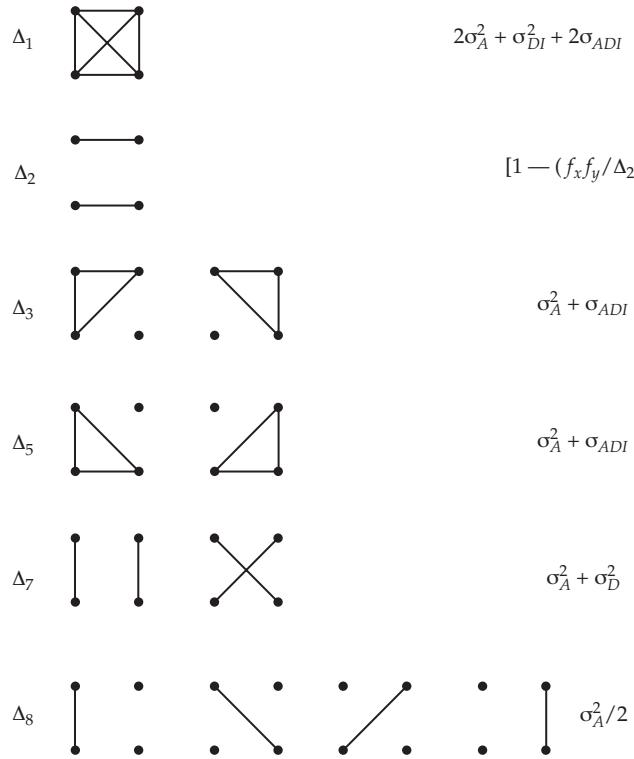

Figure 23.1 The Δ_i coefficients of relatedness and their impact on the genetic covariance between relatives. Following Figure 11.5, the upper two dots correspond to the two alleles in (diploid) relative x , and the bottom two to those in relative y . A horizontal line indicates inbreeding in that relative (the two alleles are identical by descent, IBD), while a line connecting alleles from different relatives indicates that these alleles are IBD. See Figure 11.5 and Chapter 11 for details.

although selection on the *trait* itself may still be strong. Even in the absence of major alleles, the effect of selection is to generally make individuals more inbred than expected by the particular system of inbreeding (Chapters 3 and 26). In such cases, the covariances between relatives are also affected. The other significant caveat is that, even under the infinitesimal-model, selection-induced disequilibrium between alleles at different loci can significantly alter the variances (the Bulmer effect, described in Chapter 16). By reducing the frequency of heterozygotes, inbreeding reduces the opportunities for recombination to remove linkage disequilibrium, which magnifies the Bulmer effect over its role (which is significant) under random mating. We return to this concern later in the chapter.

FAMILY SELECTION WITH INBREEDING AND RANDOM MATING

As detailed in Chapter 21, the motivation for family-based selection is to use family means to provide better estimates of the breeding values of the individuals that will be chosen to form the next cycle of selection. This section extends these results to inbreeding by allowing the sibs and / or their parents to be inbred. Here, we assume that relatives chosen on the basis of the best families are *outcrossed* to form the next generation, with the selection response when chosen relatives are *selfed* discussed later in the chapter. In the terminology of Chapter 21, the selection unit is the mean of the measured sibs, while the recombination unit is either a sib (measured or unmeasured) or the parent of a measured sib. Specifically, let x_1, \dots, x_n denote the n measured sibs in a family, with z_i denoting the value for sib i . Families are chosen based on their mean values, \bar{z} , with relatives, \mathcal{R} , of the chosen families (either one of the measured sibs, an unmeasured sib, or one of the parents of the sibs) outcrossed to

form the next generation, and with y denoting an offspring from \mathcal{R} . The expected selection response becomes

$$R = \frac{\sigma(\bar{z}, y)}{\sigma^2(\bar{z})} \bar{r} \quad (23.7)$$

where the numerator is the selection-unit offspring covariance and the denominator the selection-unit variance (Equation 21.3b). When the offspring, parents, or both, are inbred, the variances of these expressions differ from their random-mating counterparts (given in Chapter 21). Using inbred sibs and/or sibs with inbred parents can increase the selection response (R) by increasing the selection unit–offspring covariance. Conversely, by increasing the among-family variance, the use of inbred sibs also increases the selection-unit variance, $\sigma^2(\bar{z})$, which can reduce the selection response. Hence, using inbred sibs or inbred parents can, in some cases, increase the selection response, while in other situations the response is less than with family selection using randomly mated sibs from outbred parents.

Two bookkeeping issues commonly arising in family-based selection account for some of the variety of selection-response equations found in the literature. First, under strict family selection, a measured sib is used as a parent for the next generation. In this case, the covariance between the family mean, \bar{z} , and an offspring, y , starting the next cycle of selection has two components. If z_1 denotes the value of a measured sib (x_1) used as a parent of y (in the notation of Chapter 21, $x_1 = \mathcal{R}$; see Figure 21.1), then with n measured sibs in a family

$$\sigma(\bar{z}, y) = \frac{1}{n} \sum_{i=1}^n \sigma(z_i, y) = \left(\frac{1}{n} \right) \sigma(z_1, y) + \left(1 - \frac{1}{n} \right) \sigma(z_2, y) \quad (23.8a)$$

The first covariance, $\sigma(z_1, y)$, is that between a parent and its offspring, while the second, $\sigma(z_2, y)$, is that between an individual, x_2 , and the offspring, y , of its sib, x_1 . Alternatively, when sib selection occurs (such as through the use of remnant seed), the sib used in the recombination unit (i.e., as a parent of the next generation) is *not* one of the sibs measured in the selection unit, and $\sigma(\bar{z}, y) = \sigma(z_2, y)$. To simplify our results, we assume only sib or parental selection (progeny testing, where parents are chosen based on the performance of their offspring). For a moderate to large number of measured sibs (n), the difference between sib selection and family selection is expected to be very small.

The second issue relates to the variance of the selection unit, $\sigma^2(\bar{z})$. From Chapter 21, the variance in observed family means is the among-group variance, σ_b^2 , plus the error in estimating their true mean, μ , from \bar{z} , which is σ_w^2/n . Recalling (LW Chapter 18) that the variance among groups equals the covariance within groups, then $\sigma_b^2 = \sigma_z(\text{sibs})$, the covariance between sibs, which is the sum of their genetic covariance, $\sigma_G(\text{sibs})$, plus the variance of any common-family environmental effects, $\sigma_{E_c}^2$ (such as maternal effects when sibs share a common mother). Likewise, the within-family variance can be decomposed into genetic and environmental components, $\sigma_w^2 = \sigma_{G_w}^2 + \sigma_{E_s}^2$ (Equation 21.8b), where $\sigma_{G_w}^2 = \sigma_G^2 - \sigma_G(\text{sibs})$. Hence,

$$\begin{aligned} \sigma^2(\bar{z}) &= \sigma_b^2 + \sigma_w^2/n \\ &= \sigma_G(\text{sibs}) + \sigma_{E_c}^2 + [\sigma_{G_w}^2 + \sigma_{E_s}^2]/n \\ &= \sigma_G(\text{sibs}) + \sigma_e^2 \end{aligned} \quad (23.8b)$$

Because a goal of this chapter is comparing the impact of inbreeding on $\sigma_G(\text{sibs})$, we combine the common-family variance ($\sigma_{E_c}^2$; which can be considerable if the sibs share a common mother for a trait with strong maternal effects) and the error in estimating the true family mean into a single error term,

$$\sigma_e^2 = \sigma_{E_c}^2 + [\sigma_{G_w}^2 + \sigma_{E_s}^2]/n \quad (23.8c)$$

This is mainly for ease of bookkeeping, as Equations 21.41–21.43 illustrated some of the complex expressions for σ_e^2 under different family replication designs. A caveat with this

notational brevity is that different designs can have rather different σ_e^2 values. A paternal half-sib design avoids any shared maternal effects, which (for some traits) can be considerable. Likewise, because of the reproductive biology, some types of families may result in significantly more offspring, and hence a reduced sampling error in Equation 23.8c. Finally, different investigators using the same material can use very different structures for the error variances, depending on the family replication scheme chosen (Equations 21.41–21.43).

Family Selection Using Inbred Parents

One scheme for increasing the response to family selection is to cross inbred, but unrelated, parents, and then score the resulting half- or full-sib progeny as the family unit. This has two effects on selection response, one positive (increasing the covariance between relatives), and one negative (increasing the variance of the selection unit). The genetic covariance among half-sibs where the common parent is inbred (to an amount f) is

$$\sigma_G(HS) = \left(\frac{1+f}{4} \right) \sigma_A^2 + \left(\frac{1+f}{4} \right)^2 \sigma_{AA}^2 + \cdots \left(\frac{1+f}{4} \right)^k \sigma_{A^k}^2 \quad (23.9a)$$

For full sibs, if $\bar{f} = (f_1 + f_2)/2$ is the average inbreeding coefficient for the parents, then

$$\sigma_G(FS) = \left(\frac{1+\bar{f}}{2} \right) \sigma_A^2 + \left(\frac{(1+f_1)(1+f_2)}{4} \right) \sigma_D^2 + \left(\frac{1+\bar{f}}{2} \right)^2 \sigma_{AA}^2 + \cdots \quad (23.9b)$$

This inflation of the between-sib covariances relative to random mating also increases the variance of the selection unit (Equation 23.8b). For the reader wondering why the inbreeding variance components (σ_{AD1} , σ_{DI}^2 , etc.) do not appear in Equation 23.9, it is because the parents of the sibs, while being inbred, are *unrelated* (their coefficient of coancestry, Θ , is zero). Hence, alleles within the resulting sibs are not identical by descent (because their parents are unrelated). This implies that the Δ_1 to Δ_5 coefficients (those associated with at least one relative being inbred) for such sibs are zero, and hence the contributions from their associated variance components (Figure 23.1 and Equation 23.6) are also zero. This also applies to the selection unit–offspring covariances (Equation 23.10).

Turning to the selection unit–offspring covariances, we will ignore the effects of additive epistasis, as this contributes to the transient, rather than permanent, component of response (because random mating among the parents, \mathcal{R} , in the recombination unit eventually decays linkage disequilibrium). The resulting covariances between a measured individual, x , and the offspring y (through a *single* parent, \mathcal{R} , of y) are

$$\sigma_G(x, y | \mathcal{R} = P \text{ of } x) = \left(\frac{1+f}{4} \right) \sigma_A^2 \quad (23.10a)$$

$$\sigma_G(x, y | \mathcal{R} = HS \text{ of } x) = \left(\frac{1+f}{8} \right) \sigma_A^2 \quad (23.10b)$$

$$\sigma_G(x, y | \mathcal{R} = FS \text{ of } x) = \left(\frac{1+f}{4} \right) \sigma_A^2 \quad (23.10c)$$

with P , HS , and FS implying that the parent, \mathcal{R} , of y is related to the measured sibs as either a parent, a half-sib, or a full-sib (respectively). When the parents are inbred ($f > 0$), all of these covariances exceed their random-mating counterparts ($f = 0$). As mentioned, this increase is offset to some degree by the corresponding increase in the selection-unit variance that also occurs with inbreeding, as $\sigma^2(\bar{z} | f > 0) > \sigma^2(\bar{z} | f = 0)$.

Substitution of these results into Equation 21.1 yields the response to a single cycle of selection under various schemes, which are summarized in Table 23.1. As a comparison of Table 23.1 with its random-mating counterpart (Table 21.5) shows, for half-sibs, that the selection response when using inbred parents ($f > 0$) is greater than when using outbred

Table 23.1 The response to family selection when both parents are inbred (to a level of f). Depending on the trait, the common-family variance can be considerably less for paternal half-sibs than for either maternal half-sibs or full-sibs, so we index our general expression for σ_e^2 (Equation 23.8c) to remind the reader of this. Half-sibs versus full-sibs refer to the family unit being measured, while the parents for the next generation are either remnant seed (sib selection) or the parent of the selection unit itself (progeny testing). For comparison purposes, selection on both parents is assumed. Response is halved if only a single parent has been chosen by family selection. The effects of epistasis are ignored. Additive \times additive epistasis inflates the immediate response, but its contribution decays with recombination (as offspring in the next generation are formed by random mating). By inflating the selection-unit variance over the values given here, the presence of epistasis reduces the permanent response.

Selection Scheme	$R/(\sigma_A^2 \bar{t})$
Half-sibs, remnant seed	$\frac{(1+f)/4}{\sigma(\bar{z}_{HS,f})} = \frac{(1/2)\sqrt{1+f}}{\sqrt{\sigma_A^2 + [4\sigma_e^2(HS)/(1+f)]}}$
Half-sibs, parental	$\frac{(1+f)/2}{\sigma(\bar{z}_{HS,f})} = \frac{\sqrt{1+f}}{\sqrt{\sigma_A^2 + [4\sigma_e^2(HS)/(1+f)]}}$
Full-sibs, remnant seed	$\frac{(1+f)/2}{\sigma(\bar{z}_{FS,f})} = \frac{\sqrt{(1+f)/2}}{\sqrt{\sigma_A^2 + [(1+f)\sigma_D^2/2] + [2\sigma_e^2(FS)/(1+f)]}}$

parents ($f = 0$). This is also true for full-sibs when σ_D^2 is small. However, random mating can yield a larger response if σ_D^2 is sufficiently large.

Example 23.1. To get some feel for the impact of inbreeding, consider the selection response for different types of family selection as f increases. Assume we have a trait with $\sigma_A^2 = 50$ and $\sigma_D^2 = 25$. To simplify the discussion, we assume the same value of the residual variance (Equation 23.8c) over all designs, namely, $\sigma_e^2 = 50$. Using the expression summarized in Table 23.1, the response to half-sib, full-sib, and parental selection for various values of parent inbreeding (f) are given below as a fraction of the response for $f = 0$ (random mating). The values in the R/\bar{t} column are the expected responses under $f = 0$, while the values in the columns for $f > 0$ represent the ratio of response for that f value relative to the response under random mating. For example, the R/\bar{t} ratio for full-sibs with $f = 1/4$ is $2.774 \cdot 1.181 = 3.276$.

Selection	R/\bar{t}	Fraction of random-mating response				
		$f=1/8$	$f=1/4$	$f=1/2$	$f=3/4$	$f=1$
Half-sib						
Remnant seed	1.581	1.111	1.220	1.430	1.632	1.826
Parental	3.162	1.111	1.220	1.430	1.632	1.826
Full-sib	2.774	1.093	1.181	1.342	1.485	1.612

Finally, our assumption that σ_e^2 is a constant (over both f and the designs) deserves additional comment. Under the simplest design of n sibs scored in a single plot in a single environment, then from Equation 23.8c,

$$\sigma_e^2 = \sigma_{E_c}^2 + [\sigma_{G_w}^2 + \sigma_{E_s}^2]/n$$

Clearly, in the case of paternal half-sibs, $\sigma_{E_c}^2$ is expected to be smaller (and can be much smaller) relative to designs with a common mother (and hence, there is the prospect of a much larger

common-family effect). Further, different types of families might logically be expected to vary in n , for example, one can usually generate more half-sibs than full sibs. For designs with more structure in the replication scheme, we can write $\sigma_e^2 = \sigma_{E_c}^2 + \sigma^2(\epsilon)$, where Equations 21.41c, 21.42a, and 21.42b provide examples of the structure of $\sigma^2(\epsilon)$. Finally, $\sigma_{G_w}^2$ also changes with inbreeding. Our assumption of a constant value of σ_e^2 is an approximation, assuming that n is relatively large, meaning that changes in $\sigma_{G_w}^2$ with f do not significantly impact σ_e^2 .

Progeny Testing Using Inbred Offspring

Building on an earlier suggestion by Mostagee (1971), Toro (1993) proposed that sire progeny testing be performed using inbred offspring (by crossing the sire to full-sib or half-sib sisters to generate the family), with the chosen superior sires then outcrossed. In animal breeding, such a scheme can be used in species for which artificial insemination and long-term sperm storage are feasible. This suggestion takes advantage of improved accuracy for testing using inbred sibs while still having an outcrossed population (and hence no inbreeding depression in the next generation). It is important to note that the inbred sibs upon which parental selection will be made could themselves experience inbreeding depression, so the assumption is that all such tested sibs have the same f value (or else they are all corrected to adjust for this possibility).

To quantify the advantage of testing inbred progeny, consider a sire crossed to a full-sib sister. Let \mathcal{R} denote a sire and x denote one of the resulting offspring (the mean values of which are used to choose among sires). Assuming that \mathcal{R} is chosen (selected), let y denote an offspring of \mathcal{R} when now crossed (likely using stored sperm) to an unrelated dam (these sex roles can easily be reversed in designs involving plants). The selection unit–offspring covariance is that of an inbred sib (x) from a sire (\mathcal{R}) and of an outcrossed sib (y) from the same sire. The probability that the sire allele in the inbred and outcrossed offspring are identical by descent (IBD) is 1/2. Because the sire and dam are related, an IBD copy of this same allele can also be transmitted through the dam to the inbred offspring, generating a Δ_3 IBD state (both copies of an allele in x are IBD, and these are also IBD with the sire allele transmitted to its offspring, y). If the sire and dam are full-sibs, the probability of the dam transmitting this allele is 1/4, while if the sire and dam are half-sibs, this probability is 1/8. Hence, when the sire and dams are full-sibs (denoted as **SDFS**), then

$$\Delta_3 = (1/2)(1/4) = 1/8 \quad \text{and} \quad \Delta_8 = (1/2)(1 - 1/4) = 3/8 \quad (23.11a)$$

State Δ_8 corresponds to a single allele in x and y being IBD. For a half-sib sire and dam family (**SDHS**)

$$\Delta_3 = (1/2)(1/8) = 1/16 \quad \text{and} \quad \Delta_8 = (1/2)(1 - 1/8) = 7/16 \quad (23.11b)$$

Note that under either scheme $\Delta_1 = \Delta_2 = \Delta_5 = \Delta_7 = 0$. Substituting into Equations 23.6a and 23.6b gives the resulting covariance between inbred (I) and outcrossed (O) sibs for a full-sib sire and dam design as

$$\sigma_G(I, O | SDFS) = (5/16) \sigma_A^2 + (1/8) \sigma_{ADI} \quad (23.11c)$$

while for a half-sib sire and dam design

$$\sigma_G(I, O | SDHS) = (9/32) \sigma_A^2 + (1/16) \sigma_{ADI} \quad (23.11d)$$

By comparison, if the dam and sire are unrelated, the above two covariances are just that between outbred half-sibs, namely $(1/4)\sigma_A^2$. Thus, in the absence of dominance (and hence $\sigma_{ADI} = 0$), the sib covariance under SDFS (Equation 23.11c) is 125% that of outbred half-sibs ($[5/16]/[1/4] = 5/4$), and similarly, the sib covariance for SDHS (Equation 23.11c) is 112%

($[9/32]/[1/4] = 9/8$) of outbred half-sibs. When $\sigma_{ADI} < 0$, the possibility exists that these covariances are smaller than when the tested sibs are not inbred.

S₁, S₂, and S_{i,j} Family Selection

Another scheme for family selection using inbreeding is **S₁ family selection**, wherein an (outbred) individual is selfed, and the family mean of the selfed progeny is used for selection decisions (i.e., individuals are chosen based on the mean trait value of their S₁ family). This scheme takes two generations. In the first generation, the selfed seed must be grown for scoring families. An additional generation is then required for remnant S₁ seeds from superior families to be grown and outcrossed to form the start of the next cycle of selection. Note that S₁ family selection is different from S₁ seed selection (the latter is discussed in Chapter 21). While seed selection also uses remnant S₁ seeds as the recombination unit, the tested family under S₁ seed selection consists of outbred half-sibs, rather than the S₁-sibs used in family selection.

Selection can also be based on S₂ families. Under classical **S₂ family selection**, an outbred individual is selfed to form an S₁, with a single S₁ plant selfed again to form the S₂ family (upon which selection decisions are made, i.e., the selection unit is an S₂ family). Remnant seed from the S₁ is used as the recombination unit, with seed from superior families grown and crossed at random to start the next cycle of selection. There is the potential for ambiguity with S₂ selection, as either: (i) the family to be tested could be (as above), the progeny from a *single* S₁ individual; or (ii) they could be a *collection* of progeny from a *set* of S₁ individuals. Because of this ambiguity, we use a modification of the notation suggested by Wricke and Weber (1986) and consider **S_{i,j} family selection** (Wricke and Weber used I_{i,j}). Here *j* denotes the generations of inbreeding in the tested family and *i* denotes the generations of inbreeding for the founding individual for that family. Hence, S₁ family selection becomes S_{0,1} selection (the selfed progeny from a noninbred plant) and classical S₂ family selection becomes S_{1,2} (the selfed progeny from a single S₁), while S_{0,2} corresponds to **bulk S₂ family selection**, wherein the tested family are the selfed-progeny from a set of S₁ lines from a single outbred individual (and hence *i* = 0).

Expressions for the response to S₁ selection in the literature (e.g., Choo and Kannenberg 1981; Hallauer and Miranda 1981; Bradshaw 1983) are based on the result of Empig et al. (1972). Let p_i and q_i denote the frequencies of alleles $A_{i,1}$ and $A_{i,2}$ at the *i*th underlying locus for the trait, whose genotypic values are given by $-a_i : d_i : a_i$. Assuming linkage equilibrium, Empig et al. found that the covariance between an individual, *x*, in the selection unit and the offspring, *y*, of its selfed sib is given by

$$\sigma(x, y) = \sigma_A^2 + \beta \quad \text{where} \quad \beta = \sum_{i=1}^n 2p_i q_i (p_i - 1/2) d_i [a_i + (q_i - p_i) d_i] \quad (23.12)$$

Similar expressions exist for the response to S_{1,2} selection (Hallauer and Miranda 1981) and for S_{0,j} selection (Wricke and Weber 1986).

However, it is fairly easily to obtain a variance component-based expression (and hence the ability of estimate the required quantities) for response under general S_{i,j} family selection. Because a member of the recombination unit (\mathcal{R}) is outcrossed, it passes on only single alleles to each offspring, *y*. This situation excludes all of the identity states except for Δ_3 (both alleles in *x* are IBD, and one is passed on to the offspring *y* through \mathcal{R}), Δ_8 (the alleles in *x* are unrelated and one is passed onto *y* via \mathcal{R}), and Δ_9 (the alleles in *x* are unrelated to those in *y*). As a result, Equation 23.6a implies that the selection unit–offspring covariance only depends on σ_A^2 and σ_{ADI} . As shown in Example 23.2 (which can be skipped by the casual reader), the required values of Δ_i can be obtained by some simple bookkeeping as

$$\Delta_3 = f_i + (1 - f_i) \left(\frac{1 - 2^{-(j-i)}}{2} \right) = 1 - \frac{1}{2} \left(\frac{1}{2^i} + \frac{1}{2^j} \right) \quad (23.13a)$$

$$\Delta_8 = (1 - f_i) 2^{-(j-i)} = 2^{-j} \quad (23.13b)$$

Table 23.2 Coefficients for Equation 23.14, the selection unit–offspring covariance under $S_{i,j}$ family selection. The column under σ_A^2 gives the coefficient for the additive variance (which is a function of only i), while the σ_{ADI} coefficient is also a function of j and is shown in the remaining columns.

i	σ_A^2	Coefficient on σ_{ADI} for $j =$					
		$i + 1$	$i + 2$	$i + 3$	$i + 4$	$i + 5$	∞
0	1.00	0.50	0.75	0.88	0.94	0.97	1.00
1	1.50	1.25	1.38	1.44	1.47	1.48	1.50
2	1.75	1.63	1.69	1.72	1.73	1.74	1.75
3	1.88	1.81	1.84	1.86	1.87	1.87	1.88
4	1.94	1.91	1.92	1.93	1.93	1.94	1.94
5	1.97	1.95	1.96	1.96	1.97	1.97	1.97
6	1.98	1.98	1.98	1.98	1.98	1.98	1.98
7	1.99	1.99	1.99	1.99	1.99	1.99	1.99
8	2.00	1.99	2.00	2.00	2.00	2.00	2.00

Substituting these results into Equation 23.6b yields

$$2\Theta_{xy} = \Delta_3 + \Delta_8/2 = 1 - \frac{1}{2^{i+1}} \quad (23.13c)$$

The covariance $\sigma_G(x, y)$ immediately follows from Equations 23.6a and 23.6b, where only Δ_3 and Δ_8 are nonzero. Because both of the parents of y come from superior (i.e., selected) families, we double the covariance to give the total (i.e., accounting for both parents of y) selection unit–offspring covariance under $S_{i,j}$ family selection as

$$\begin{aligned} 2\sigma_G(x, y) &= 4\theta_{x,y}\sigma_A^2 + 2\Delta_3\sigma_{ADI} \\ &= 2\sigma_A^2 \left(1 - \frac{1}{2^{i+1}}\right) + 2\sigma_{ADI} \left(1 - \frac{1}{2^{i+1}} - \frac{1}{2^{j+1}}\right) \end{aligned} \quad (23.14)$$

Numerical values for these coefficients are presented in Table 23.2. Using the results in Table 11.1, a little algebra shows that $\beta = \sigma_{ADI}/2$, which connects Equations 23.12 and 23.14.

Finally, the genetic variance among $S_{i,j}$ families is

$$\begin{aligned} \sigma_G^2(S_{i,j}) &= (2 - 2^i)\sigma_A^2 + 2^{-(2j-i)}\sigma_D^2 + (2 - 2^{-i} - 2^{-j})\sigma_{ADI}^2 \\ &\quad + (1 + 2^{-(2j+1-i)} - 2^{-j} - 2^{-(i+1)})\sigma_{DI}^2 + 2^{-(2j-i)}(1 - 2^{-i})\iota^* \end{aligned} \quad (23.15)$$

This expression is derived below in Example 23.7. Substituting Equation 23.14 and 23.15 into Equation 23.7 yields the general expression for a single generation of response to $S_{i,j}$ family selection as

$$R_{S_{i,j}} = \bar{\iota} \frac{2\sigma_A^2(1 - 2^{-(i+1)}) + 2\sigma_{ADI}(1 - 2^{-(i+1)} - 2^{-(j+1)})}{\sqrt{\sigma_G^2(S_{i,j}) + \sigma_e^2(S_{i,j})}} \quad (23.16)$$

In particular, the response to S_1 family selection ($i = 0, j = 1$) is

$$R_{S_{0,1}} = \bar{\iota} \frac{\sigma_A^2 + (1/2)\sigma_{ADI}}{\sqrt{\sigma_A^2 + (1/4)\sigma_D^2 + (1/2)\sigma_{ADI} + (1/8)\sigma_{DI}^2 + \sigma_e^2(S_{0,1})}} \quad (23.17a)$$

The response to “classic” S_2 family selection ($i = 1, j = 2$) is

$$R_{S_{1,2}} = \bar{\iota} \frac{(3/2)\sigma_A^2 + (5/4)\sigma_{ADI}}{\sqrt{(3/2)\sigma_A^2 + (1/8)\sigma_D^2 + (5/4)\sigma_{ADI} + (9/16)\sigma_{DI}^2 + (1/16)\iota^* + \sigma_e^2(S_{1,2})}} \quad (23.17b)$$

while the response to bulk S_2 family selection ($i = 0, j = 2$) is

$$R_{S_{0,2}} = \bar{\iota} \frac{\sigma_A^2 + (3/4)\sigma_{ADI}}{\sqrt{\sigma_A^2 + (1/16)\sigma_D^2 + (3/4)\sigma_{ADI} + (9/32)\sigma_{DI}^2 + \sigma_e^2(S_{0,2})}} \quad (23.17c)$$

Table 23.3 Comparison of the different types of family-based selection, under the assumption of no dominance. $R^* = R/[\bar{t} \sigma_A^2 \sigma(\bar{z})]$ is the scaled selection response *per cycle* per selected parent (using the contribution to the selection unit–offspring covariance from a *single* parent), g is the number of generations per cycle, and c (1 or 2) is the number of parents under selection. The response per generation is shown in the final column, $c R^*/g$.

Type	R^*	g	c	$c R^*/g$
S_1	1/2	2	2	1/2
$S_{1,2}$	3/4	3	2	1/2
$S_{0,2}$	1/2	3	2	1/3
Full-sibs	1/4	2	2	1/4
HS, S_1 seed	1/4	2	2	1/4
HS, remnant seed	1/8	2	2	1/8
HS, Parent	1/4	2	1	1/8

Starting with F_1 s from a pure-line cross (and hence $\sigma_{DI}^2 = \sigma_{ADI} = 0$ and $\iota^* = \sigma_D^2$, as $p = q = 1/2$; see Chapter 11), Equation 23.16 reduces to

$$R_{S_{i,j}} = \bar{t} \frac{2\sigma_A^2(1 - 2^{-(i+1)})}{\sqrt{(2 - 2^i)\sigma_A^2 + 2^{-(2j-i-1)}(1 - 2^{-(i+1)})\sigma_D^2 + \sigma_e^2(S_{i,j})}} \quad (23.18)$$

The simplifications for Equations 23.17a–23.17c in this setting follow in a similar fashion.

How does the use of selfed families compare with other types of among-family selection? Equation 23.16 shows that the response depends on $\sigma_G(x, y)$ in the numerator and $\sigma^2(\bar{z}) = \sigma_G^2(S_{i,j}) + \sigma_e^2(S_{i,j})$ in the denominator, making formal comparisons between methods a bit tedious. If we assume that the denominators are roughly similar (i.e., $\sigma^2(\bar{z})$ is roughly equal over different schemes), then we can simply compare the numerators. Because different schemes take different number of generations, the scaled response ratio, $R/[\bar{t} \sigma_A^2 \sigma(\bar{z})]$, should be expressed in terms of response per generation. We also need to adjust for whether one or both parents have been chosen from superior families. Table 23.3 presents the response per cycle after accounting for all these factors under the assumption of no dominance (i.e., $\sigma_{ADI} = 0$).

Table 23.3 shows that S_1 and $S_{1,2}$ selection are superior to the other approaches that were listed (under the assumption of no dominance and roughly equal family variances among the different approaches). While we have not included comparisons with methods using inbred parents, these are easily obtained by multiplying the scaled response per generation by $1 + f$ (see Table 23.1). While $S_{1,2}$ selection yields a larger response per cycle ($R^* = 3/4$), this is countered by increased cycle time ($g = 3$). Note that S_2 bulk-family selection ($S_{0,2}$) is not as efficient as S_1 or $S_{1,2}$. For other types of $S_{i,j}$ selection, the tradeoff between an increase in additive variance, scaling as $2(1 - 2^{-(i+1)})\sigma_A^2$, versus the increase in cycle time (g increasing with i) is such that the scaled response per generation, $R/(\sigma_A^2 \bar{t})$, is under 1/2 for $i > 2$ and hence not as efficient as either S_1 or $S_{1,2}$ selection.

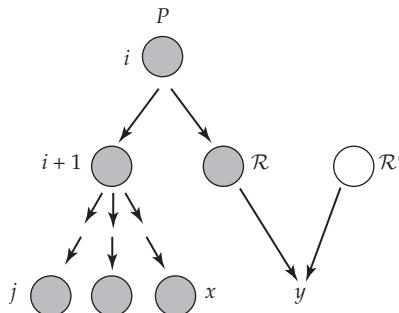

Choo and Kannenberg (1979a, 1979b) compared (via computer simulations allowing for dominance) the relative efficiencies of S_1 family, mass, and modified (Lonnquist) ear-to-row selection (Chapter 21). S_1 selection was found to be overall superior, with the largest advantage occurring at low heritabilities. Similar conclusions were reached by Eberhart (1972), who found that favorable allele frequencies change most rapidly under S_1 , but that the loss of genetic variance is also the fastest under this method. Both of these features are likely consequences of the smaller effective population size associated with S_1 selection (which is about 1/3 of a comparable mass or ear-to-row scheme). Indeed, Choo and Kannenberg (1979b) and Bradshaw (1984) observed that S_1 selection had the highest loss of favorable alleles, although this was not seen by Wright (1980), who assumed higher initial allele frequencies. Choo and Kannenberg also noted that linkage can slow S_1 response, as

recombination occurs only every other generation (as opposed to every generation under mass and ear-to-row selection).

Consistent with these theoretical predictions, several researchers found that S_1 recurrent selection was better than testcross (half-sib) selection for increasing yield in maize (Duclos and Crane 1968; Burton et al. 1971; Carangal et al. 1971; Geneter 1973; Moll and Smith 1981; Tanner and Smith 1987) and sorghum (Doggett 1972). Likewise, Moll and Smith (1981) reported that S_1 selection for yield in maize resulted in a roughly 50% greater response than full-sib selection. S_1 lines, however, did show an increased loss of genetic variation (Mulamba et al. 1983; Tanner and Smith 1987). A caveat is that S_1 lines can show greater genotype \times environment interaction (Lonnquist and Lindsey 1964; Wricke 1976; Jan-orn et al. 1976). Caution is thus in order for declaring the general superior of S_1 or $S_{1,2}$ selection over other family-based approaches.

The results in Table 23.3 rely on two assumptions: no dominance and equal among-family variance. Both among-family genetic differences over the different schemes, as well as $G \times E$ and other replication-dependent error terms in $\sigma^2(\bar{z})$, can cause this latter assumption to be incorrect (e.g., Equations 21.42a and 21.42b). One can easily imagine situations where the difference in error variance more than compensates for the difference in the selection unit-offspring covariances. For example, half-sib selection may generate far more family members for testing than an S_1 , thus greatly reducing the error variance (by increasing n in Equation 23.8c). Likewise, σ_{ADI} can be negative, thus reducing the expected advantage of S_1 and $S_{1,2}$ selection. Indeed, Jan-orn et al. (1976) estimated that σ_{ADI}/σ_A^2 was around -0.5 for many traits in sorghum, suggesting that σ_{ADI} can be both negative and substantial.

Example 23.2. To compute the probabilities of the IBD states Δ_3 , Δ_8 , and Δ_9 required to predict the response under S_{ij} family selection, first recall the various relatives involved:

P is the parent that has undergone i generations of selfing, and it generates both a remnant seed, R (that will be grown and crossed with an unrelated individual, R' , to form the offspring, y), and a collection of S_j families that will be scored. As in Chapter 21, x denotes a measured sib from the family that is used for selection decisions.

Consider a random locus. If the alleles at this locus are IBD in P (which occurs with a probability of f_i), then the only IBD state between x and y is Δ_3 , as both alleles in x are IBD and this allele is also passed onto R , and hence to y . Otherwise (with a probability of $1 - f_i$), a locus in P is not IBD, and we denote P 's two alleles as **A** and **a** (these designations are only for the purpose of following IBD alleles, and in fact, the two alleles could be identical in state). There are then three possible genotypes for x , **AA**, **Aa**, and **aa**, while y can receive either **A** or **a** from R (and an unrelated allele from R'). The IBD states for these different combinations are as follows:

Genotype of x	Allele in y from R	
	A	a
AA	Δ_3	Δ_9
Aa	Δ_8	Δ_8
aa	Δ_9	Δ_3

Hence, Δ_8 equals the probability that a locus in P is not IBD, $(1 - f_i)$, times the probability that the locus is still not IBD by generation j (state **Aa**). Because the probability that a locus is not converted to an IBD state is $1/2$ for each generation of selfing,

$$\Delta_8 = (1 - f_i) 2^{-(j-i)}$$

recovering Equation 23.13b.

If the two alleles in P are not IBD (probability $1 - f_i$), Δ_3 can still arise as twice the probability that x is the genotype **AA** and y receives allele A. The factor of two arises because of symmetry, as the case of **aa** and **a** have equal probability. Turning to the transmission for \mathcal{R} , if the focal locus in P is not IBD, then after one generation of selfing, $1/2$ of the time \mathcal{R} is IBD, and in half of these cases it will be **AA**. Otherwise, \mathcal{R} 's alleles are not IBD, in which case $1/2$ are A, giving the chance of transmitting A to its selfed offspring as $(1/2)(1/2) + (1/2)(1/2) = 1/2$. Hence, the probability that y gets A from \mathcal{R} is $1/2$, while the probability x is **AA** (given that \mathcal{R} was not IBD in generation i) is $(1 - 2^{-(j-i)})(1/2)$, which is the probability of the locus becoming IBD (i.e., not staying as non-IBD) times $(1/2)$ for randomly fixing allele A. Hence,

$$\begin{aligned}\Delta_3 &= f_i + 2 [(1 - f_i)(1/2)(1 - 2^{-(j-i)})] (1/2) \\ &= f_i + (1 - f_i)(1/2)(1 - 2^{-(j-i)})\end{aligned}$$

recovering Equation 23.13a.

Other Inbreeding-based Family-selection Schemes

Other family-selection schemes involving inbreeding have been proposed, such as the **selfed half-sib (SHS)** and **selfed full-sib family (SFS)** methods of Burton and Carver (1993). Here, progeny from either a half- or full-sib family are selfed, and these selfed individuals are then used as the family mean for selection decisions. The advantage of this approach is a large increase in the amount of seed (and hence the ability to more fully replicate a family, reducing the error variance)—in other words, if there are M initial sibs, each of which is selfed to obtain N selfed offspring, there are MN offspring per family. Burton and Carver suggested that this approach can be at least as efficient as S_1 family selection, largely due to the decreased sampling variance in the selection unit, $\sigma^2(\bar{z})$, compared to S_1 families.

Another variant is joint **half-sib, S_1 family selection**, which was proposed by Goulas and Lonnquist (1976) for maize. On prolific (multieared) plants, the lower ear is selfed, while the upper ear is outcrossed. Both the HS (upper ear) and S_1 (lower ear) progenies are jointly evaluated and the best families are chosen, with the remnant HS seed from the best families used as the parents for the next generation. Dhillon (1991b) proposed the **alternate recurrent selection** of S_1 and half-sib families, involving alternate cycles of S_1 selection and either ear-to-row or half-sib selection. The idea here is to take advantage of breeding situations that involve a trial field season and a winter nursery (and hence an extra generation per year) for creating and recombining new families. Under the right settings, this approach can exceed the per-year response of S_1 selection.

Cycles of Inbreeding and Outcrossing

Dickerson (1973) and Dickerson and Lindhé (1977) have suggested that, in some cases, the response to selection under a scheme of random mating alternating every other generation with full-sib mating enhances short-term response. Their logic is that a generation (or two) of inbreeding increases the among-group variance, and this increase can be exploited by selection. However, given the extra generation(s) used for inbreeding (instead of selection), the conditions for such a cyclic inbreeding-selection system to give a larger response than mass selection are rather stringent. Dickerson and Lindhé showed that the ratio of response under cyclic inbreeding (R_I) to response under mass selection (R_m) is approximately

$$\frac{R_I}{R_m} \simeq \left(\frac{\bar{t}_m g_I}{\bar{t}_I g_m} \right) \sqrt{\frac{(1 + f)r_f}{h^2}} \quad (23.19a)$$

where g is the generation time per cycle (typically $g_m = 1$, $g_I = 2$) and r_f is the genetic correlation among the inbred line members. For example, if one crosses full-sibs and then crosses and selects on inbred families in alternate years, $f = 0.25$, $r_f = 0.6$, and $g_I/g_m = 1/2$, which implies that

$$\frac{R_I}{R_m} \simeq \left(\frac{\bar{t}_m}{\bar{t}_I} \right) \sqrt{\frac{0.1875}{h^2}} \quad (23.19b)$$

Under equal selection intensities ($\bar{t}_m = \bar{t}_I$), Equation 23.19b implies that $h^2 < 0.1875$ for cyclic inbreeding to exceed mass selection (Dickerson and Lindhé 1977). Further, Equation 23.19a assumes that there is no significant impact from inbreeding depression.

Given these stringent conditions, it is not surprising that experimental support for the advantage of cyclic inbreeding is lacking. Dion and Minvielle (1985) used 15 generations of cyclic full-sib versus random mating to select for increased pupal weight in *Tribolium castaneum*, and found no differences in the response or realized heritabilities relative to random mating. Similar results were observed in Japanese quail (Example 23.3). While López-Fanjul and Villaverde (1989) observed that one generation of full-sib mating resulted in a fourfold increase in the realized heritability of egg to pupal viability in *Drosophila melanogaster*, this was more than offset by the reduction in the mean from inbreeding depression.

Another cyclic scheme, **S_1 mass selection**, was proposed by Dhillon (1991a). Here, individuals are crossed and the resulting offspring are selfed. The S_1 are then evaluated by individual selection, with the superior individuals outcrossed to start the cycle again. To evaluate the expected selection response under such a scheme, we need to compute the covariance between an S_1 and its outbred offspring, which is obtained as follows. With probability of 1, an S_1 individual passes on a single allele to its outbred offspring, so $\Delta_3 + \Delta_8 = 1$. With probability 1/2, the S_1 individual has both alleles IBD at a locus (due to the generation of selfing), giving $\Delta_3 = \Delta_8 = 1/2$. More generally, if k generations of selfing are used before random mating, then (using the same logic as in Example 23.2) $\Delta_3 = f_k = 1 - 2^{-k}$, $\Delta_8 = 1 - f_k = 2^{-k}$, and $2\theta = \Delta_3 + \Delta_8/2 = (1/2)(2 - 2^{-k})$, returning the S_k -parent and offspring covariance as

$$\sigma(S_k, y) = (1/2)(2 - 2^{-k})\sigma_A^2 + (1 - 2^{-k})\sigma_{ADI} \quad (23.20a)$$

Assuming selection on both parents, the response per generation is then

$$R_{S_K} = \left(\frac{\bar{t}}{k+1} \right) \frac{(2 - 2^{-k})\sigma_A^2 + 2(1 - 2^{-k})\sigma_{ADI}}{\sqrt{\sigma_g^2(S_k) + \sigma_e^2(S_k)}} \quad (23.20b)$$

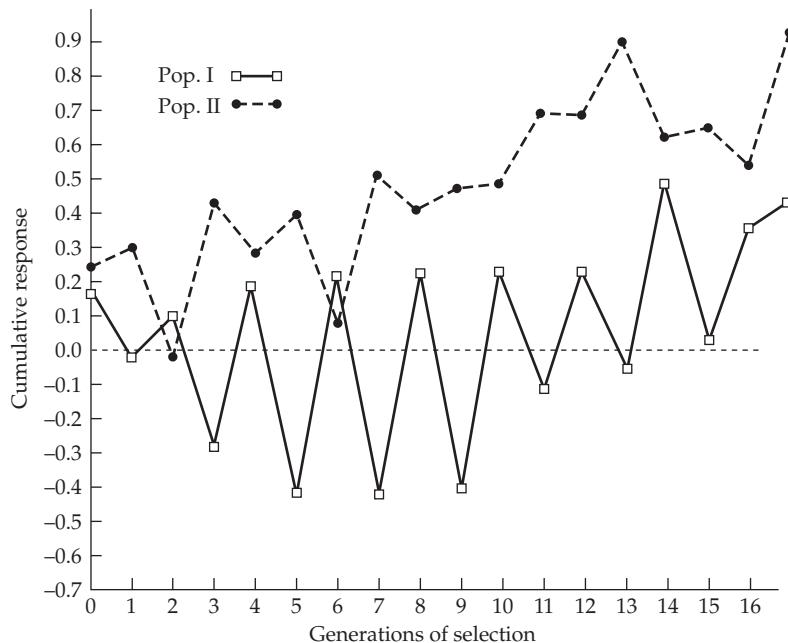

The factor of $1/(k+1)$ arises because there are k generations of selfing for each single generation of selection. The genetic variance, $\sigma_g^2(S_k)$, among S_k individuals is given (below) by Equation 23.23, and $\sigma_e^2(S_k)$ is the error variance for single S_k individuals, which is expected to be considerably larger than the error variance for families, as no replication is involved. For strict additivity, the ratio of per-generation response under S_k mass selection relative to standard mass selection is

$$\frac{R_{S_k}}{R_m} = \left(\frac{2 - 2^{-k}}{k+1} \right) \sqrt{\frac{\sigma_A^2 + \sigma_e^2(m)}{(2 - 2^{-k})\sigma_A^2 + \sigma_e^2(S_k)}} \quad (23.20c)$$

Note that $R_{S_k} < R_m$ for all values of k (assuming the error variances are roughly equal).

Dhillon assumed that a greenhouse could be used for the S_1 , giving one cycle (i.e., two generations) per field generation. In this case, there is no generational cost for inbreeding, and the ratio in the parentheses of Equation 23.20c becomes $(2 - 2^{-1}) = 3/2$. However, a major biological limitation in the assumptions behind Equation 23.20c is that the selected traits must be expressed before reproduction. For traits expressed during or after reproduction, only a single sex will be selected upon (as presumably the S_1 is outcrossed to random individuals). In such cases, the response ratio (in this greenhouse setting) is reduced to $(1/2)(3/2) = 3/4$ of mass selection.

Example 23.3. MacNeil et al. (1984) subjected two populations of Japanese quail (*Coturnix coturnix japonica*) for an index of total egg mass divided by female weight. Standard mass selection with random mating was used for population two (filled circles), while alternative cycles of full-sib and random mating were used for population one (open squares).

While both populations ultimately responded to selection, significant inbreeding depression was seen in population one. The cyclic mating scheme produced inbred individuals every odd generation, resulting in population one showing dramatic shifts between positive selection response and significant inbreeding depression, which countered any positive response.

INDIVIDUAL SELECTION UNDER PURE SELFING

Under pure selfing, one starts with a collection of individuals and continually selfs each to form a series of inbred lines. Let S_k denote such a line after k generations of selfing, with the S_0 being the collection of outbred individuals that are initially selfed to start the lines, and the S_∞ the collection of the completely inbred lines. A variety of options exist for generating the initial collection of lines. The simplest is to use a random sample of individuals from an outbred population. Another common situation is the **pure-line cross**, wherein one crosses two completely inbred (pure) lines, and continually selfs starting with the F_1 . In this case, the initial cross produces a number of F_1 individuals, and even though these are selfed to create a series of F_2 lines, the first generation of selfing is formally defined as the F_3 . The reason is that all of the F_1 s are genetically identical, being heterozygous at every locus at which the two lines differ. Such a population consisting of only heterozygotes is not in Hardy-Weinberg equilibrium, but the F_2 population is (for diploid autosomal loci). Thus, the F_2 defines the base population, and this is the population from which variance components are extracted. The F_2 also sets the initial value for counting generations of selfing, so that $S_0 = F_2$, $S_1 = F_3$, and so on. If the loci are unlinked, then linkage disequilibrium (which is maximal in the F_1) is zero in the F_2 . The instant achievement of linkage equilibrium in the F_2 from a pure-line cross arises because all F_1 individuals are genetically identical and heterozygous at all segregating loci, which is not the situation for crosses of three (or more) lines. If the loci are linked, it may take several rounds of random mating to mitigate the effects of the

F_1 disequilibrium between tightly linked loci. Finally, recall that $\sigma_{ADI} = \sigma_{DI}^2 = 0$ in this line-cross setting (Chapter 11).

Several other line-cross designs can form the foundational population from which individuals are drawn for selfing. If one intermates a collection of lines, the first generation will not be in Hardy-Weinberg equilibrium unless the allele frequencies are the same in each line. However (for diploid autosomal loci), Hardy-Weinberg will be reached with an additional generation of random mating (sex-linked loci and polyploids take several additional generations; see LW Chapter 4). Linkage disequilibrium is also created in such a cross, due to differences in the gamete frequencies across lines. Unlike the case for crossing two pure lines, the F_2 from a multiple-line cross will not necessarily be in linkage equilibrium, even for unlinked loci. In this case, the disequilibrium decays as $(1/2)^t$, where t is the number of generations of random mating that the starting F_1 population experiences. For linked loci, the disequilibrium decays as $(1 - c)^t$, where c is the recombination frequency. Other common types of line crosses are **three-way hybrids**, $(L_1 \times L_2) \times L_3$ (the F_1 from an $L_1 \times L_2$ crossed to L_3), and **double-crosses** (or **four-way hybrids**) $(L_1 \times L_2) \times (L_3 \times L_4)$, which commonly arose in maize breeding. Again, it is often advisable to take such crosses through at least one additional round of random mating to achieve Hardy-Weinberg (meaning that our expressions for response are valid) and approach linkage equilibrium before starting inbreeding.

Response Under Pure Selfing

Suppose we commence selfing from a collection of individuals that are in Hardy-Weinberg and linkage equilibrium. After all lines have become completely inbred, there is no response to selection *within* a line as there is no within-line genetic variation (in the absence of mutation). However, the response *among* lines involves the entire genotypic variance, as selection is among clones.

We first consider one extreme, inbreeding each line entirely to fixation and then selecting among the lines. At this point, a parent and its (selfed) offspring are genetically identical, and the resulting parent-offspring covariance equals the total genetic variance in the population (i.e., the variation over all sets of inbred lines). Inbreeding alters the total genetic variation from its random-mating value of $\sigma_A^2 + \sigma_D^2$ to a new value of $\tilde{\sigma}_G^2$ over the entire collection of pure lines. The resulting parent-offspring covariance among fully inbred lines is

$$\sigma(z_p, z_o) = \tilde{\sigma}_G^2 = 2\sigma_A^2 + 2\sigma_{ADI} + \sigma_{DI}^2 \quad (23.21)$$

When k th-order additive epistasis is present, $2^k \sigma_{A^k}^2$ is added in Equation 23.21 (e.g., $4\sigma_{AA}^2$, $8\sigma_{AAA}^2$, etc.). Assuming linearity of the parent-offspring regression, the response to a generation of selection among these inbred lines produces an expected response of

$$R = S \frac{\tilde{\sigma}_G^2}{\tilde{\sigma}_G^2 + \sigma_e^2} \quad (23.22)$$

Even if selection is moderate, a single generation is likely to significantly alter the distribution of remaining genotypes (and hence change the genetic variance), and thus the validity of Equation 23.22 over more than a few generations is, at best, questionable. There are a number of subtleties when attempting to select the best pure line from a collection, which are examined in Volume 3.

Instead of waiting for inbreeding to be complete, suppose instead that we select among individuals while inbreeding is still ongoing (i.e., $f < 1$). This entails choosing individuals and then following their selfed offspring. The response in generation T from selection in generation $t < T$ is then a function of the **cross-generational covariance**, $\sigma_G(T, t)$. For strict selfing, Equation 11.16c yields the covariance between a relative from generation T and its ancestor in generation $t < T$ as

$$\sigma_G(T, t) = (1 + f_t)\sigma_A^2 + (1 - f_T)(\sigma_D^2 + f_t \sigma_{DI}^2) + \frac{f_T + 3f_t}{2} \sigma_{ADI} + f_t \sigma_{DI}^2 \quad (23.23)$$

where $f_t = 1 - \left(\frac{1}{2}\right)^t$ is the amount of inbreeding in generation t . The phenotypic variance in generation t is $\sigma^2(z_t) = \sigma_G(t, t) + \sigma_e^2$, where $\sigma_G(t, t) = \sigma_G^2(t)$ is obtained from Equation 23.23 by setting $T = t$. Equation 23.21 follows if we note that $f_\infty = 1$. Recall (Chapter 17; LW Chapter 6) that the environmental variance, σ_e^2 , may increase with inbreeding, and thus we may need to account for this factor as well. Cockerham and Matzinger (1985) extend Equation 23.23 to include additive by additive epistasis (but still assuming gametic-phase equilibrium). If additive epistasis up to order k is present, extra terms are added to the covariance provided by Equation 23.23, namely,

$$(1 + f_t)^2 \sigma_{AA}^2 + \cdots + (1 + f_t)^k \sigma_{A^k}^2$$

When all possible types of pairwise epistasis (e.g., $A \times A$, $A \times D$, $D \times D$) occur, 12 variance components are required to describe $\sigma_G(T, t)$ under selfing (Wright 1987, 1988), but we will ignore this level of complication.

Substitution of Equation 23.23 into Equation 23.4 gives the response to selection while the line is being inbred. For complete additivity, $\sigma_G(T, t) = (1 + f_t)\sigma_A^2 = (2 - 2^{-t})\sigma_A^2$, yielding a response of

$$R(T) = \sum_{t=0}^{T-1} S_t \frac{(2 - 2^{-t})\sigma_A^2}{(2 - 2^{-t})\sigma_A^2 + \sigma_e^2} \quad (23.24)$$

as obtained by Brim and Cockerham (1961) and, under much more general conditions, by Pederson (1969a). If dominance is present, the selection response under selfing has both a transient and a permanent component (Chapter 15). When selection is relaxed (short of complete inbreeding), the mean potentially changes as the transient component decays. The expected total change in the mean after n generations, the first T of which were under selection (generations 0 to $T - 1$), is thus given by

$$R(n | T) = \sum_{t=0}^{T-1} S_t \frac{\sigma_G(n, t)}{\sigma_G(t, t) + \sigma_e^2} = \sum_{t=0}^{T-1} \bar{\iota}_t \frac{\sigma_G(n, t)}{\sqrt{\sigma_G(t, t) + \sigma_e^2}} \quad (23.25)$$

The permanent response to T generations of selection, $\tilde{R}(T)$, is given by

$$\tilde{R}(T) = R(\infty | T) = \sum_{t=0}^{T-1} S_t \frac{\sigma_G(\infty, t)}{\sigma_G(t, t) + \sigma_e^2} = \sum_{t=0}^{T-1} \bar{\iota}_t \frac{\sigma_G(\infty, t)}{\sqrt{\sigma_G(t, t) + \sigma_e^2}} \quad (23.26)$$

Because $f_\infty = 1$, Equation 23.23 calculates the covariance between an individual in generation t and a completely inbred (F_∞) line descended from it as

$$\sigma_G(\infty, t) = \left(2 - \frac{1}{2^t}\right) \sigma_A^2 + \left(2 - \frac{3}{2^{t+1}}\right) \sigma_{ADI} + \left(1 - \frac{1}{2^t}\right) \sigma_{DI}^2 \quad (23.27)$$

which is essentially $\tilde{\sigma}_G^2$ (Equation 23.21) for $t > 5$. Thus, additive variance contributes to the permanent response, while σ_D^2 and ι^* contribute to the transient, but not the permanent, response. Dominance does, however, make a contribution to the permanent response, through σ_{DI}^2 and σ_{ADI} . To see why, consider the case when inbreeding is complete. Here the only genotypes are of the form $\mathbf{A}_i \mathbf{A}_i$ and have a genotypic decomposition of $2\alpha_i + \delta_{ii}$. The frequency of such genotypes (in the collection of completely inbred lines) is $\simeq p_i$, assuming that there is no change in the population allele frequencies (i.e., our assumption of weak selection on the underlying loci). Recalling the definitions of σ_{DI}^2 and σ_{ADI} (Table 11.1), the resulting genetic variance among lines is

$$\tilde{\sigma}_G^2 = \sigma^2(2\alpha_i + \delta_{ii}) = 4\sigma^2(\alpha_i) + 2 \cdot 2\sigma(\alpha_i, \delta_{ii}) + \sigma^2(\delta_{ii}) = 2\sigma_A^2 + 2\sigma_{ADI} + \sigma_{DI}^2$$

The contribution from standard dominance variance, $\sigma_D^2 = \sigma^2(\delta_{ij})$, decays as $\mathbf{A}_i \mathbf{A}_j$ heterozygotes are lost due to inbreeding, leaving only the contribution from homozygotes, $\sigma_{DI}^2 = \sigma^2(\delta_{ii})$.

Example 23.4. As an example of what fraction of the response from various generations of selection is ultimately passed on to the completely inbred line, assume the genotypic values and frequencies from Example 11.1, which computed the components required to predict the selection response under inbreeding as

$$\sigma_A^2 = 0.629, \quad \sigma_D^2 = \iota^* = 0.046, \quad \sigma_{DI}^2 = 0.103, \quad \sigma_{ADI} = -0.361$$

Assume $\sigma_e^2 = 1$ (which corresponds to narrow- and broad-sense heritabilities of $h^2 = 0.38$ and $H^2 = 0.41$, respectively). If we substitute these values into Equation 23.23, and recall that $\sigma_z^2(t) = \sigma_G^2(t, t) + \sigma_e^2$, we get the response in various generations (t) of inbreeding. The fifth column in the table below shows the expected single-generation response (the response in $t + 1$ from selection in t) and the fourth column shows the eventual contribution ($T = \infty$), while the final column shows the percentage of the response from that particular generation that is translated into the final response.

t	$\sigma_G(\infty, t)$	$\sigma_G^2(t, t)$	$\frac{\sigma_G(\infty, t)}{\sigma_z^2(t)}$	$\frac{\sigma_G(t+1, t)}{\sigma_z^2(t)}$	%
0	0.449	0.675	0.268	0.335	79.86
1	0.544	0.669	0.326	0.363	89.73
2	0.592	0.657	0.357	0.377	94.78
3	0.616	0.649	0.374	0.384	97.37
4	0.628	0.645	0.382	0.387	98.68
5	0.634	0.642	0.386	0.389	99.34
7	0.639	0.641	0.389	0.390	99.83

For example, if selection is among individuals that have experienced three generations of inbreeding ($t = 3$), then 97.4% of the response seen in generation 4 is seem among the fully inbred lines. This calculation essentially assumes that this is only a single generation of selection, as multiple generations of selection (especially among largely inbred lines) will quickly remove most of the existing among-line variation. Note that the largest reduction between the initial and permanent responses occurs in the first generation of selection, where selected individuals are selfed for the first time. As selfing progresses, the genotypic values between ancestors and descendants become increasingly more similar, and hence they retain almost all of their initial response. While more dramatic changes are expected under different combinations of σ_{ADI} , σ_{DI}^2 , and ι^* , inbreeding will largely be complete after the first six generations, and the offspring will be almost genetically identical to their parents.

This example highlights the dilemma faced by plant breeders. Selection decisions based on early cycles of the inbreeding (**early-generations selection**) may be poor predictors of the ultimate inbred product (especially when dominance is present), but carrying out additional generations of inbreeding (to increase the genetic covariance between the tested and fully inbred genotypes) takes additional time. For the values assumed here, only 80% of the first-generation ($t = 0$) response is retained in fully inbred lines, which increases to almost 95% for the third-generation ($t = 2$) response. The use of doubled-haploids, which can make a plant fully inbred in a single generation, can have significant advantages in an inbred line breeding program (Gallais 1989; Volume 3).

It is important to again stress that these results for the expected selection response are based on infinitesimal-model approximations. The covariances between relatives under inbreeding that drive these equations are based on the assumption (as was the case for the breeder's equation) that selection does not significantly change the variance components (the values of σ_A^2 , σ_D^2 , σ_{ADI} , etc. remain largely unchanged). Clearly, selection with a small number of loci can substantially change allele frequencies, thus violating the assumptions leading to Equations 23.24 through 23.27. Likewise, with a small number of lines and/or strong selection, these results will also be biased. Another, more subtle, violation of this

basic model will occur if some lines are disproportionately chosen over others (as one might expect might happen). In such cases, the covariances that are now appropriate are not those for the population as a whole, but rather those for individuals *within* particular sublines. The unstated assumption of Equation 23.23 is that when individuals are being compared for selection, their most recent ancestors are those that are drawn from the base population. If their most recent ancestor is more current, however, the covariances will be incorrect and the estimated response biased. Finally, as developed shortly, selection-generated gametic-phase disequilibrium can significantly reduce response.

Response When Inbreeding Pure-line Crosses

Considerable simplification occurs when two pure lines are crossed. In the resulting F_1 , each locus will have only two segregating alleles (one from each line; both at frequency 1/2), and as a result, $\iota^* = \sigma_D^2$ and $\sigma_{DI}^2 = \sigma_{ADI} = 0$ (Chapter 11). Equation 23.23 then becomes

$$\sigma_G(T, t) = c_t \sigma_A^2 + 2^{-T} c_t \sigma_D^2 + c_t^2 \sigma_{AA}^2 + \cdots c_t^k \sigma_{A^k}^2, \quad \text{where } c_t = 2 - \frac{1}{2^t} \quad (23.28)$$

If we start selection on the F_2 population and denote this generation as generation 0, Equation 23.25 simplifies (Pederson 1969a) to

$$R(n | T) = \sum_{t=0}^{T-1} \bar{\iota}_t \frac{(2 - 2^{-t})(\sigma_A^2 + 2^{-n}\sigma_D^2)}{\sqrt{(2 - 2^{-t})(\sigma_A^2 + 2^{-t}\sigma_D^2) + \sigma_e^2}} \quad (23.29)$$

However, Equation 23.29 carries the unstated assumption that the environmental variance, σ_e^2 , is unchanged over levels of inbreeding, which may not be correct (Chapter 17). More generally, σ_e^2 can be replaced by $\sigma_e^2(t)$ to accommodate this concern. Note that any initial contribution to the selection response from dominance will quickly decay (as 2^{-n}).

Example 23.5. Suppose a cross between two inbred lines is subjected to truncation selection for the uppermost 20% in the first two generations of selfing ($t = 0, 1$). What is the cumulative response to selection at the n th generation of selfing? Here $\bar{\iota} = 1.402$, and we assume random-mating variance components (i.e., values in the F_2 population) of $\sigma_A^2 = 50$, $\sigma_D^2 = 25$, and $\sigma_e^2 = 50$, yielding random-mating heritabilities of $h^2 = 0.4$ and $H^2 = 0.6$. The total phenotypic variances in the first two generations are $\sigma_z^2(0) = \sigma_G^2(0) + \sigma_e = 125$ and $\sigma_z^2(1) = \sigma_G^2(1) + \sigma_e = 143.75$. If we let $r(n, t)$ denote the response to selection in generation t that is present at generation n and let $R(n) = \sum_t r(n, t)$ denote the cumulative response from selection that is still present at generation n , Equation 23.39 returns the following values:

n	t	$\sigma_G(n, t)$	$r(n, t)$	$R(n)$
1	0	62.5	7.837	7.837
2	0	56.3	7.054	
2	1	84.4	9.866	16.920
3	0	53.1	6.662	
3	1	79.7	9.318	15.980
4	0	51.6	6.466	
4	1	77.3	9.044	15.510
5	0	50.8	6.368	
5	1	76.2	8.907	15.275
10	0	50.0	6.273	
10	1	75.0	8.774	15.047
∞	0	50	6.270	
∞	1	75	8.770	15.040

For example, by generation 3 ($n = 3$), the remaining amount of response from selection in generations 0 and 1 are 6.662 and 9.318, respectively, for a total response of 15.98. Of this response, only 15.04 persists when the lines are fully inbred, 6.27 from generation 0 and 8.77 from generation 1. Hence, for these starting variance-component values, only 80% (6.27/7.837) and 89% (8.77/9.866), respectively, of the initial first- and second-generation response is permanent.

The Bulmer Effect Under Selfing

Recall from Equation 16.2 that we can decompose the additive-genetic variance as $\sigma_A^2 = \sigma_a^2 + d$, the sum of the genic variance, σ_a^2 , plus the impact, d , from any gametic-phase disequilibrium. In Chapter 16, we showed that directional selection generates $d < 0$, decreasing σ_A^2 from its linkage-equilibrium value of σ_a^2 (the Bulmer effect). Under random mating, recombination (for unlinked loci) removes half of the existing d in each generation, which quickly balances any new d introduced by selection (Chapter 16). Under inbreeding, the frequency of heterozygotes (where such recombination takes place) quickly declines, significantly enhancing the impact of linkage disequilibrium (LD) by slowing its decay from recombination.

The first attempts to study the impact of LD when inbreeding is present were in small-scale simulation studies by Bliss and Gates (1968) and Stam (1977), who assumed a finite number of loci in a completely additive model (with no dominance or epistasis). As expected, they found that linkage reduces the rate of selection response, while (for fixed σ_A^2) the per-generation response increases as the number of loci decreases. This latter observation is also to be expected, as increasing the number of loci (with σ_A^2 fixed) reduces the allelic effect at any single locus, reducing the amount of selection on that locus (Chapters 24 and 25).

The first analytical investigations on the magnitude of Bulmer effect during selfing were done by Silvela and Diez-Barra (1985) and Cornish (1990a, 1990b). Assume an F_2 population of lines is continually selfed until it is fully inbred, yielding an F_∞ collection of lines. In Cornish's model, a single generation of selection occurs in the F_2 , and its effect on the final (F_∞) lines was examined. Cornish assumed directional truncation selection, whereby the upper fraction (p) of the population is saved. Recall (Equation 16.11a) that in this setting, the phenotypic variance following selection is reduced by $\bar{\tau}(\bar{\tau} - x_{[1-p]})\sigma_z^2$, where the selection intensity, $\bar{\tau}$, is a function of p (Equation 14.3a) and $x_{[1-p]}$ satisfies $\Pr(U > x_{[1-p]}) = p$, where U is a unit normal. Cornish found that the genetic variance in the offspring of the selected parents is reduced by $h^2\bar{\tau}(\bar{\tau} - x_{[1-p]})\sigma_A^2$, as only a fraction (h^2) of the phenotypic change is passed on to the offspring. In a randomly mating population, the reduction in variance from selection-induced negative LD rapidly approaches an equilibrium value (Equation 16.12e). Upon relaxation of selection under random mating, the variance eventually returns to its preselection value under the infinitesimal model as d decays to zero (Chapter 16). By contrast, because of the dramatic reduction in the fraction of heterozygotes in a selfing population, part of this reduction in variance from LD is permanent. Thus, while LD in a randomly mating population reduces the *rate* of response, with selection in a selfing population, it also impacts the final selection *limit*.

A far more detailed investigation of the Bulmer effect under the infinitesimal model was performed by Hayashi and Ukai (1994) and Kelly (1999a). We examine the results of Hayashi and Ukai here and return to Kelly's more general treatment (under partial selfing) at the end of the chapter. Hayashi and Ukai obtained recursion equations for the changes in variance and covariance for a pure-line cross. They assumed that truncation selection starts in the F_2 generation and continues for t generations. If only additive variance is present,

$$\sigma_A^2(t+1) = \sigma_{A_o}^2(t+1) - \sigma_{A_o}^2(t) + \left[1 - \bar{\tau}(\bar{\tau} - x_{[1-p]}) \frac{\sigma_A^2(t)}{\sigma_A^2(t) + \sigma_e^2}\right] \sigma_A^2(t) \quad (23.30)$$

where $\sigma_{A_o}^2(t) = (2 - 1/2^t) \sigma_A^2(0)$ is the total additive variance in an unselected population of lines following t generations of selfing (this is akin to the genic variance, σ_a^2 , in Equations

16.2 and 16.8b, which remains unchanged by selection under the infinitesimal when under random mating). Hence, $\sigma_{A_o}^2(t+1) - \sigma_{A_o}^2(t)$ can be regarded as the within-line segregation variance, which (for unlinked loci) is unaffected by selection (Equation 16.8b), but (unlike the random mating case) is strongly influenced by inbreeding, as

$$\sigma_{A_o}^2(t+1) - \sigma_{A_o}^2(t) = [(2 - 1/2^{t+1}) - (2 - 1/2^t)] \sigma_A^2(0) = \sigma_A^2(0)/2^{t+1}$$

which shrinks to zero as lines become progressively inbred. This fraction represents the opportunity for recombination in any remaining heterozygotes to reduce selection-induced disequilibrium. The remaining component in the brackets of Equation 23.30 represents the change in the among-line variance (the variance in progeny means), which is reduced by selection, and represents the impact of disequilibrium (akin to the generation of d in Chapter 16). Note that for the first generation of selection, this reduces to $[1 - h^2\bar{v}(\bar{v} - x_{[1-p]})]\sigma_A^2$, namely, Cornish's result. Note, however, that Equation 23.30 shows that Cornish's result neglects the partial decay of this disequilibrium due to recombination in any remaining heterozygotes (the $\sigma_{A_o}^2(t+1) - \sigma_{A_o}^2(t)$ term), and thus is an overestimation of $\sigma_A^2(t)$.

If both additive and dominance effects are present, they will have correlated changes and the recursion equations will be more complex. Some simplifications occur because of the pure-line cross assumption (as $\sigma_{ADI} = \sigma_{DI}^2 = 0$ and $\iota^* = \sigma_D^2$). By letting $\sigma_{G_o}(T, t)$ denote the cross-generational covariance under pure selfing (starting with a pure-line cross), Hayashi and Ukai showed (for unlinked loci) that

$$\sigma_G(T, t) = \sigma_{G_o}(T, t) - \bar{v}(\bar{v} - x_{[1-p]}) \sum_{k=0}^{t-1} \frac{\sigma_G(t, k) \sigma_G(T, k)}{\sigma_G(k, k) + \sigma_e^2} \quad (23.31a)$$

where

$$\sigma_{G_o}(T, t) = (2 - 2^{-t}) (\sigma_A^2 + 2^{-T} \sigma_D^2) \quad (23.31b)$$

is simply the covariance between relatives in generations t and T in the absence of selection (when $\sigma_{ADI} = \sigma_{DI}^2 = 0$ and $\iota^* = \sigma_D^2$, Equation 23.23 reduces to Equation 23.31b). Equation 23.31a is solved by iteration, starting with

$$\sigma_G(T, 0) = \sigma_{G_o}(T, 0) = \sigma_A^2 + 2^{-T} \sigma_D^2 \quad (23.31c)$$

As mentioned, part of the relative simplicity of these expressions arises from the assumption of a pure-line cross. Kelly (1999a) considered more general cases, which require iterative expressions for the changes in σ_{DI}^2 and σ_{ADI} from disequilibrium (see Equations 23.67–23.68).

Example 23.6. As an application of the Hayashi-Ukai variance correction, assume the values used in Example 23.5 ($\sigma_A^2 = 50$, $\sigma_D^2 = 25$, and $\sigma_e^2 = 50$). The fraction saved was $p = 0.2$, and hence $\bar{v} = 1.402$. Likewise, $x_{[1-p]} = x_{[0.8]} = 0.84$ (Example 16.3), so $\bar{v}(\bar{v} - x_{[1-p]}) = 0.788$. From Equation 23.31c, the genetic covariance between a selected F₂ individual (generation $t = 0$) and a relative after T generations of selfing is

$$\sigma_G(T, 0) = \sigma_{G_o}(T, 0) = \sigma_A^2 + 2^{-T} \sigma_D^2 = 50 + 25/2^T$$

Note that this covariance is the same as with pure selfing. The covariance between an individual selected in the next generation (1) and its relative in generation T of selfing does, however, show a reduction, with Equation 23.31a yielding

$$\sigma_G(T, 1) = \sigma_{G_o}(T, 1) - \bar{v}(\bar{v} - x_{[1-p]}) \frac{\sigma_G(1, 0) \sigma_G(T, 0)}{\sigma_G(0, 0) + \sigma_e^2}$$

The first term is the pure-selfing covariance, and the second is the reduction due to selection. To obtain the value of the latter, first note that $\sigma_G(1, 0) = 50 + (25/2) = 62.5$, while $\sigma_G(0, 0) + \sigma_e^2 = 125$ and (Equation 23.31b) $\sigma_{G_o}(T, 1) = (3/2) [50 + (25/2^T)]$, yielding

$$\begin{aligned}\sigma_G(T, 1) &= (3/2) [50 + (25/2^T)] - 0.788 \frac{62.5 \cdot [50 + (25/2^T)]}{125} \\ &= [50 + (25/2^T)] \left(3/2 - 0.788 \frac{62.5}{125} \right)\end{aligned}$$

Because the quantity in the square brackets is proportional to $\sigma_{G_o}(T, 1)$, it follows that $\sigma_G(T, 1)/\sigma_{G_o}(T, 1) = 0.737$ is a constant independent of T , which shows a significant (27%) reduction (over all T) in the predicted response from generation 1 when disequilibrium is ignored. Similarly, applying Equation 23.31c, the genetic variance in generation 1 becomes

$$\begin{aligned}\sigma_G(1, 1) &= \sigma_{G_o}(1, 1) - \bar{t}(\bar{t} - x_{[1-p]}) \frac{\sigma_G(1, 0) \sigma_G(1, 0)}{\sigma_G(0, 0) + \sigma_e^2} \\ &= (3/2)(50 + 25/2) - 0.788 \frac{(62.5)^2}{125} = 69.125\end{aligned}$$

Again, the first quantity is the pure-inbreeding value and the second is the correction for disequilibrium. In this case, the correct genetic variance is only 0.737 of the pure-inbreeding value (which Equation 23.31b gives as 93.75). Because neither the genetic variance nor the covariance for generation 0 are affected by selection ($\sigma_G(0, 0) = \sigma_{G_o}(0)$, and $\sigma_G(T, 0) = \sigma_{G_o}(T, 0)$), the response to selection in generation 0 is unaffected by disequilibrium (this is also the case for a random mating population; see Chapter 16). The response of σ_G^2 in generation 2, however, is influenced by selection. Because both covariance and the genetic variance are reduced by the same fraction (0.737) relative to strict inbreeding, applying Equation 23.3 with the above covariances shows that the ratio of response at generation T from selection in generation 1, $R(T, 1)$, to its predicted value, ignoring disequilibrium, $R_0(T, 1)$, is

$$\frac{R(T, 1)}{R_0(T, 1)} = \left(\frac{\sigma_G(T, 1)}{\sigma_{G_o}(T, 1)} \right) \left(\frac{\sqrt{\sigma_{G_o}(1, 1)}}{\sqrt{\sigma_G(1, 1)}} \right) = \frac{0.737}{\sqrt{0.737}} = 0.859$$

The presence of gametic disequilibrium thus reduces the selection response by 14%.

FAMILY SELECTION UNDER PURE SELFING

Predicting response to family selection—using the phenotypic means of the selfed offspring (perhaps several generations' worth) to choose lines—requires a consideration of the hierarchical structure among the selfed lines in a population (Figure 23.2). The collection of lines descended from a parent at time t (which we can think of as this individual's extended family) are expected to show less within-line variation than a collection of lines from an earlier ancestor at time $k < t$. For family selection, the goal is to predict the selection response, given that we select individuals from generation t on the basis of the performance of their offspring in generation $\tau > t$. We may then wish to know what fraction of this response still persists in some future generation, $T > \tau$ (such as the permanent response, i.e., $T = \infty$). For example, we may select the best lines in generation t based on the performance of their selfed offspring and using remnant seed from the selected families to form the next generation. In this case, $\tau = t + 1$. If individual plants do not produce sufficient seed for family testing, two generations of selfing may be needed to generate a sufficiently large family, in which case $\tau = t + 2$.

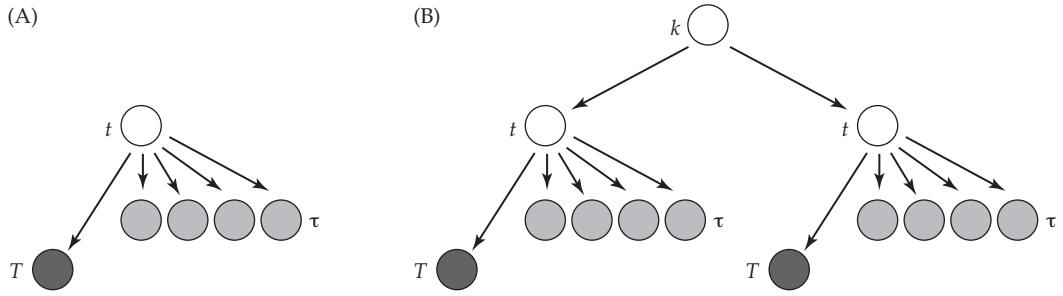

Figure 23.2 The hierarchical structuring of selfed populations. The gray circles denote sibs in the selection unit, the solid circles denote relatives of interest, and k , t , T , and τ denote the generations of selfing experienced by an individual. The arrows denote lines of descent through selfing and may be longer than one generation. **A:** Often we select using a parent in generation t of selfing by scoring its (selfed) offspring in generation τ , and we need the covariance between τ and some future generation, T , where the common relative to both is from generation t . **B:** Another level of hierarchical structuring of selfed populations: When selecting within a substructure of the selfing pedigree, we may be interested in the response using parents in generation t whose offspring are scored in generation τ and for which the response is across those families in the pedigree sharing an earlier common parent in generation $k < t$.

The Covariance Between Relatives in a Structured Selfing Population

Given the need to account for the structure in a selfing population, Cockerham (1983) and Cockerham and Martzinger (1985), built on concepts from Horner (1952) and Gates et al. (1957) and generalized the covariance given by Equation 23.23 to $\sigma_G(T, \tau, t)$, the covariance between a relative in generation T and another relative in generation $\tau \leq T$, when the last common relative of both is from generation $t \leq \tau$ (Figure 23.2A). This covariance was given by Equation 11.15, namely,

$$\begin{aligned} \sigma_G(T, \tau, t) = & (1 + f_t) \sigma_A^2 + \left(\frac{(1 - f_T)(1 - f_\tau)}{1 - f_t} \right) \sigma_D^2 + \left(f_t + \frac{f_T + f_\tau}{2} \right) \sigma_{ADI} \\ & + \left(f_t + \frac{(f_T - f_t)(f_\tau - f_t)}{2(1 - f_t)} \right) \sigma_{DI}^2 + \left(\frac{f_t(1 - f_T)(1 - f_\tau)}{1 - f_t} \right) \iota^* \\ & + (1 + f_t)^2 \sigma_{AA}^2 + (1 + f_t)^3 \sigma_{AAA}^2 + \dots + (1 + f_t)^k \sigma_{A^k}^2 \end{aligned} \quad (23.32)$$

where $t \leq \tau \leq T$. Notice that Equation 23.32 reduces to Equation 23.23 when $\tau = t$ (parents are the selection unit), as $\sigma_G(T, t, t) = \sigma_G(T, t)$. The epistatic terms are often ignored, and Equation 23.32 does not account for nonadditive epistatic terms and assumes linkage equilibrium. For cross-generational covariances indexed by two or more relatives, such as $\sigma_G(T, t)$ and $\sigma_G(T, \tau, t)$, we use the convention that the rightmost index (t in this case) references the oldest (earliest-generation) individual, while the leftmost (T in this case) references the youngest (latest-generation). Thus, as one proceeds right-to-left in the index, more recent relatives are being considered; see Figure 23.2. Again, to use these covariances in predicting the selection response, we must make the strong assumption that selection does not significantly modify this covariance from the unselected version (Equation 23.32). The covariance between a parent in generation t and an offspring in generation T follows by noting that here $t = \tau$ and Equation 23.32 reduces to Equation 23.23.

For the special case of a pure-line cross ($\iota^* = \sigma_D^2$, $\sigma_{DI}^2 = \sigma_{ADI} = 0$), Equation 23.32 simplifies considerably, to

$$\begin{aligned} \sigma_G(T, \tau, t) = & (1 + f_t) \sigma_A^2 + \left(\frac{(1 + f_t)(1 - f_T)(1 - f_\tau)}{1 - f_t} \right) \sigma_D^2 + (1 + f_t)^2 \sigma_{AA}^2 + \dots \\ = & \left(2 - \frac{1}{2^t} \right) \left(\sigma_A^2 + \frac{\sigma_D^2}{2^{T+\tau-t}} + \left(2 - \frac{1}{2^t} \right) \sigma_{AA}^2 + \dots \right) \end{aligned} \quad (23.33)$$

The permanent selection response is given by the covariance between a completely inbred F_∞ line ($f_\infty = 1$) and a relative (for example, from the selection unit) in generation τ who last both shared a relative in generation t (as would occur if remnant seed from t was used to form the new lines). Here, Equation 23.32 reduces to

$$\begin{aligned}\sigma_G(\infty, \tau, t) &= (1 + f_t)\sigma_A^2 + \frac{1 + 2f_t + f_\tau}{2} \sigma_{ADI} + \frac{f_t + f_\tau}{2} \sigma_{DI}^2 \\ &\quad + (1 + f_t)^2 \sigma_{AA}^2 + (1 + f_t)^3 \sigma_{AAA}^2 + \cdots (1 + f_t)^k \sigma_{A^k}^2\end{aligned}\quad (23.34a)$$

For offspring resulting from selfing a pure-line cross, $\sigma_{ADI} = \sigma_{DI}^2 = 0$, leaving the permanent response as only a function of the additive (and additive epistatic) effects,

$$\sigma_G(\infty, \tau, t) = (1 + f_t)\sigma_A^2 + (1 + f_t)^2 \sigma_{AA}^2 + \cdots (1 + f_t)^k \sigma_{A^k}^2 \quad (23.34b)$$

Equation 23.33 also provides the genetic variance for any particular generation. For the sake of a clearer exposition, we will ignore additive epistasis in what follows (although their inclusion is trivial). First, the total genetic variance in generation T is given by

$$\sigma_G(T, T, T) = (1 + f_T)\sigma_A^2 + (1 - f_T)\sigma_D^2 + 2f_T\sigma_{ADI} + f_T\sigma_{DI}^2 + f_T(1 - f_T)\iota^* \quad (23.35a)$$

This is the genetic variance across the entire population (across *all* the lines present in generation T). For a pure-line cross, this reduces to

$$\sigma_G(T, T, T) = (1 + f_T)\sigma_A^2 + (1 - f_T)(1 + f_T)\sigma_D^2 \quad (23.35b)$$

We also require the genetic variance in generation T among the subset of lines that descend from a single individual in generation t . Here, $\tau = T$ and the variance becomes

$$\begin{aligned}\sigma_G(T, T, t) &= (1 + f_t)\sigma_A^2 + \frac{(1 - f_T)^2}{1 - f_t} \sigma_D^2 + (f_t + f_T)\sigma_{ADI} \\ &\quad + \left(f_t + \frac{(f_T - f_t)^2}{2(1 - f_t)} \right) \sigma_{DI}^2 + \frac{f_t(1 - f_T)^2}{1 - f_t} \iota^*\end{aligned}\quad (23.36a)$$

An example of this would be the genetic variance across the collection of F_3 or F_4 **bulk families** from a single F_2 parent. For an F_3 family this is $\sigma_G(1, 1, 0)$, as the F_2 represents generation 0 of selfing, while the entire collection of F_4 families that trace back to this F_2 individual has a variance of $\sigma_G(2, 2, 0)$. For the selfed offspring from a pure-line cross, Equation 23.36a simplifies to

$$\sigma_G(T, T, t) = (1 + f_t)\sigma_A^2 + \frac{(1 - f_T)^2}{1 - f_t} (1 + f_t) \sigma_D^2 \quad (23.36b)$$

Example 23.7. Suppose we wish to know the among-family genetic variance for $S_{i,j}$ families, namely, the bulk collection of S_j families from a single individual in generation i ? From Equation 23.36a, $\sigma_G^2(S_{i,j}) = \sigma_G(j, j, i)$. Substitution of $f_t = 1 - 2^{-t}$ and simplifying yields

$$\begin{aligned}\sigma_G^2(S_{i,j}) &= (2 - 2^i)\sigma_A^2 + 2^{-(2j-i)}\sigma_D^2 + (2 - 2^{-i} - 2^{-j})\sigma_{ADI}^2 \\ &\quad + \left(1 + 2^{-(2j+1-i)} - 2^{-j} - 2^{-(i+1)} \right) \sigma_{DI}^2 + 2^{-(2j-i)} (1 - 2^{-i}) \iota^*\end{aligned}$$

Some particular results of interest are

$$\sigma_G(S_{0,1}) = \sigma_A^2 + (1/4)\sigma_D^2 + \sigma_{ADI}/2 + (1/8)\sigma_{DI}^2$$

$$\sigma_G(S_{0,2}) = \sigma_A^2 + (1/16)\sigma_D^2 + (3/4)\sigma_{ADI} + (9/32)\sigma_{DI}^2$$

$$\sigma_G(S_{1,2}) = (3/2)\sigma_A^2 + (1/8)\sigma_D^2 + (5/4)\sigma_{ADI} + (9/16)\sigma_{DI}^2 + (1/16)\iota^*$$

Again, under the common setting of a pure-line cross, these simplify as $\iota^* = \sigma_D^2$ and $\sigma_{DI}^2 = \sigma_{ADI} = 0$.

Finally, it will prove useful to decompose the total genetic covariance, $\sigma_G(T, t)$, into within- and among-family covariances, $\sigma_{Gw}(T, t)$ and $\sigma_{Gb}(T, t)$, respectively, where

$$\sigma_G(T, t) = \sigma_{Gw}(T, t) + \sigma_{Gb}(T, t) \quad (23.37a)$$

The among-family covariance in generation t is the covariance between sibs from a parent in generation $t - 1$

$$\sigma_{Gb}(T, t) = \sigma_G(T, t, t - 1) \quad (23.37b)$$

The within-family genetic covariance follows as

$$\begin{aligned} \sigma_{Gw}(T, t) &= \sigma_G(T, t) - \sigma_{Gb}(T, t) \\ &= \sigma_G(T, t, t) - \sigma_G(T, t, t - 1) \end{aligned} \quad (23.37c)$$

For more general families, $t - 1$ is replaced by $t - j$ when the last common ancestor to the family occurred j generations before the collection of families was scored. Note that the within- and among-family genetic variances in generation t are given by $\sigma_{Gw}(t, t)$ and $\sigma_{Gb}(t, t)$, respectively. Recalling Equation 23.8b, this implies a phenotypic variance for the among-family means of $\sigma_{\bar{z}}(t, t) = \sigma_{Gb}(t, t) + \sigma_e^2$.

Example 23.8. Consider the within- and among-family genetic variances for an $S_{j-1,j}$ family (the offspring from a single S_{j-1} individual). Here $T = \tau = j$ and $t = j - 1$, and from Equation 23.37b, the among-family genetic variance is

$$\sigma_{Gb}(j, j) = \sigma_G(j, j, j - 1)$$

For a pure-line cross, Equation 23.33 (ignoring epistasis) returns

$$\sigma_{Gb}(j, j) = \sigma_G(j, j, j - 1) = \left(2 - \frac{1}{2^{j-1}}\right) \left(\sigma_A^2 + \frac{\sigma_D^2}{2^{j+1}}\right)$$

while from Equation 23.37a, the within-family variance becomes

$$\sigma_{Gw}(j, j) = \sigma_G(j, j, j) - \sigma_G(j, j, j - 1)$$

For a pure-line cross, the genetic variation (ignoring epistasis) in the population is

$$\sigma_G(j, j, j) = \left(2 - \frac{1}{2^j}\right) \left(\sigma_A^2 + \frac{\sigma_D^2}{2^j}\right)$$

giving the within-family variance as

$$\sigma_{Gw}(S_j) = \sigma_G(j, j, j) - \sigma_G(j, j, j - 1) = \left(\frac{1}{2^j}\right) \sigma_A^2 + \left(\frac{3 - 2^{j+1}}{4^j}\right) \sigma_D^2$$

As Figure 23.2B illustrates, we can consider ever-deeper hierarchical levels of population structure with selfing. Suppose we are interested in the response in generation T due to selection among parents in generation t chosen on the basis of their relatives in generation τ , but that we are considering only the response among the subpopulation that descended from a common ancestor in generation k . For example, among all the descendants from a particular S_3 individual, what is the response to selection on their S_4 offspring if we base selection on the S_6 family means? Here T is the generation of interest for the response ($T = \infty$ for the permanent response), $k = 3$, $t = 4$, and $\tau = 6$.

Defining $\sigma_G(T, \tau, t, k)$ as the covariance between T and τ , and given that they shared an ancestor in generation t from subpopulation k , Wright and Cockerham (1986b), following Gates (1954), showed that

$$\sigma_G(T, \tau, t, k) = \sigma_G(T, \tau, t) - \sigma_G(T, \tau, k) \quad \text{for } t > k \quad (23.38)$$

Hence, Equation 23.32 can be used to compute these covariances.

Example 23.9. As an example of the difference between $\sigma_G(T, \tau, t, k)$ and $\sigma_G(T, \tau, t)$, consider the following situation. Suppose we randomly choose F_2 s from a pure-line cross and self a large collection of them, generating a total of 1000 lines. While there are a number of options for advancing these lines, two extremes are to advance single lines from each of the original F_2 s or to advance 1000 lines from a single F_2 . Lacking any other information on the lines, it is obvious that keeping all of the original lines is likely the better strategy (indeed, this was proposed by Compton 1968), but just how much better is it? For both situations, consider the contribution to response in a completely inbred individual ($T = \infty$) from an individual in generation t chosen by the evaluation of relatives in generation $\tau \geq t$.

Because we assumed a pure-line cross, $\sigma_{ADI} = \sigma_{DI}^2 = 0$, and Equation 23.34 yields, for the first strategy,

$$\sigma_G(\infty, \tau, t) = \left(1 - \frac{1}{2^{t+1}}\right) 2\sigma_A^2$$

If selection is delayed until at least the fifth generation of selfing, this is essentially $2\sigma_A^2$. Conversely, the covariance for the second strategy (advancing all the lines from a single F_2) is given by $\sigma_G(\infty, \tau, t, 0)$, as all individuals trace back to a single individual in generation 0 (the F_2). Here Equation 23.38 yields

$$\begin{aligned} \sigma_G(\infty, \tau, t, 0) &= \sigma_G(\infty, \tau, t) - \sigma_G(\infty, \tau, 0) \\ &= \left(1 - \frac{1}{2^{t+1}}\right) 2\sigma_A^2 - \left(1 - \frac{1}{2}\right) 2\sigma_A^2 = \left(1 - \frac{1}{2^{t+1}}\right) \sigma_A^2 \end{aligned}$$

This is one half of the covariance when the entire collection of lines is used. This makes sense, as under the infinitesimal model, in an outbred population (such as the collection of F_2 s), half the additive variance is between individuals and half is generated by segregation within individuals (Chapter 16). The first covariance, $\sigma_G(\infty, \tau, t)$, considers both the variance within a particular line and also the variance among the initial line founders, while the second, $\sigma_G(\infty, \tau, 0)$, focuses solely on the variance within a particular line.

Response to Family Selection

Our earlier discussions of selection with selfing (Equations 23.23–23.28) assumed that the selection unit was the parent (individual selection), meaning that $\tau = t$. More generally, consider a parent in generation t where we save selfed seed from this individual for the recombination unit and test the parent using the mean of its bulked selfed offspring in generation τ , namely, an $S_{t,\tau}$ family (Figure 23.3). For such cases, the response in generation T from

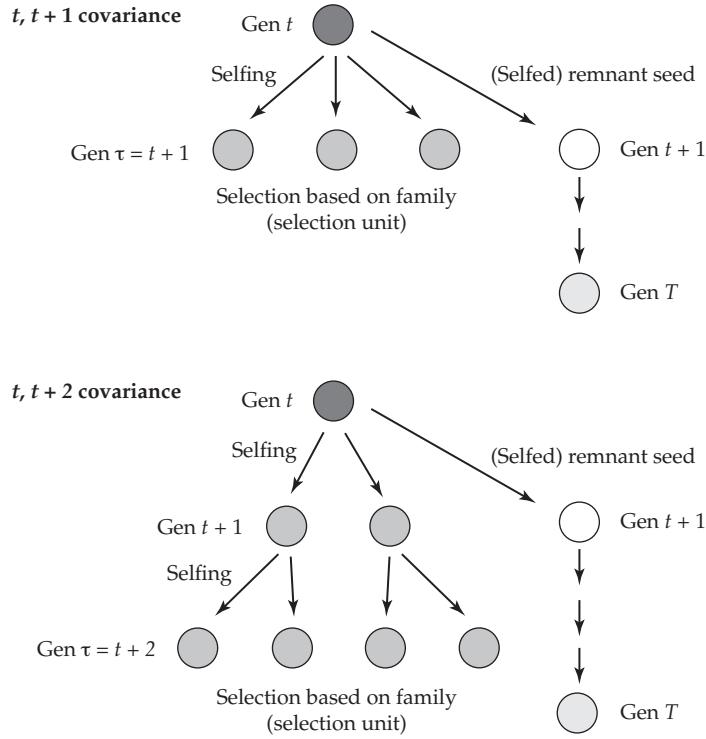

Figure 23.3 Examples of family selection in selfed lines. **Top:** The selection unit is the selfed offspring of a parent, and the recombination unit is a (selfed) remnant seed from this parent, so that selection is based on $S_{t,t+1}$ families. The covariance of interest is between an individual in the selection unit (generation $\tau = t + 1$) and a descendant of the recombination unit (measured in generation T), which had a common parent in generation t . **Bottom:** In species with a low seed set, a single plant may not generate sufficient seed for family testing. In this case, additional seed can be generated by a second round of selfing. If selection is based upon such $S_{t,t+2}$ families, and we use a remnant (selfed) seed from the parent as the recombination unit, the common parent is two generations removed from the selection unit ($\tau = t + 2$).

selection among parents in generation t is

$$R(T, \tau, t) = \bar{r} \frac{\sigma_G(T, \tau, t)}{\sqrt{\sigma_G(\tau, \tau, t) + \sigma_e^2}} \quad (23.39)$$

where σ_e^2 is the error variance for the mean of the $S_{t,\tau}$ family. Equation 23.39 follows because the genetic variance of the selection unit is $\sigma_G(\tau, \tau, t)$, while the covariance between the selection unit (τ) and an offspring of the recombination unit measured in generation T have their last common parent in generation t , and hence the appropriate covariance is given by $\sigma_G(T, \tau, t)$ (Figure 23.3).

For the cases in Figure 23.3, where families are selected and remnant seed from those families is used to form the next (selfed) generation, then for selection based on such $S_{t,t+1}$ families, Equation 23.34 returns the permanent response to selection (that remaining in the fully inbred lines) as

$$\sigma_G(\infty, t + 1, t) = (1 + f_t) \sigma_A^2 + \frac{3 + 5f_t}{4} \sigma_{ADI}^2 + \frac{1 + 3f_t}{4} \sigma_{DI}^2 + (1 + f_t)^2 \sigma_{AA}^2 \quad (23.40a)$$

while for selection based on $S_{t,t+2}$ families,

$$\sigma_G(\infty, t + 2, t) = (1 + f_t) \sigma_A^2 + \frac{7 + 9f_t}{8} \sigma_{ADI}^2 + \frac{3 + 5f_t}{8} \sigma_{DI}^2 + (1 + f_t)^2 \sigma_{AA}^2 \quad (23.40b)$$

As pointed out by Cockerham and Matzinger (1985), the long-term response under these two schemes differs only in the dominance-related terms, σ_{DI}^2 and σ_{ADI} . Because both of these terms are zero in lines derived from the cross of two pure lines, the permanent response in such cases is entirely a function of additive and additive-epistatic effects.

If instead of using remnant seed, a measured sib from the selected families is selfed (strict family selection, as opposed to sib—remnant seed—selection), the expressions become a little more complex. If n family members are scored, the appropriate covariance for the permanent response selection based upon families from one generation of selfing is

$$\frac{1}{n} \sigma_G(\infty, t+1, t+1) + \frac{n-1}{n} \sigma_G(\infty, t+1, t) \quad (23.41a)$$

This arises if we follow the logic leading to Equation 23.8b. Because selection is based on the family mean, $1/n$ is the weight on the individual in the family that is also the recombination unit (hence, the common ancestor is simply this individual, which is in generation $t+1$) and the remainder ($1 - 1/n$) are sibs of this individual (and the common ancestor is in the previous generation). If the number, n , of family members tested is large, the correction given by Equation 23.41a can be ignored and the simpler version (Equation 23.40a) can be used instead. Similarly, if family selection is based on two generations of selfing, then the appropriate covariance becomes

$$\frac{1}{n^2} \sigma_G(\infty, t+2, t+2) + \frac{n-1}{n^2} \sigma_G(\infty, t+2, t+1) + \frac{n-1}{n} \sigma_G(\infty, t+2, t) \quad (23.41b)$$

For large values of n , this reduces to Equation 23.40b.

Within-family Selection Under Selfing

Our results for selfing thus far have only been concerned with selection among lines. If selection is practiced entirely *within* a single selfed lineage (e.g., within the progeny of a single selfed individual), genetic variation is quickly removed and the selection response rapidly ceases. Pederson (1969b) obtained the response remaining in generation T from within-family selection in generation t as

$$r_w(T, t) = \bar{\imath}_t \frac{\sigma_{Gw}(T, t)}{\sqrt{\sigma_{Gw}(t, t) + \sigma_{Ew}^2}} \quad (23.42a)$$

where σ_{Ew}^2 is the within-family environmental variance among individuals. If we apply Equation 23.37c, this becomes

$$r_w(T, t) = \bar{\imath}_t \frac{\sigma_G(T, t, t) - \sigma_G(T, t, t-1)}{\sqrt{\sigma_G(t, t, t) - \sigma_G(t, t, t-1) + \sigma_{Ew}^2}} \quad (23.42b)$$

Recalling Equation 23.34, for a pure-line cross, we have

$$\begin{aligned} \sigma_G(T, t, t) - \sigma_G(T, t, t-1) &= \\ 2^{-t} \sigma_A^2 + 2^{-T} \sigma_D^2 + \sum_{\ell=2}^k &\left[\left(2 - \frac{1}{2^t}\right)^\ell - \left(2 - \frac{1}{2^t}\right)^{\ell-1} \right] \sigma_{A^\ell}^2 \end{aligned} \quad (23.42c)$$

where the sum is over the degree of A -epistasis. Ignoring epistasis, the cumulative response to k generations of selection at generation $T > k$ is

$$R(T | k) = \sum_{t=1}^k \bar{\imath}_t \frac{2^{-t} \sigma_A^2 + 2^{-T} \sigma_D^2}{\sqrt{2^{-t} (\sigma_A^2 + \sigma_D^2) + \sigma_{Ew}^2}} \quad (23.42d)$$

(Pederson 1969b). Note that the sum here begins at selfing generation 1, as selection starts within the S_1 inbred family. Because any within-family genetic variation rapidly decays, after only a few generations the response essentially stops, with the amount of permanent response due to selection in generation t depending on $\sigma_A^2 / 2^t$. Because

$$\sigma_{E_w}^2 \leq 2^{-t} (\sigma_A^2 + \sigma_D^2) + \sigma_{E_w}^2 \leq \sigma_z^2 \quad (23.43a)$$

it follows that the permanent response ($T \rightarrow \infty$) can be bounded by noting

$$\bar{\iota} \frac{\sigma_A^2}{\sigma_{E_w}} \sum_{t=1}^{\infty} 2^{-t} \geq \bar{\iota} \sigma_A^2 \sum_{t=1}^{\infty} \frac{2^{-t}}{\sqrt{2^{-t} (\sigma_A^2 + \sigma_D^2) + \sigma_{E_w}^2}} \geq \bar{\iota} \frac{\sigma_A^2}{\sigma_z} \sum_{t=1}^{\infty} 2^{-t} \quad (23.43b)$$

Because the leftmost and rightmost power series sum to one, the total permanent response $R(\infty | \infty)$ under continued within-family selection (ignoring new mutation) is

$$\bar{\iota} \sigma_A^2 / \sigma_{E_w} \geq R(\infty | \infty) \geq \bar{\iota} h \sigma_A \quad (23.43c)$$

showing that the total response is at least twice the response of the first generation ($\bar{\iota} h \sigma_A / 2$).

Combined Selection

Suppose n_2 F_2 individuals are collected and selfed to create F_3 families of size n_3 for each of the F_2 founding lines. In trying to choose the best F_3 line, we might consider **combined selection**, basing the choice of which individuals to save on both their individual values (z_{ij}) and the average value of the entire F_2 family (\bar{z}_i) from which they derive, with

$$\bar{z}_i = \frac{1}{n_3} \sum_{j=1}^{n_3} z_{ij}$$

where n_3 is the number of measured sibs in the family. By analogy with the family index (Chapter 21), we can select individuals using the index

$$I_{ij} = b \bar{z}_i + z_{ij} \quad (23.44)$$

As with the standard family index, a large value of b places more weight on the family average, while a small value of b places more weight on the individual value. Individuals chosen on the basis of a superior I value are then selfed to complete fixation in order to generate a fully inbred line. The expected response in generation T of selfing follows from a slight modification to the generalized breeder's equation (Equation 13.10b), and is

$$R_y(T) = \bar{\iota} \frac{\sigma(I_{ij}, y_T)}{\sigma(I_{ij})} \quad (23.45)$$

where y_T is a direct descendant of the individual z_{ij} in generation T of selfing. The permanent response is given by considering $T = \infty$.

It will be useful at this point to introduce two variance components that will (somewhat) simplify our results. First define

$$\sigma_c^2(T) = \sigma_G(T, 1, 0) \quad (23.46a)$$

as the variance between crosses (the different F_2 s) and

$$\sigma_{\ell|c}^2(T) = \sigma_G(T, 1, 1) - \sigma_G(T, 1, 0) \quad (23.46b)$$

as the variance in lines within crosses (the variance in deviations from the mean cross effect). For a pure-line cross, these variances are

$$\sigma_c^2(T) = \sigma_A^2 + 2^{-(T+1)}\sigma_D^2 + \sigma_{AA}^2 + \cdots \sigma_{A^k}^2 \quad (23.47a)$$

$$\sigma_{\ell|c}^2(T) = (1/2)\sigma_A^2 + 2^{-T}\sigma_D^2 + (5/4)\sigma_{AA}^2 + \cdots + \left[\left(\frac{3}{2}\right)^k - 1\right]\sigma_{A^k}^2 \quad (23.47b)$$

With these variance components in hand, consider the numerator of Equation 23.45. First note that

$$\sigma(I_{ij}, y_T) = b\sigma(\bar{z}_{i.}, y_T) + \sigma(z_{ij}, y_T)$$

Because y_T is a direct descendant of line ij , $\tau = t = 1$, hence

$$\sigma(z_{ij}, y_T) = \sigma_G(T, 1, 1) \quad (23.48a)$$

Likewise,

$$\sigma(\bar{z}_{i.}, y_T) = \frac{1}{n_3} \sum_{k=1}^{n_3} \sigma(z_{ik}, y_T) = \frac{\sigma(z_{ij}, y_T)}{n_3} + \left(1 - \frac{1}{n_3}\right) \sigma(z_{ik}, y_T)$$

The first term is given by Equation 23.48a, while the second is the covariance between a sib, z_{ik} , of individual ij . Here, the common parent between ik and y is the F_2 , meaning that $t = 0$, $\tau = 1$, and this covariance is $\sigma_G(T, 1, 0)$. Putting these together,

$$\sigma(\bar{z}_{i.}, y_T) = \sigma_G(T, 1, 0) + \frac{\sigma_G(T, 1, 1) - \sigma_G(T, 1, 0)}{n_3} = \sigma_c^2(T) + \frac{\sigma_{\ell|c}^2(T)}{n_3} \quad (23.48b)$$

The numerator covariance in Equation 23.45 thus becomes

$$\sigma(I_{ij}, y_T) = b \left(\sigma_c^2(T) + \frac{\sigma_{\ell|c}^2(T)}{n_3} \right) + \sigma_c^2(T) + \sigma_{\ell|c}^2(T) \quad (23.49)$$

Now turning to the variance of the selection index,

$$\sigma^2(I_{ij}) = \sigma^2(b\bar{z}_{i.} + z_{ij}) = b^2\sigma^2(\bar{z}_{i.}) + \sigma^2(z_{ij}) + 2b\sigma(\bar{z}_{i.}, z_{ij}) \quad (23.50a)$$

First, consider the variance of a random F_3 line,

$$\sigma^2(z_{ij}) = \sigma_G(1, 1, 1) + \sigma_\epsilon^2 = \sigma_c^2(1) + \sigma_{\ell|c}^2(1) + \sigma_\epsilon^2 \quad (23.50b)$$

where σ_ϵ^2 is the within-line error variance. Next, note that

$$\sigma^2(\bar{z}_{i.}) = \frac{n_3 \sigma^2(z_{ij})}{n_3^2} + \frac{n_3(n_3 - 1) \sigma(z_{ij}, z_{ik})}{n_3^2} = \frac{\sigma^2(z_{ij})}{n_3} + \left(1 - \frac{1}{n_3}\right) \sigma(z_{ij}, z_{ik})$$

The first covariance is given by Equation 23.50b, while the second is the covariance between sibs, $\sigma(1, 1, 0)$, which yields

$$\sigma^2(\bar{z}_{i.}) = \frac{\sigma(1, 1, 1) + \sigma_\epsilon^2}{n_3} + \left(1 - \frac{1}{n_3}\right) \sigma(1, 1, 0) = \sigma_c^2(1) + \frac{\sigma_{\ell|c}^2(1) + \sigma_\epsilon^2}{n_3} \quad (23.50c)$$

Finally, we can show that $\sigma(\bar{z}_{i.}, z_{ij}) = \sigma^2(\bar{z}_{i.})$. Putting all these together gives

$$\sigma^2(I_{ij}) = b(b+2) \left(\sigma_c^2(1) + \frac{\sigma_{\ell|c}^2(1) + \sigma_\epsilon^2}{n_3} \right) + \left(\sigma_c^2(1) + \sigma_{\ell|c}^2(1) + \sigma_\epsilon^2 \right) \quad (23.51)$$

Substitution of Equations 23.49 and 23.51 into 23.45 shows the expected response for arbitrary b and $T > 1$.

An obvious question is what value of b maximizes response? Taking the derivative of Equation 23.45 with respect to b and solving for zero returns the optimal value as

$$b = \frac{n_3 \left[\sigma_c^2(T) \sigma_\epsilon^2 - \sigma_c^2(1) \sigma_{\ell|c}^2(1) + \sigma_c^2(T) \sigma_{\ell|c}^2(1) \right]}{\sigma_{\ell|c}^2(T) \left[n_3 \sigma_c^2(1) + \sigma_{\ell|c}^2(1) + \sigma_\epsilon^2 \right]} \quad (23.52)$$

As with family-index selection (Chapter 21), the selection intensity is reduced by the fact that F_3 lines from the same F_2 are related and hence correlated, and we must correct for this correlation. Letting ρ be the correlation between the index scores from lines in the same cross, if we choose the best K from $N = n_2 n_3$ total lines (n_3 lines from each of $n_2 F_2$'s), then Equation 21.57b returns the adjusted selection intensity as

$$\bar{t}_{n_2 n_3, K} = \bar{t}_q - \frac{1-q}{2\bar{t}_q q [n_2 n_3 (1-\rho) + n_2 \rho + 1]} \quad (23.53)$$

where $q = K/N$ is the fraction saved (we use q in place of our normal usage of p to avoid confusion here with ρ) and \bar{t}_q the infinite-population size selection intensity (Equation 14.3a). To compute the correlation, ρ , between index scores, first note that

$$\begin{aligned} \sigma(I_{ij}, I_{ik}) &= \sigma(b\bar{z}_{i..} + z_{ij}, b\bar{z}_{i..} + z_{ik}) \\ &= b^2 \sigma^2(\bar{z}_{i..}) + 2b\sigma(\bar{z}_{i..}, z_{ij}) + \sigma(z_{ij}, z_{ik}) \\ &= [b^2 \sigma^2(\bar{z}_{i..}) + 2b\sigma(\bar{z}_{i..}, z_{ij}) + \sigma^2(z_{ij})] - \sigma^2(z_{ij}) + \sigma(z_{ij}, z_{ik}) \\ &= \sigma^2(I_{ij}) - (\sigma_c^2 + \sigma_{\ell|c}^2 + \sigma_\epsilon^2) + \sigma_c^2 \\ &= \sigma^2(I_{ij}) - (\sigma_{\ell|c}^2 + \sigma_\epsilon^2) \end{aligned} \quad (23.54a)$$

The third step follows upon recalling Equation 23.50a. The correlation between index scores among individuals from the same line thus becomes

$$\rho = \frac{\sigma(I_{ij}, I_{ik})}{\sigma^2(I)} = \frac{\sigma^2(I_{ij}) - (\sigma_{\ell|c}^2 + \sigma_\epsilon^2)}{\sigma^2(I_{ij})} = 1 - \frac{\sigma_{\ell|c}^2 + \sigma_\epsilon^2}{\sigma^2(I_{ij})} \quad (23.54b)$$

Substitution of this value into Equation 23.53 yields the appropriate selection intensity, which is corrected for both finite population size and correlation between lines.

When there is a fixed total number of lines to examine, there is a tradeoff between selection intensity and accuracy. The optimal design for known (or estimated) genetic variances can be obtained by numerically evaluating different combinations of the n_2/n_3 ratio (for fixed values of N) in Equation 23.45 (and its associated components, Equations 23.49 and 23.51–23.53). Weber (1982, 1984; Wricke and Weber 1986) examines index selection under selfing, including both optimal design (in the absence of dominance) and its extension to additional generations of selfing. For example, Weber (1982) considered the more general situation where each F_2 family consists of $n_3 F_3$ families, with each F_3 family consisting of $n_4 F_4$ families and so on to F_j families. In this case, the full index is

$$I = b_2(\bar{z}_2 - \bar{z}) + b_3(\bar{z}_3 - \bar{z}_2) + \cdots + b_j(\bar{z}_j - \bar{z}_{j-1}) \quad (23.55a)$$

The weights, b_k , are chosen to maximize the correlation between the index, I , and the final genetic value of the completely inbred lines (which we denote as g_∞), which (Weber 1982) implies

$$b_k = \frac{\sigma(\bar{z}_k - \bar{z}_{k-1}, g_\infty)}{\sigma^2(\bar{z}_k - \bar{z}_{k-1})} \quad (23.55b)$$

Table 23.4 The covariances required to predict response under partial selfing using Equation 23.56. The probability of selfing is η , with an equilibrium level of inbreeding of $f = \eta/(2 - \eta)$. Let $\sigma_{G_O}(P,O)$ and $\sigma_{G_O}(P,O)$ denote the parent-offspring covariance under outcrossing and selfing (respectively) at equilibrium, while $\sigma_{G(BR)}$ and $\sigma_{G(AR)}$ denote the population-averaged (i.e., over outcrossing and selfing) parent-offspring regression for selection before and after reproduction. (After Wright and Cockerham 1985.)

Cov	σ_A^2	σ_D^2	σ_{ADI}	σ_{DI}^2	ι^*	$\iota^2 - \iota^*$
$\sigma_{G_O}(P,O)$	$\frac{1+f}{2}$	0	$\frac{f}{2}$	0	0	0
$\sigma_{G_S}(P,O)$	$1 + f$	$\frac{1-f}{2}$	$\frac{1+7f}{4}$	f	$\frac{f(1-f)}{2(2+f)}$	$\frac{f(1-f^2)}{2(2+f)}$
$\sigma_{G(AR)}$	$\frac{1+3f}{2}$	$\frac{f(1-f)}{1+f}$	$\frac{2f(1+3f)}{2(1+f)}$	$\frac{2f^2}{1+f}$	$\frac{f^2(1-f)}{(1+f)(2+f)}$	$\frac{f^2(1-f^2)}{(1+f)(2+f)}$
$\sigma_{G(BR)}$	$1 + f$	$\frac{f(1-f)}{1+f}$	$\frac{f(3+5f)}{2(1+f)}$	$\frac{2f^2}{1+f}$	$\frac{f^2(1-f)}{(1+f)(2+f)}$	$\frac{f^2(1-f^2)}{(1+f)(2+f)}$
σ_G^2	$1 + f$	$1 - f$	$2f$	f	$\frac{f(1-f)}{2+f}$	$\frac{f(1-f^2)}{2+f}$

Consult Weber (1982) for further details. Finally, an important extension of combined selection schemes is the work of Cowling et al. (2015), who incorporated multiple-generation family information into a BLUP-based index (i.e., they used the animal model to predict the breeding values of focal individuals).

RESPONSE UNDER PARTIAL SELFING

One of the most widespread natural systems of inbreeding is **partial selfing**, wherein each individual can either self or outcross. If η is the probability of selfing, then an unselected population approaches a *mean* inbreeding value of $f = \eta/(2 - \eta)$, but there is a *distribution* of inbreeding values among individuals within the population. In particular, the probability that an individual is inbred to a level of $f_i = 1 - 2^{-i}$ follows a geometric distribution with a success parameter, η , yielding $\Pr(f_i) = (1 - \eta)\eta^i$. This lack of uniformity in f greatly complicates the prediction of selection response. In particular, nonlinear parent-offspring regressions can occur and selection can change the distribution of inbreeding-value classes away from a simple geometric form (Wright and Cockerham 1985; Kelly 1999a). Our treatment first presents approximate results using covariances by treating the entire population as a single unit. We then consider a more careful treatment due to Kelly (1999a, 1999b) that considers the selection response *within* each group at a given level of inbreeding (i.e., all group members have the same f value), which also examines the impact of selection-induced disequilibrium.

An Approximate Treatment Using Covariances

Partial selfing has been examined by Wright and Cockerham (1985, 1986a) and Wright (1988), who obtained the appropriate cross-generational covariances and predicted response when using the method on ancestral regression. They assumed that the population is at the equilibrium mean inbreeding value and that each individual has the same probability (η) of selfing (i.e., there is no genetic variation in selfing vs. outcrossing rates). Because a parent can either self or outcross (or both, e.g., on different flowers on the same plant), the parent-offspring covariance must take this into account. Further, because of selfing, the covariances for selection before and after reproduction are slightly different. For selection before reproduction (BR), the single-generation response is given by

$$R_{BR} = \bar{\iota} \frac{\sigma_{G(BR)}(t+1, t)}{\sqrt{\sigma_G^2 + \sigma_e^2}} \quad (23.56a)$$

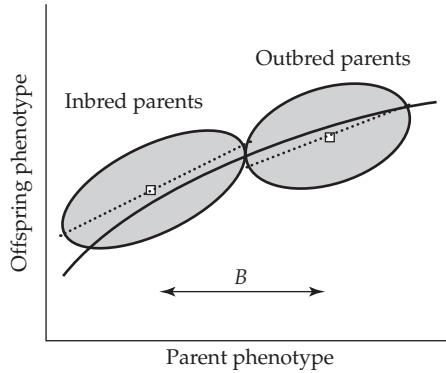

Figure 23.4 When inbreeding depression is present, the parent-offspring regression under partial selfing can be nonlinear. To see this, suppose we have just two groups: $f = 0$ (outcrossed) and $f = 1$ (fully inbred). Within each group, parent-offspring regressions are linear (as indicated by the dashed lines). However, for the population as a whole (i.e., examining individuals without knowledge of which group they belong to), the regression is nonlinear. Here B denotes the inbreeding depression (the change in mean, the open squares, between the outcrossed and fully inbred populations). (After Kelly 1999a.)

where the genetic covariance for selection before reproduction is

$$\sigma_{G(BR)}(t+1, t) = 2(1 - \eta)\sigma_{GO}(P, O) + \eta\sigma_{GS}(P, O) \quad (23.56b)$$

where $\sigma_{GO}(P, O)$ is the parent-offspring covariance under outcrossing and $\sigma_{GS}(P, O)$ is the parent-offspring covariance under selfing. Because the population is assumed to be at its inbreeding equilibrium, the parent-offspring covariances and total genetic variation (σ_G^2) are assumed to be constants, independent of t . Table 23.4 shows the coefficients for these covariances, as well as those for σ_G^2 . Note that an additional quadratic component, $\iota^2 - \iota^*$, also appears in the covariance between relatives (which arises because there is a distribution of inbreeding values in the population). As we will see, there is a significant transient component to the immediate response. For selection after reproduction (AR), an outcrossed individual has only one parent under selection (the pollen parent not being under selection), and the covariance in the numerator of Equation 23.56a is replaced by

$$\sigma_{G(AR)}(t+1, t) = (1 - \eta)\sigma_{GO}(P, O) + \eta\sigma_{GS}(P, O) \quad (23.56c)$$

The permanent response to selection is given by replacing the numerator covariance in Equation 23.56a by the appropriate version of $\sigma_G(\infty, t)$. For selection before reproduction, Wright and Cockerham showed that this equals

$$\sigma_{G(BR)}(\infty, t) = (1 + f)\sigma_A^2 + \left[\frac{\eta(3 - \eta)}{(2 - \eta)^2} \right] \sigma_{ADI} + \left[\frac{\eta^2}{(2 - \eta)^2} \right] \sigma_{DI}^2 \quad (23.57a)$$

Further, the before- and after-selection covariances are related by

$$\sigma_{G(AR)}(\infty, t) = \left(\frac{1 + \eta}{2} \right) \sigma_{G(BR)}(\infty, t) \quad (23.57b)$$

While the coefficient on σ_A^2 is unchanged in $\sigma_G(\infty, t)$ ($1 + f$ for any value of t), the limiting contributions ($T = \infty$) from all the other quadratic components have rather different coefficients relative to their single-generation values. Thus, the transient component of response is expected to be considerable. Wright and Cockerham found that

$$\sigma_{G(BR)}(t + T, t) = \sigma_{G(BR)}(\infty, t) + \left[\sigma_G^2 - \sigma_{G(BR)}(\infty, t) \right] \left(\frac{\eta}{2} \right)^T \quad (23.58)$$

with a similar expression for the covariance for selection after reproduction. The transient component decays rather rapidly, as the rate of decay is no slower than 2^{-T} . Wright and Cockerham also showed that the final change in the mean from a generation of selection can be predicted from the response in the first two generations after selection, with

$$\bar{z}_\infty = \frac{2\bar{z}_2 - \eta\bar{z}_1}{2 - \eta} \quad (23.59)$$

where \bar{z}_i is the mean i generations after a generation of selection. Family selection was also examined by Wright and Cockerham (1986a) and Edwards (2008). With partial-selfing, there are a number of potential families that one can consider for the selection unit: outcrossed half- and full-sibs, selfed individuals, or naturally pollinated individuals (a mixture of selfed and outcrossed progeny). Consult Wright and Cockerham for details on response under these different systems.

While straightforward (beyond some tedious bookkeeping), there are several potential problems with this covariance approach for accommodating partial selfing, which arise from individuals varying in the amount of selfing. In particular, selected individuals may not be a random sample of the inbreeding classes. If the focal trait shows inbreeding depression, the less-inbred individuals are expected to be chosen by selection more often. This has the effect of creating a nonlinear parent-offspring regression (Figure 23.4). If the nonlinearity is significant, the covariance approach (which makes predictions based on a *linear* regression) is inappropriate. Even in the absence of inbreeding depression on the focal trait, more-inbred individuals are often expected to be generally less fit. Together with any inbreeding depression on the focal trait, this skews the distribution of selected individuals that have selfed for i generations away from the geometric value $(1-\eta)\eta^i$ predicted under no selection (Kelly 1999a).

A More Careful Treatment: Kelly's Structured Linear Model

Kelly (1999a, 1999b; Kelly and Williamson 2000) proposed an alternative approach for examining the selection response with partial selfing. By analogy with a geographically structured population, he suggested that a more careful approach is to consider the population as a set of cohorts, within which all individuals have the same level of inbreeding. Cohort 0 contains all individuals that arose through random mating in the previous generation, cohort 1 contains those individuals that arose from selfing in the previous generation, and cohort i contains those individuals that have undergone i rounds of selfing before they last enjoyed random mating, with $f_i = 1 - 1/2^i$. Kelly terms this approach a **structured linear model (SLM)**, as within each cohort, it is assumed that the parent-offspring regressions are linear. The response under selfing is then predicted by specifying both the within-cohort variances and covariances and the among-cohort transitions. Besides properly accounting for the structured nature of partly selfing populations, Kelly's treatment also accommodates the effects of linkage disequilibrium (under the infinitesimal-model assumptions).

Before examining the SLM approach, we discuss several important observations from simulations reported by Kelly (1999a; Kelly and Williamson 2000). If directional dominance is present (which implies that inbreeding depression occurs; LW Chapter 10), then the distribution of the cohorts will not follow the geometric distribution predicted from the strict (i.e., no selection) partial-selfing model. Instead, selection greatly skews this distribution. For example, when advantageous alleles are recessive, inbred individuals will be overrepresented, while when advantageous alleles are dominant, inbreds are underrepresented. In either setting, the Wright-Cockerham covariance approach provides incorrect results, as it assumes that there is a geometric distribution of inbreeding values. The deviation from this distribution caused by selection can be quite striking. For example, after 10 generations of selection when beneficial recessives are present, the cohort distribution is strongly bimodal, with peaks at 0 (outbreeding) and 10 (selfing for all 10 generations). A second feature seen in Kelly's simulations was that linkage disequilibrium generated significant changes in the variances and covariances. Changes in the value of f for the population directly impact the

usable level of additive variance, and selfing reduces the chance for recombination in heterozygotes to break down nonrandom associations generated by selection. Such selection-induced changes in the covariances from their strict (i.e., no-selection) partial-selfing values also compromises the results from the covariance approach.

Turning to the details of Kelly's approach, define cohort i as the collection of individuals that have undergone i generations of selfing since their last outcrossing. Let $\pi_i(t)$ denote the frequency of cohort i in generation t , where $\pi_i(t) = (1 - \eta)\eta^i$ in the absence of selection. If we assume that selection acts before reproduction, the transition probabilities between cohorts are as follows: with probability $1 - \eta$, an individual outcrosses, so

$$\pi_0(t + 1) = 1 - \eta \quad (23.60a)$$

For an individual to enter cohort $i + 1$, it must have been a member of cohort i in the previous generation and it must self. Further, Kelly allows for selection against cohorts (for example, highly inbred individuals may have lower fitness). If $W(t)$ and $W_i(t)$ denote the average fitness of a random individual from the population and from cohort i (respectively) in generation t , then the fraction of the population that is in cohort i after selection (but before reproduction) is $\pi_i(t) W_i(t)/W(t)$. Putting all these together, the fraction of the population in cohort $i + 1$ in the next generation is

$$\pi_{i+1}(t + 1) = \eta \left(\frac{W_i(t)}{W(t)} \right) \pi_i \quad (23.60b)$$

In the absence of selection, namely, $W_i(t) = W(t)$ for all i , Equation 23.60b generates a geometric distribution, with $\pi_i(t) = (1 - \eta)\eta^i$.

Now consider the dynamics of the mean. Because a member of cohort i has an inbreeding level of $f_i = 1 - 2^{-i}$, the mean value of inbreeding for the population is

$$f(t) = \sum \pi_i(t) f_i = \sum \pi_i(t) (1 - 2^{-i}) = 1 - \sum \pi_i(t)/2^i \quad (23.61)$$

Denote the allele frequency-weighted sum of average effects by A (the average breeding value) and the weighted sum of homozygous dominance deviations by B , so that

$$A = 2 \sum_k \sum_j \alpha_{kj} p_{kj}, \quad B = \sum_k \sum_j \delta_{kjj} p_{kj} \quad (23.62)$$

where α_{kj} is the average effect for allele j from locus k , p_{kj} is the allele frequency, and δ_{kjj} represents the dominance deviations for homozygotes (where α_{kj} and δ_{kjj} are the values for a base population in Hardy-Weinberg equilibrium with the same allele frequencies, p_{kj}). If $A(t)$ and $B(t)$ denote the average values of A and B at generation t , then the mean population phenotype is

$$z(t) = \mu + A(t) + f(t)B(t) \quad (23.63a)$$

This is simply a restatement of Equation 23.1c, as $A(t)$ is the response in the absence of inbreeding and $f(t)B(t)$ is the amount of inbreeding depression (Equation 23.1b). If we let $A_i(t)$ and $B_i(t)$ denote the average value of A and B in cohort i in generation t , it follows that

$$A(t) = \sum \pi_i(t) A_i(t), \quad \text{and} \quad B(t) = \sum \pi_i(t) B_i(t) \quad (23.63b)$$

Kelly assumed that *within* each cohort, the parent-offspring regressions are linear, which means that the value, A' , of A following selection in cohort i is

$$A'_i(t) = A_i(t) + \frac{\sigma_{Az,i}(t)}{\sigma_{z,i}^2(t)} S_i(t) \quad (23.64a)$$

where $\sigma_{Az,i}$ is the covariance between A and z (the breeding value and phenotype, respectively) prior to selection at an inbreeding level of f_i . Because the mean additive value of selfed offspring (now in cohort $i+1$) equals that of their parent (from cohort i),

$$A_{i+1}(t+1) = A'_i(t) = A_i(t) + \frac{\sigma_{Az,i}(t)}{\sigma_{z,i}^2(t)} S_i(t) \quad (23.64b)$$

Likewise, the mean additive value of outcrossed offspring equals the average additive values of their parents,

$$A_0(t+1) = \sum_i \pi_i(t) A'_i(t) = A(t) + \sum_i \pi_i(t) \frac{\sigma_{Az,i}(t)}{\sigma_{z,i}^2(t)} S_i(t) \quad (23.64c)$$

Under linkage equilibrium, Kelly showed that these covariance functions are given by

$$\sigma_{Az,i}(t) = (1 + f_i) \sigma_A^2 + f_i \sigma_{ADI} \quad (23.65a)$$

Similar expressions exist for $B_i(t)$, with B replacing A in Equations 23.64a–23.64c (under linkage equilibrium), and with the cohort- i covariance between B and z given by

$$\sigma_{Bz,i}(t) = \sigma_{ADI} (1 + f_i)/2 + f_i \sigma_{DI}^2 \quad (23.65b)$$

Finally, again under linkage equilibrium, the phenotypic variance in cohort i is given by

$$\sigma_{z,i}^2(t) = \sigma_G^2(i, i) + \sigma_{e,i}^2 \quad (23.65c)$$

where $\sigma_G^2(i, i)$, the genetic variance after i generations of selfing, is shown by Equation 23.23. Iteration of these equations calculates the evolution of the $A_i(t)$ and $B_i(t)$ values, from which the population mean in generation t can be obtained from Equations 23.63b and 23.63c.

As mentioned throughout this chapter, selection-induced gametic-phase disequilibrium (LD) can have a dramatic effect on the covariances (even for unlinked loci), and indeed this was observed in Kelly's above-mentioned simulations. To accommodate this concern, Kelly suggested an iterative approach (along the lines of our results for random mating from Chapter 16 and of Hayashi and Ukai's (1994) results for pure selfing; Equation 23.30) for computing all the required covariances when disequilibrium is present. As in Chapter 16, let

$$\kappa_i(t) = 1 - \frac{\sigma_{z^*,i}^2(t)}{\sigma_{z,i}^2(t)} \quad (23.66)$$

denote the reduction in the phenotypic variance (in this case, in cohort i) caused by selection, where $\sigma_{z^*,i}^2(t)$ is the phenotypic variance (in inbreeding cohort i) after selection. Under the infinitesimal-model assumptions, Kelly showed that the recursion equations for the variances and covariances in the inbred cohorts ($i \geq 1$) become

$$\sigma_{A,i+1}^2(t+1) = \sigma_{A,i}^2(t) - \kappa_i(t) \frac{[\sigma_{Az^*,i}(t)]^2}{\sigma_{z,i}^2(t)} + 2^{-(i+1)} \sigma_A^2 \quad (23.67a)$$

$$\sigma_{AB,i+1}^2(t+1) = \sigma_{AB,i}^2(t) - \kappa_i(t) \frac{\sigma_{Az^*,i}(t) \sigma_{Bz^*,i}(t)}{\sigma_{z,i}^2(t)} + 2^{-(i+2)} \sigma_{ADI} \quad (23.67b)$$

$$\sigma_{B,i+1}^2(t+1) = \sigma_{B,i}^2(t) - \kappa_i(t) \frac{[\sigma_{Bz^*,i}(t)]^2}{\sigma_{z,i}^2(t)} + 2^{-(i+2)} \sigma_{DI}^2 \quad (23.67c)$$

where

$$\sigma_{Az^*,i}(t) = \sigma_{A,i}^2(t) + (1 - 2^{-i}) \sigma_{AB,i}(t) \quad (23.67d)$$

$$\sigma_{Bz^*,i}(t) = \sigma_{AB,i}(t) + (1 - 2^{-i}) \sigma_{B,i}^2(t) \quad (23.67e)$$

For Equations 23.67a–23.67c, the first term is the variance (covariance) before selection, the second term is the reduction from selection, and the final term is the contribution from segregation (these are the extensions of Equation 16.8b to selfing). These generalize the previous results of Hayashi and Ukai (1994; Equation 23.30). If we note that $B = 0$ when only additive gene action is present, then recalling Equation 16.11a recovers Equation 23.30.

The recursion equations for the outbred cohort are more involved, as parents are inbred to differing degrees. Letting $f'(t)$ denote the average value of inbreeding among selected parents, then

$$\sigma_{A,o}^2(t+1) = \frac{1}{2} \sigma_{A'}^2(t) + \frac{1}{2} [1 - f'(t)] \sigma_A^2 \quad (23.68a)$$

$$\sigma_{AB,o}(t+1) = \frac{1}{2} \sigma_{AB'}(t) + \frac{1}{4} [1 - f'(t)] \sigma_{ADI} \quad (23.68b)$$

$$\sigma_{B,o}^2(t+1) = \frac{1}{2} \sigma_{B'}^2(t) + \frac{1}{4} [1 - f'(t)] \sigma_{DI}^2 \quad (23.68c)$$

Variances and covariances denoted by a prime are the population averages in the selected parents, and f' denotes the average inbreeding over all selected parents. Unfortunately, these cannot be simply expressed as base-population genetic components; see Kelly (1999a) for expressions.

CONCLUSIONS: AN INCOMPLETE THEORY FOR SHORT-TERM RESPONSE

For all of the detailed formulae presented in this chapter, it must be stressed that predicting even the short-term selection response under inbreeding is based on a very incomplete theory. Most of the covariance expressions assume linear parent-offspring regressions and make the strong assumption that selection does not significantly change covariances from their neutral expectations under the mating system. While this may not be an unreasonable assumption in regard to allele-frequency change when many genes of small effect underlie a trait, it ignores the important impact of gametic-phase disequilibrium (LD), which can be dramatic (i.e., a 27% reduction after one generation was seen in Example 23.6). One effect of inbreeding is suppressing the impact of recombination, as the frequency of heterozygotes (which facilitate the breakdown of gametic phase disequilibrium via recombination) quickly becomes very small under inbreeding before vanishing entirely. Thus, gametic-phase disequilibrium is significantly more impactful than under random mating, where its effects are not trivial (Chapter 16).

Further, a practical concern is that, even if the above expressions are reasonable approximations despite these concerns, the inbreeding variance-components (ι^* , σ_{DI}^2 , σ_{ADI}) are challenging, at best, to estimate. However, Chapter 11 shows that in those few cases where attempts have been made to estimate these, they are often very small, suggesting that standard additive and dominance terms dominate the covariances in many settings. If correct, this substantially reduces the complexity of predicting short-term selection response. Conversely, the impact from inbreeding depression, especially when starting from largely outbred populations, is typically not trivial (LW Chapter 10). Fortunately, it is straightforward to both estimate its impact and include its effect in standard models of short-term response (Equation 23.2b). It needs to be stressed, however, that the assumption that there is only a small amount of allele-frequency change is critical here, as the composite parameter B (Equations 23.1a, 23.1b, and 23.62) for the impact of inbreeding depression is a function of allele frequencies.

The robust results from all of this theory are that: (i) inbreeding can facilitate among-family selection while hampering within-family selection, (ii) when dominance is present, gains from early generations of inbreeding may significantly erode by the time inbreeding is complete, and (iii) inbreeding depression can have a significant impact on selection response in outbred species (depressing both the apparent response and the overall fitness of

the population). From an applied standpoint, progeny testing and family selection can be improved with the judicious use of either inbred offspring or parents, but the cost in terms of additional time and resources can more than offset any gain.

THE EVOLUTION OF SELFING RATES

Finally, as we saw in Chapter 4, selection shapes the parameters of fundamental genetic processes, and the selfing rate is no exception. Monoecy (the lack of separate sexes, namely, **hermaphroditism**) is not uncommon among multicellular organisms, occurring in ~94% of angiosperms (Renner and Ricklefs 1995) and ~6% of animals (Järne and Auld 2006). Hermaphroditism is common in 14 animal phyla, including the major phyla Porifera, Cnidaria, Platyhelminthes, Mollusca, and Annelida. When arthropods are excluded, the fraction of hermaphroditic animals increases to about 1/3 (Järne and Auld 2006). Hence, the *opportunity* for selfing is widespread throughout multicellular life in that hermaphroditic species are widespread. However, many of these species have either genetic (self-incompatibility systems) or behavioral and morphological features that encourage outcrossing. Examples of the latter include flower morphology in the angiosperms (Barrett 2002), such as the distance between the anthers and stigma and their placement. Similarly, the timing of pollen release and the receptivity of a stigma may be completely or largely nonoverlapping (**dichogamy**), while sexually mature hermaphroditic animals often have a significant **waiting time** before they will engage in selfing.

Morphological, phenological, and behavioral features that influence the selfing rate are standard quantitative traits and hence have the potential to respond to selection. For example, selfing rates could potentially be changed by altering the timing of pollen release and stigma receptivity or the distance between anthers and stigma (Example 23.10). It could also be modified by selection for other features, such as reduced floral displays, an extreme example being **cleistogamy** (flowers whose petals do not open, facilitating self-pollination). These observations raise the widely debated question of the nature of the forces behind the evolution of various mating systems. While this is a very active and diverse field, we limit our discussion here to a brief overview of the forces influencing the selfing rate among hermaphrodites and mainly focusing on monoecious angiosperms.

Automatic Selection, Inbreeding Depression, and Reproductive Assurance

As first noticed by Fisher (1941), the foundational question of mating-system evolution is, “Why are not all hermaphrodites selfers?” This is because of **transmission bias**, which is often referred to as **automatic selection** or the **cost of outcrossing**. Consider a hermaphrodite that selfs. It contributes both eggs and pollen or sperm to its resulting selfed offspring, and it can potentially contribute sperm or pollen to other conspecifics that outcross. Conversely, an outcrossing hermaphrodite contributes an egg that combines with the pollen or sperm of another individual and pollen or sperm that fertilizes the egg of another conspecific. Hence, there is a three to two transmission bias in favor of selfers, generating a 50% selective advantage of an allele that promotes selfing (Fisher 1941; Nagylaki 1976b; Lloyd 1979).

As noticed by Nagylaki (1976b), such a selfing gene only spreads if it is also contributes to the pollen or sperm pool for outcrossers (otherwise, the allele never spreads beyond its selfed lineage). The generalization of this latter observation is the notion of **pollen discounting**, wherein the 50% selection advantage due to increased transmission of the selfing allele becomes discounted if the allele also results in reduced pollen for outcrossing, with any transmission advantage vanishing completely in the limit when no pollen is available for outcrossing.

Given this intrinsic selective advantage deriving solely from the genetics of transmission, coupled with the potential ecological advantage of not having to require pollinators or nearby conspecifics in order to produce offspring (**reproductive assurance**), why, then, are not fully selfing species more frequent? Especially in plants, the evolutionary transition from outcrossing to selfing is not uncommon. Yet despite these factors, only a small

fraction (~10-15%) of plants are strictly selfing (Wright et al. 2013), with roughly half of all angiosperms having outcrossing enforced by either self-incompatibility (SI) systems or by dioecy (separate sexes) (Igic and Kohn 2006). Indeed, SI systems have evolved independently at least 35 times, and are found in at least 100 families of angiosperms, occurring in ~40% of all species (Igic et al. 2008). Hence, there must be strong selective pressure to maintain outcrossing. Conversely, SI is also frequently lost, for example, on at least 60 different occasions in the Solanaceae alone (Igic et al. 2008). Despite this loss, it is important to note that the transition from SI to self-compatibility is not sufficient for selfing, as other physical or temporal barriers may still have to be overcome. Evolutionary explanations for the relative lack of species with high rates of selfing, given all its apparent advantages, have been proposed at both the individual and group levels of selection, and we consider each in turn.

Because mating systems are products of individuals, any initial focus on evolutionary mechanisms should be on individual selection, namely, on the immediate fitness consequences to individuals that self (Charlesworth 2006b). The most obvious fitness cost is inbreeding depression (Darwin 1876, 1877; Charlesworth and Charlesworth 1995). Following Lande and Schemske (1985), we let \bar{w}_0 and \bar{w}_1 denote the fitnesses of random offspring produced by outcrossing and selfing, respectively. Let η denote the selfing rate, and assume identity equilibrium and linkage equilibrium, namely, random associations between loci involved in selfing and those involved in fitness. (Recall from Chapter 11 that inbreeding levels are correlated among loci when identity-disequilibrium is present.) Assuming no gamete discounting, the expected fitness of a genotype with selfing rate η becomes

$$w(\eta) = \eta \bar{w}_1 + \frac{1}{2} (1 - \eta) \bar{w}_0 + \frac{1}{2} (1 - \bar{\eta}) \bar{w}_0 \quad (23.69a)$$

The first term corresponds to a selfing event, the second term to the focal individual producing outcrossed seed, and the last term to pollen or sperm from the focal individual fertilizing others (where $\bar{\eta}$ is the selfing rate for the population). The selection coefficient associated with a small change in the selfing rate becomes

$$\frac{\partial w(\eta)}{\partial \eta} = \bar{w}_1 - \frac{\bar{w}_0}{2} \quad (23.69b)$$

Hence, if the reduction in the fitness of selfed offspring is 50% or greater relative to outcrossed offspring ($\bar{w}_1/\bar{w}_0 < 0.5$), the intrinsic transmission bias of selfing is overcome, and other evolutionary forces would be required for a selfing allele to spread. With pollen discounting, this difference in fitness due to inbreeding depression to halt the spread of selfing can be much smaller than 50%.

Selfers can also have an immediate advantage when reproductive assurance is important, such as in low-density populations or when pollinators are scarce or absent (Darwin 1876). Hence, at least three different contributions to individual fitness potentially impact the evolution of selfing rates: transmission bias (and potential pollen discounting), the amount of inbreeding depression, and issues of reproductive assurance.

Stebbins (1957) suggested that the relative scarcity of predominately selfing species was the result of another level of selection, namely, at the species level. Stebbins envisioned obligatory selfing species as being an evolutionary dead end, as such populations have reduced genetic variation and hence are less likely to adapt to changing environments. Further, they can also accumulate higher levels of deleterious mutations (Muller's ratchet; Chapter 7). Both features suggest that the rate of taxon expansion (species formation minus loss from extinction) of fully selfing species may be less than that of outcrossers. Hence, even if selfing might be favored by individual selection, its long-term evolutionary footprint over a phylogeny would be reduced.

Beyond these simple verbal descriptions of potential sources of individual and group selection, what do theory and data have to say about the relative importance of the above features for the evolution of selfing rates?

The Lande-Schemske Model: Theory

A watershed paper on the evolution of selfing was published by Lande and Schemske (1985), who made the critical observation (as did Ohta and Cockerham 1974) that the amount of inbreeding depression may itself evolve during selfing. If inbreeding depression is largely caused by the presence of deleterious recessive or partly recessive alleles (as appears to be consistent with much of the data; Charlesworth and Willis 2009; LW Chapter 10), then the increased frequency of homozygotes under inbreeding increases the efficiency of selection for removing such alleles, which in turn can reduce the amount of inbreeding depression. Using the machinery presented in Chapter 7, Lande and Schemske showed that selfing results in lower equilibrium frequencies of recessive or partly recessive deleterious alleles under mutation-selection balance. For example, with 5000 loci, each with a mutation rate to lethal recessives of 2×10^{-6} , the expected fitness reduction in first-generation inbreds relative to outcrossed offspring is 97% based on the equilibrium allele-frequencies under outcrossing. This fitness reduction decreases to 61%, 15%, and 10% when based on the expected equilibrium frequencies for selfing rates of 0.01, 0.05, and 0.10, respectively. Hence, as the selfing rate increases, the fitness cost imposed by inbreeding depression can decrease over time, facilitating the spread of alleles that increase the selfing rate by reducing the fitness differences between outcrossed and selfed offspring.

Based on this observation, the simple Lande-Schemske model (with no pollen discounting or other selection from factors such as reproductive assurance, and ignoring any linkage or identity disequilibrium) suggests that, at equilibrium, one might expect a largely bimodal distribution of selfing rates. In other words, some species are predominately selfing (with reduced levels of inbreeding depression) and others are predominately outcrossing (with high levels of inbreeding depression), and there are relatively few species with intermediate levels of outcrossing. Their augment further suggests that once a species becomes predominately selfing, the (expected) reduced levels of inbreeding depression make it difficult for modifiers that increase the outcrossing rate to evolve. Hence, while the transition from outcrosser to selfing can occur under individual selection, the reverse transition, from selfer to outcrosser, is generally expected to be opposed by individual selection.

The simple equilibrium prediction of a bimodal selfing-rate distribution is compromised when there is selection for reproductive assurance. Even in settings where inbreeding depression cannot be purged, in the absence of pollinators (or under low population densities), even lower-fitness offspring produced under selfing are better than no offspring at all, potentially leading to a **mixed-mating** strategy, namely, an intermediate selfing rate. Lande and Schemske (1985) noted that pollinator failure or population bottlenecks (resulting in sufficiently low density to greatly reduce the potential for outcrossing) can favor the evolution of selfing. They noted that the approximate time scale for perturbed allele frequencies to return to their (random-mating) mutation-selection equilibrium frequency is $\sim 1/\sqrt{\mu}$ generations for lethal recessives (roughly a thousand generations for $\mu = 2 \times 10^{-6}$), while it is $\sim 1/(hs)$ generations for partial recessives, where hs is the selection against heterozygotes. For $h = 0.02$ for lethals, this is on the order of a hundred generations. Hence, they suggested that pollinator or population bottlenecks occurring roughly every hundred generations or so may result in selection favoring predominately selfers.

Schoen et al. (1996) argued that selection for selfing from reproduction assurance is more likely to involve multiple population bottlenecks than is automatic selection. They suggested looking for specific patterns in the reduction of genetic diversity (akin to the polymorphism-based tests for selection examined in Chapter 9) to examine whether such bottlenecks occurred during the initial transition to selfing. Unfortunately, as shown by Barrett et al. (2014), a number of confounding factors (such as increased background selection from the reduction in the effective recombination rate) lead to, at best, an ambiguous signal.

The Lande-Schemske Model: Data

The Lande-Schemske model makes two empirical predictions. First, levels of inbreeding depression should be less in organisms that have an evolutionary history of predominately

selfing. This trend is supported by the data. A survey of 54 species of vascular plants from 23 different families examined by Husband and Schemske (1996) found a negative correlation between the amount of inbreeding depression and the selfing rate. The average fitness reduction when comparing offspring produced by selfing with those produced by outcrossing was 23% in predominately selfing species, while it was 53% for species that predominately outcross. However, a more detailed survey by Winn et al. (2011) gave a more nuanced view, in that species with intermediate levels of outcrossing displayed as much inbreeding depression as predominately outcrossing species. Such an outcome was suggested earlier by Lande et al. (1994), who showed that if inbreeding depression is sufficiently strong, no purging will occur until a threshold level of selfing is approached. If the amount of selfing is less than this threshold, little reduction in inbreeding depression is expected.

Turning to animals, a survey of 17 species of hermaphroditic gastropods by Escobar et al. (2011) found that selfing rates were negatively correlated with both inbreeding depression and the waiting time until an individual chooses to self. Further, they found that species showing higher levels of inbreeding depression had longer waiting times, presumably balancing the cost of delayed reproduction against the decrease in fitness when offspring are produced by selfing.

The second, and more direct, prediction of the Lande-Schemske model is that of a U-shaped distribution of selfing rates, namely, a bimodal distribution, with most species being either predominately selfing or predominately outcrossing. Here the data are less clear. The distribution of selfing rates is consistent with aspects of both the Lande-Schemske model and fitness advantages from reproductive assurance by at least some selfing. The original analysis of 55 species of vascular plants (both angiosperms and gymnosperms) by Schemske and Lande (1985) placed the estimated outcrossing rates into five bins (0–0.2, 0.2–0.4, etc.). In accordance with the predictions of the Lande-Schemske model, they observed a U-shaped distribution, with significant excesses in the upper (0.8 to 1.0; predominately outcrossing) and lower (0.0 to 0.2; predominately selfing) bins and far fewer species (31%) in the intermediate (0.2 to 0.8) range. Subsequent analyses of larger datasets of vascular plants also showed excesses of the upper and lower values, but also a higher fraction of species in the intermediate range than observed in the original Schemske and Lande dataset (Voglert and Kalisz 2001; Goodwillie et al. 2005). For example, 42% of the 345 vascular plant species considered by Goodwillie et al. were in the intermediate range of outcrossing (0.2 to 0.8). Estimates of the distribution of selfing rates for 142 species of hermaphroditic animals were also similar to the distribution seen in vascular plants, with modes at the high and low ends, but also with a substantial fraction (47%) in the intermediate range (Järne and Auld 2006).

Given that the bimodal prediction is for populations that have reached equilibrium, intermediate selfing values might represent populations in transition (from outcrossing to selfing). The Lande-Schemske model predicts that such transient populations would show reduced levels of inbreeding depression, as they are in the process of purging deleterious alleles on their way to a predominately selfing existence. However, the data of Winn et al. (2011) showing that the levels of inbreeding depression in mixed-mating species are as high as those of predominately outcrossers suggests that these are unlikely to be transient populations and may instead be relatively stable states. One potential factor could be pollen discounting, which can result in stable, intermediate levels of selfing (Holsinger 1991; Porcher and Lande 2005, 2013). Pollinator behavior itself could also result in some fraction of selfing, leading to stable mixed-mating systems (Devaux et al. 2014).

Another force behind relatively stable mixed-mating systems could be selection for reproductive assurance. One suggestion from the data that reproductive assurance may be partially driving the intermediate selfing values is that when species are partitioned into wind- versus animal-pollinated, the former showed a more U-shape distribution (fewer species in the intermediate range) than the latter. In particular, Goodwillie et al. (2005) found that 46.5% of their 267 animal-pollinated species were in the immediate range, while only 26.9% were for their 78 wind-pollinated species. Although still impacted by population

density, wind-pollinated species are not vulnerable to a lack of pollinators, and hence their selfing rates may be less impacted by reproductive assurance issues than those species that require pollinators.

Example 23.10. Two artificial selection experiments when outcrossing opportunities were reduced resulted in fairly rapid evolution of selfing and reduction in inbreeding depression. Bodbyl Roels and Kelly (2011) subjected yellow monkey flower (*Mimulus guttatus*) lines to either five generations with abundant bumblebees pollinators or five generations with no pollinators. The no-pollinator lines showed reduced seed set over the first few generations, but largely rebounded by generation five. Anther-stigma separation distances decreased in the no-pollinator lines, and this distance was negatively correlated with seed set (smaller differences resulting in larger seed set).

Noël et al. (2016) subjected populations of a hermaphroditic freshwater gastropod (*Physa acuta*) to either outcrossing each generation or to a constrained setting where mates were often scarce, forcing selfing. The starting populations initially had high levels of inbreeding depression. After approximately 20 generations, the constrained lines showed a roughly 60% decrease in their waiting time (i.e., initiating selfing earlier) and a decrease in inbreeding depression (indicated by higher survival of offspring from selfing).

Baker's Law and the Demographic Advantages of Selfing

There are some significant ecological and demographic correlates with selfing among the flowering plants. Many annuals are predominately selfing, as are many species associated with frequent colonization events (such as weedy species) and those living in ephemeral habitats. Conversely, long-lived woody species tend to be predominately outcrossing (Vogler and Kalisz 2001; Barrett et al. 2014). Annuals and species in higher-risk ecological settings periodically run the risk of lack of pollinators or reduced population density in any given year, while these risks are reduced by averaging for species whose individuals have the capacity for reproduction over a number of years. Selfing is also more common in the marginal populations of a species range, again suggestive of some selection to mitigate a lack of outcrossing from either low population density and/or insufficient pollinators. Indeed, in a study involving approximately 200 species from 20 genera spanning 15 plant families, selfers tended to have larger geographic ranges (by about twofold) relative to outcrossing sister taxa (Grossenbacher et al. 2015), which was likely due to the ability of selfers to reproduce in more marginal environments.

The above observations are all loose correlates of **Baker's Law**, so named by Stebbins (1957), which is based on the suggestion that island species tend to be selfers (Baker 1955). For example, island species are much less likely to be self-incompatible (Igic et al. 2008). However, it was fairly quickly noted that dioecious species are common among native Hawaiian plants, suggesting that Baker's original observation is more of a trend than a law. Much has been written about Baker's Law and how much it may generalize to the above correlations between selfing and demography. We agree with the suggestion by Pannell et al. (2015) that species colonizing by long-distance dispersal are much more likely to be enriched for the *potential* to self (as opposed to being predominately selfing). Obviously, any low-density colonizer faces potentially serious reproductive assurance issues, and the ability (even if only sporadically) to self creates a demographic sieve enriching for such species among successful colonizing taxa.

Group-level Selection Against Selfing

The above individual selection pressures (transmission, reproductive assurance, and inbreeding depression) suggest how selfing can evolve, and also what individual-selection forces can enforce outcrossing. However, once a population undergoes a sufficient amount

of selfing to reduce its level of inbreeding depression, any transition back towards increased outcrossing is expected to be opposed by individual selection. Hence, much of the historical discussion on the modest frequency of predominately selfing species is based on the Stebbins (1957) notion of the **SEDE** (Selfing as an Evolutionary Dead End) hypothesis.

The two tenets of SEDE are that: (i) selfing is largely irreversible; and (ii) selfed lineages have lower rates of species diversification than outcrossers, presumably because of higher extinction rates. The assumption of a very low reversion rate from selfers to outcrossers is not controversial, as the theory from individual selection suggests that such back transitions are rarely favored. Further, phylogenetic evidence suggests that such reversions are very rare (Takebayashi and Morrell 2001).

Identifying direct evidence for increased extinction rates in predominately selfing species is more problematic. Such evidence would be based on species comparisons over a phylogeny, which are limited by the precision of the reconstruction of the ancestral states (here, selfing or outcrossing) at the appropriate nodes of the phylogenetic tree. Given this difficulty, it is not surprising that while the current phylogenetic data appear to be consistent with the SEDE model, there is still uncertainty about its veracity (Takebayashi and Morrell 2001; Igic and Busch 2013).

The main arguments advanced in favor of increased extinction risk for predominately selfing populations are genetic: reduced genetic variation, excess accumulation of deleterious alleles, and slower rates of adaptation (Hartfield et al. 2017). The arguments for all three of these factors are based on the decreased effective population size of a selfed population, coupled with the reduction in recombination (due to a deficiency of heterozygotes). The latter magnifies both the role of sweeps and background selection in reducing standing variation (Chapters 3 and 8) and amplifies Hill-Robertson effects, reducing the efficiency of selection (Chapters 3 and 8). These factors are expected to result in an increased accumulation of deleterious alleles in lineages with reduced recombination (Muller's ratchet; Chapter 7) and reduction in the rate of fixation of favorable alleles.

A more careful examination of the theory shows that there are a number of subtleties with these initial predictions. First, consider the reduction in genetic variance from a reduction in the effective population size. The effect of inbreeding is to reduce the effective population size to $N_e = N/(1 + f)$, which follows from Equation 3.20 with $f = \eta/(2 - \eta)$. For a strictly neutral (and additive) trait, the expected mutation-drift equilibrium additive variance is $\tilde{\sigma}_A^2 = 2N_e\sigma_m^2$ (Chapter 11), showing that inbreeding does indeed reduce the additive variance, yielding

$$\tilde{\sigma}_A^2 = \frac{2N\sigma_m^2}{1 + f} \quad (23.70a)$$

However, recall that selfing also *redistributes* the genetic variance, as the population is a collection of lineages, can still contain significant among-lineage variation. In particular, for an additive trait, the population-level variance is $(1 + f)\sigma_A^2$ (Chapter 11). Putting these two expressions together, the expected equilibrium additive variance in the presence of inbreeding becomes

$$(1 + f)\tilde{\sigma}_A^2 = (1 + f)\frac{2N\sigma_m^2}{1 + f} = 2N\sigma_m^2 \quad (23.70b)$$

and hence the same over all values of f . Hence, for a neutral, additive trait, the reduction N_e from selfing alone is not expected to reduce the standing variation. The subtlety is that the second key feature of inbreeding—reduction in recombination—*further* reduces N_e due to a more important role for background selection when recombination is rare. Hence, it is *selection* that reduces the standing amount of genetic variation for a neutral trait in inbreds relative to outcrossers.

The strictly neutral model is a bit of a caricature, in that many traits are expected to be under stabilizing selection in natural populations (Chapters 28 and 29), so a more relevant comparison of the differences in the levels of genetic variation between inbred and outcrossed populations might be that expected under mutation-stabilizing-selection balance. This is the subject of Chapter 28. Initially, Lande (1977a) showed that the mating

system has little effect on the amount of additive-genetic variation at equilibrium under stabilizing selection-mutation balance. However, as we detail in Chapter 28, this is a very model-dependent result (Table 28.2). Charlesworth and Charlesworth (1995) found that the amount of variation maintained under stabilizing selection-mutation balance is much lower in selfers than in outcrossers. These apparent discrepancies results were reconciled by Lande and Porcher (2015), who showed that outcrossers and selfers have very similar levels of variation under stabilizing-selection-mutation balance up to some threshold selfing value. With selfing rates higher than this threshold value, purging of inbreeding depression occurs, resulting in much less variation in selfed lineages. Hence, while predominately selfing populations *may* harbor less standing genetic variation than outcrossed populations, this may not always be true.

The second subtlety is *dominance*. Reduced effective population size and enhanced Hill-Robertson (HR) effects due to reduction in recombination weaken the efficiency of selection (Chapter 26), increasing the fixation of deleterious new mutations and decreasing the fixation of advantageous mutations (relative to an outcrossing population). However, when such alleles show partial or complete dominance, the efficiency of selection under inbreeding can be *increased* relative to outbreds (Charlesworth et al. 1993b; Glémén 2007, 2012; Hartfield et al. 2017). In particular, the fixation probabilities of partly to completely recessive beneficial alleles can increase, and their fixation times decreased, under inbreeding (Glémén 2012). Hence, if deleterious alleles tend to be recessive, the decreased efficiency from reduced N_e and HR effects may be partly countered by increased selection efficiency against recessives in inbreds. The same is true for recessive to partly recessive favorable alleles. Thus, while the initial effects of inbreeding appear to be rather unfavorable, if most selected alleles tend to be somewhat recessive, these negative effects may be somewhat offset.

Given that theory offers a bit of mixed message, what do the data say? The empirical data on reduced levels of genetic variation (and hence reduced ability to respond to a selective challenges) in predominately selfing species are mixed. Charlesworth and Charlesworth (1995) found little evidence of a reduction in either heritability or evolvability (Chapter 13) in highly selfed species. They noted the quality of data in their meta-analysis was rather mixed, and that a slight trend for reduced evolvability in predominately selfing species appeared when only the higher-quality data were used. Hence, the empirical evidence at present does not strongly support reduced standing genetic variation in predominately selfing populations.

Perhaps the more important evolutionary constraint faced by a predominately selfing population under adaptive pressure is not the amount of starting variation at the beginning of a new ecological challenge, but rather how it exploits this variation following the challenge. Outcrossing populations continue to generate new variation by segregation. In a strictly selfing population, this avenue is closed, and among-line selection will eventually result in only a few genotypes being present. This bottleneck in generating new variation to keep pace with environmental change may be the real impediment to the persistence of many selfing populations.

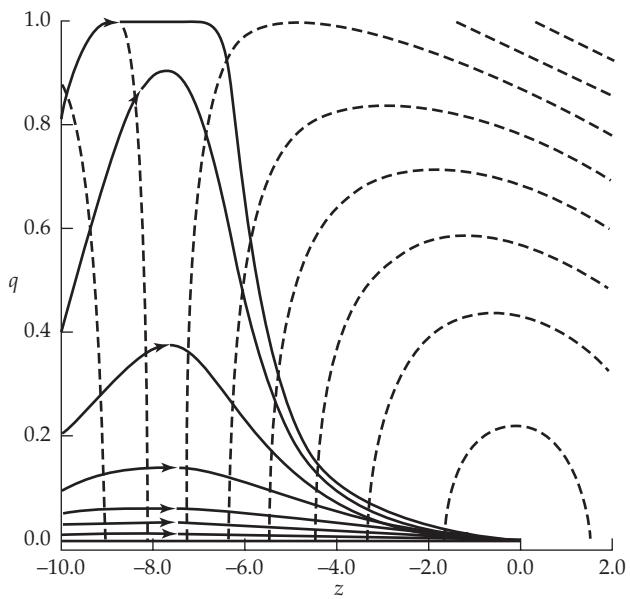

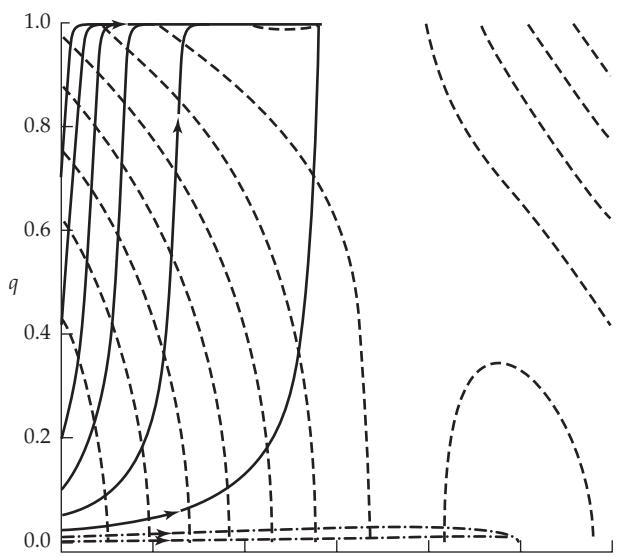

Example 23.11. Two recent animal-based studies examined the impact of selfing rates on the evolutionary fate of a population. Morran et al. (2009) used a very clever genetic approach in the nematode *Caenorhabditis elegans*, introducing either the *xol-1* or *fog-2* mutations into a wild-type line (with an outcrossing rate of roughly 5%). These mutations generate obligately selfing and obligately outcrossing lines, respectively, in otherwise identical genetic backgrounds. The authors applied this system to address two possible costs of selfing: a reduced rate of elimination of new deleterious mutations and a reduced ability to mount an adaptive response in a changing environment. They first artificially inflated the mutation rate (by roughly four-fold) by exposing individuals to the chemical mutagen EMS. The obligately selfing lines showed a significant decline in fitness, while the obligately outcrossing lines did not. Further, the wild-

type lines showed an increased level of outcrossing after several generations of exposure. These observations are consistent with outcrossing (and hence recombination) facilitating the removal of deleterious mutations, suggesting that their accumulation could be a potential cost of selfing. Next, they subjected the three distinct mating-type lines (now under natural mutation rates) to 50 generations of selection in the presence of a novel bacterial pathogen. The obligately outcrossing and wild-type lines were able to adapt (evolve resistance) while the obligately selfing lines were not. Further, as with the EMS experiment, the outcrossing rate in the wild-type line had increased by the end of the selection experiment.

A second experiment was conducted by Noël et al. (2017), who examined the selection response in the gastropod *Physa acuta*. They contrasted response in populations with different starting histories of outcrossing and selfing, and also under different outcrossing and selfing regimes during the actual artificial selection itself. Their C lines had outcrossing each generation, while their S lines had self-fertilization imposed every other generation. Selection response with lines of approximately 30 generations of either the S or the C treatment as the base population were compared, as were settings where 100% selfing or 100% outcrossing occurred once selection started. Selection response was larger when the base population had a history of outcrossing (C) as opposed to selfing (S). Further, while the selection response (in this case, for shell morphology) was initially more rapid in lines undergoing 100% selfing during the course of selection, this response only lasted a few generations, after which it rapidly diminished. In contrast, the fully outcrossed populations continued to show a relatively constant response over the course of the experiment. Again, a history of either past or ongoing selfing resulted in a reduced selection response, and hence the potential (in some settings) for selfed populations being unable to mount an adaptive response given a sufficient environmental challenge.

VI

Population-Genetic Models of Trait Response

24

The Infinitesimal Model and Its Extensions

Normal theory is clearly the most powerful and problematic hypothesis in the present analysis. Chevalet (1988)

What, me normal? Turelli and Barton (1994)

As detailed in Chapters 6, 13, and 16, the response to a single generation of selection in a quantitative trait can often be closely predicted from **macroscopic** (observable) features of that trait, namely, its variance components. This is in sharp contrast to predicting selection response under one- and two-locus models, which requires detailed knowledge of the underlying genotype frequencies and effects (Chapter 5). Hence, population-genetic predictions typically require knowledge of **microscopic** (largely unobservable) genetic parameters. The breeder's equation (13.1) and the Bulmer equation (16.7b) are examples of macroscopic-based predictors. In contrast, the Price equation (6.8) is a microscopic-based predictor, given its composite transmission parameter, $\sigma(w, \delta)$, which is, at best, very challenging to measure (and is even harder to iterate over generations).

These variance-component predictors, which underlie much of the quantitative-genetic theory of response, are, of course, approximations, but often very good ones, especially over short time scales. Their single-generation versions follow from the assumption of a linear and homoscedastic parent-offspring regression, and their extension to multiple generations requires not only that linearity and homoscedasticity hold following selection, but also that any selection-induced changes in the variance components (which determine the slopes of these regressions) are largely predictable from macroscopic parameters (for example, via the Bulmer equation).

The justification for these approaches is usually framed by invoking a set of assumptions that we have been loosely calling the infinitesimal model. At various times, we have used either one, or more, of the assumptions of: (i) a very large (effectively infinite) number of loci, each with very small (effectively infinitesimal) effects; (ii) a normally distributed genotypic distribution in a randomly mating population under no selection, and, hence parent-offspring regressions that are linear and homoscedastic; and (iii) that the genotypic distributions stay at least close to **Gaussian** (normal) following selection such that the linear and homoscedastic regressions approximately hold.

The goal of this chapter, which is rather technical in places, is to examine in more detail the various infinitesimal approximations that we have made and to examine the consequences for selection response when they fail. We start by deconstructing what we have called the **standard infinitesimal model** (the joint assumptions of very large numbers of loci and parent-offspring regressions that are linear and homoscedastic) into its components and examine how these are connected, and also when they fail. As we will see, despite the use of the term *standard*, there is actually a nested family of infinitesimal models that make increasingly stringent assumptions, which correspond to assumptions (i) through (iii), which were just mentioned (Table 24.1).

We then introduce the **Gaussian approximation**, one of a broad group of **continuum-of-alleles** (or **COA**) **models**, assuming a *finite* number of loci, with a *distribution* of allelic effects at a locus (as opposed to a fixed number of possible alleles), with mutation likely generating alleles not previously segregating in the population. The Gaussian approximation assumes that the distribution of allelic effects at *each locus* is normal. With a large number of loci, the results from Gaussian COA models approach those obtained under the infinitesimal

Table 24.1 Classification of the different versions of the infinitesimal model, based on Turelli (2017). Note that these models are nested, such that a model makes all of the assumptions of any model that proceeded it in the table.

Infinitesimal genetics	A large number of loci, each with vanishingly small effects.	Fisher (1918)
Gaussian descendants (Fisher-Bulmer Infinitesimal)	Within-family segregation variance independent of parental phenotypes, depending only on the relatedness of parents.	Bossert (1963)
	In the limit, results in a Gaussian distribution of breeding values in their unselected descendants. Parent-offspring regressions are linear and homoscedastic.	Fisher (1918), Bulmer (1971b), Barton et al. (2017)
Gaussian populations	The distribution of breeding values in a population is Gaussian.	

model, thus serving as a bridge between models assuming effectively an infinite number of loci (each with a small number of possible alleles, typically biallelic) and models assuming a very large (effectively infinite) potential number of alleles at a finite number of loci. We then examine the effects of linkage on the behavior of these models, and conclude by examining the selection response when the distribution of breeding values is no longer Gaussian.

The goal of this chapter is to start to bridge short-term predictors of response based on macroscopic parameters with predictors of long-term response based on microscopic parameters. After sufficient allele-frequency change accrues, these bridging models break down, thus imposing the need for explicit population-genetic models (Chapter 5), which are examined in Chapters 25–28.

THE INFINITESIMAL: A FAMILY OF MODELS

We have been somewhat cavalier in our use of the term *infinitesimal model*, as there is considerable ambiguity as to what this term formally means. Further, what is required from an infinitesimal assumption depends on the problem being considered: Is one making the assumption of very small allele-frequency change? The assumption of a linear, and homoscedastic, parent-offspring regression? The assumption that the distribution of breeding values in a population is Gaussian (normally distributed) and is largely unaltered by selection? As shown in Table 24.1, there is a nested hierarchy of models, which impacts the assumptions one is actually making when invoking the infinitesimal.

Following Turelli (2017), one can consider three nested versions of the model. The simplest, **infinitesimal genetics**, matches Fisher's (1918) approximation of describing the trait architecture as consisting of a very large number of loci, each of small effect. A direct consequence of this model is that allele-frequency changes are very small, as the time scale for frequency change scales with the inverse of allelic-effect size (Equation 5.21).

The next-level model, which Turelli (2017) named **Gaussian descendants**, starts with the assumption (for unrelated and outbred parents) of a constant within-family variance that is independent of the phenotypes of these parents. Such a constant **segregation kernel** variance was first considered in Bossert's (1963) unpublished thesis, and this is simply half of the genic variance (Equation 16.2). As we saw in Example 16.2, the within-family segregation variance is reduced when parents are inbred, so a slightly more generalized assumption is a segregation variance that only depends on the relatedness of the parents (Bulmer 1971b, Barton et al. 2017). As suggested by Fisher (1918), and most generally shown by Barton et al. (2017), the assumption of a large number of loci (the infinitesimal genetics model) in the limit (provided linkage is not too extreme) leads to a Gaussian (normally) distribution of breeding values among the offspring of a set of parents, whose variance

only depends on the parental relationship. Hence, the oft-used infinitesimal assumption of linear regressions and homoscedastic variances follows from this limit.

The Gaussian descendants version of the infinitesimal model is the starting point for most of our previous discussions about the impact of a single generation of selection from an unselected base population, and it forms the foundation for BLUP. We take this version—an efficiently infinite number of loci, a segregation variance that only depends upon relatedness, and a Gaussian distribution of breeding values in the absence of selection (and hence linear and homoscedastic parent-offspring regression)—as the standard infinitesimal model. We will also refer to this particular set of assumptions as the **Fisher-Bulmer infinitesimal model**.

The most restrictive of the infinitesimal family of models is what Turelli (2017) called the **Gaussian populations** assumption. Here, the *population* (as opposed to the *within-family*) distribution of breeding values is Gaussian. This is the infinitesimal assumption which is used to predict selection response over multiple generations. As we will show later in the chapter, this generally does not hold, even when starting with the Fisher-Bulmer infinitesimal model, as selection (through generating disequilibrium) will drive any initially Gaussian distribution away from normality. The key observation is that while the distribution of breeding values *within* a family may stay Gaussian following selection, a population is a *collection* of families. If the distribution of *family means* is highly non-Gaussian (as might be expected to be generated following selection on a trait), then the population distribution will depart from normality. Gaussian within-family segregation will recover some of the normality in the offspring generation, and the critical question is whether this is usually enough to approximately recover the Gaussian populations assumption.

The key points we will make below are as follows: First, allele-frequency change from selection on a trait with a finite number of loci tends to drive the distribution of breeding values away from a Gaussian, but the degree of subsequent departure quickly diminishes as the number of loci increases. Second, selection-induced correlations over alleles from different loci (linkage disequilibrium) will drive even a trait with infinitesimal genetics away from a Gaussian. And third, when the within-family segregation remains Gaussian, this will partly restore a population-level Gaussian distribution, but departures away from a Gaussian will remain in the population until selection has ceased and recombination removes among-locus correlations.

THE INFINITESIMAL GENETICS MODEL: EMPIRICAL DATA

Fisher's (1918) motivation for the infinitesimal genetics model, which assumed that many genes of small effect underlie a typical trait, was part mathematical convenience and part biological approximation. Early on, many geneticists, trained in dissecting the action of single genes of modest to large effect, questioned the validity of this biological motivation. This objection was reinforced in the mid-1980s when QTL mapping experiments seemed to detect abundant major-effect QTLs, each accounting for 10% or more of the phenotypic variation (LW Chapter 15). However, with the advent of more powerful genomic tools, attempts to isolate the underlying nucleotide sites behind these major QTLs grew increasingly frustrating. A major QTL (indicated by a large peak in the likelihood surface spanning some genomic region; LW Chapter 15) seen in the cross of two inbred lines often fractionated into several minor peaks upon finer mapping, and each of these minor peaks further fractionated as attention was turned to them. While genes of large effect have been found, what frequently appeared to be a single major gene turned out to be a number of tightly linked regions of much smaller effect (reviewed by Flint and Mackay 2009; Mackay et al. 2009).

This trend continued during the GWAS (genome-wide association study) phase of quantitative genetics (starting in the early 2000s). Association mapping (LW Chapter 16) uses population-level disequilibrium and therefore allows for mapping on a kilobase scale, as opposed to the tens of megabase scale for QTL resolution (the typical confidence interval in a QTL mapping experiment; LW Chapter 15). The broad conclusions from a large number

of studies on human traits (mainly, but not exclusively, diseases) with enormous sample sizes (in the tens of thousands or greater) are twofold (Visscher et al. 2012a).

First, the effects of detected sites (measured by the marker-associated variance) tend to be very small. For example, over 600 variants associated with human height variation have been detected, most of which typically account for only a minuscule fraction of the additive variance (Lango Allen et al. 2010; Yang et al. 2010; Wood et al. 2014). Further, estimates suggest that the actual number of genes influencing human height is significantly greater than 600, running from over 1600 (Kemper et al. 2012) to “a very large but finite number (thousands) of causal variants” (Wood et al. 2014). Gene knockout experiments (Reed et al. 2008) have suggested roughly 6000 genes with the potential to influence body weight in mice, while the response to artificial selection on body size in *Drosophila* involves between 300 and 1200 regions (Turner et al. 2011). Finally, in a number of studied traits the fraction of additive-genetic variation accounted for by SNPs on a per-chromosome basis is proportional to chromosomal length (Visscher et al. 2007; Yang et al. 2011b; Yang et al. 2013). This observation is consistent with an infinitesimal-like model of a very large number of small-effect loci uniformly distributed over the genome.

Second, the total additive variance accounted for by *all* detected sites is only a small fraction (around 10%) of the total additive variance for the same trait estimated from the resemblance between relatives (in humans, typically twin studies). The latter observation led to concerns about “**missing heritability**” (Mather 2008; Manolio et al. 2009) and a large number of subsequent papers attempting to account for this apparent paradox. In reality, this observation of missing heritability provides strong support for the infinitesimal genetics model. In testing up to millions of SNPs for association in a GWAS, stringent thresholds are set to control for multiple comparisons (Appendix 4). This, in turn, requires larger effect sizes in order for a given marker to be declared significant, which excludes many biologically relevant SNPs from the model using all of the *detected* sites.

By using mixed-model approaches that allow *all* SNPs to be incorporated (by shrinking the effects of most SNPs toward zero), Yang et al. (2010) could account for ~45% of the additive variance in human height. Similar findings were seen for schizophrenia (Purcell et al. 2009) and a growing number of other traits (e.g., Hill 2010; Vinkhuyzen et al. 2013; Yang et al. 2013; Robinson 2014). Example 24.1 illustrates how incomplete linkage disequilibrium (in which the marker and causative alleles are less than completely associated) can easily account for the remaining fraction of the “missing” heritability. Lee et al. (2011) reviewed approaches for estimating this **hidden** (not missing) **heritability** in GWAS studies using mixed models (and hence essentially assuming the Gaussian descendants version of the infinitesimal model). Thus, we have come full-circle from the early QTL days in that current genomic data for many traits are most consistent with a very large number of loci, each with a small effect. This is not to say that major alleles do not exist, but rather that they tend to be rare. Indeed, the effect detected in a GWAS study is the additive variance associated with a marker SNP (LW Chapter 16), so finding that the vast majority of sites have a low effect *variance* does not imply that they involve alleles of *small effects*. If alleles of large effect tend to be rare, they will display small variances, although the presence of such alleles has consequences for the prediction of selection response (as we detail below). Notably, Kemper et al. (2012) found a negative correlation between frequency and effect size of alleles influencing human height (see Figure 28.5).

Example 24.1. As an example of one source of “missing heritability,” consider a site at which a new QTL allele, Q , with an additive effect of a , arises on a SNP marker background, with M and m being the two marker alleles. The strongest marker association occurs when Q is completely restricted to the background on which it arose, so we assume this here, with Q only found on M -bearing haplotypes. Moreover, only a fraction, ξ , of M haplotypes will harbor Q , and (as we now demonstrate), this results in hidden heritability. Summarizing these assumptions, we have:

Gamete	Frequency	Effect
MQ	$p\xi$	a
Mq	$p(1 - \xi)$	0
mq	$1 - p$	0
mQ	0	a

Hence, the frequencies of M and Q are, respectively, p and $p\xi$. The resulting additive variance due to the causal site becomes

$$\sigma_A^2(QTL) = 2a^2(p\xi)(1 - p\xi) \simeq 2a^2p\xi$$

with the approximation following because $p\xi \ll 1$. Conversely, the average effect of marker allele M is $a\xi + 0(1 - \xi) = \xi a$, while the value for m is zero, making the additive variance associated with this marker

$$\sigma_A^2(M) = 2(\xi a)^2(p)(1 - p) = 2a^2p(1 - p)\xi^2$$

The resulting ratio of the marker to causal additive variances is

$$\sigma_A^2(M)/\sigma_A^2(QTL) = \xi(1 - p)/(1 - \xi p) \simeq \xi$$

Thus, if Q is somewhat rare on M backgrounds, only of a fraction, ξ , of the actual variance is accounted for by the linked SNP. This situation would occur if the site-frequency spectrum (SFS) for QTLs alleles is shifted toward smaller values relative to the SFS for the marker alleles. Both the ascertainment for common SNPs and weak selection against QTL alleles could generate such a shift.

While the value of ξ is unknown, suppose that, on average, $\xi \simeq 0.5$: then, at most 50% of the total variation from the causative sites can be captured by markers. This value is very close to the value of 45% of the variance accounted for by Yang et al. (2010) for human height. Further, this calculation is biased in favor of marker variances as it assumes complete disequilibrium (i.e., Q is *only* found on the M background). If some of the m -bearing chromosomes also carry Q , the fraction of the causal variance accounted for by the marker variance will be even less.

THEORETICAL IMPLICATIONS OF THE INFINITESIMAL GENETICS MODEL

Under the classic infinitesimal genetics model introduced by Fisher (1918), a character is determined by an infinite number of unlinked and nonepistatic loci, each with an infinitesimal effect. It is occasionally assumed that each locus has two alleles and that the effects and frequencies are the same (or very similar) across all loci, although these constraints can be relaxed. Here we examine some of the properties resulting from the various infinitesimal assumptions (Table 24.1), providing a starting point for evaluating the consequences on the short-term selection response when they fail.

Selection Does Not Change Allele Frequencies

Recall from Chapter 16 that we can express the additive genetic variance, σ_A^2 , as the sum of the *genic* variance, σ_a^2 , and the disequilibrium contribution, d , with $\sigma_A^2 = \sigma_a^2 + d$. This partition decouples the effect of allele-frequency change (changes in σ_a^2) from the effect of changes from linkage disequilibrium (d).

Under the infinitesimal genetics model, *allele frequencies are essentially unchanged by selection*, and thus σ_a^2 is assumed to be constant over time (in an infinite population). Large changes in the mean can nonetheless occur via summation of infinitesimal allele-frequency changes over a large number of loci. To see this, consider a character determined by n completely additive biallelic loci. Suppose that all loci are **interchangeable**, with each having the same effects and frequencies (the **exchangeable model**). Each locus has two alleles, Q and q , with the genotypes QQ , Qq , and qq contributing $2a$, a , and 0 (respectively) to the

genotypic value, so that allele Q has effect a , and let p denote the frequency of Q . The resulting mean is then $2nap$, with the change in mean due to a single generation of selection being $\Delta\mu = 2na\Delta p$.

Ignoring any contribution from gametic-phase disequilibrium (i.e., $d = 0$), the additive variance is $\sigma_A^2 = \sigma_a^2 = 2na^2p(1-p)$. For σ_A^2 to remain bounded as the number of loci increase, a must then scale as $n^{-1/2}$. Assuming the frequency of Q changes by the same amount at each locus, then $\Delta p = \Delta\mu/(2na)$. Because a is of order $n^{-1/2}$, Δp is of order $1/(n \cdot n^{-1/2}) = n^{-1/2}$, and approaches zero as the number of loci becomes very large. The infinitesimal genetics model thus allows for arbitrary changes in the mean with essentially no change in the allele frequencies at underlying loci. Biologically (i.e., with a finite number of loci), the infinitesimal genetics model implies that large changes in the mean of a trait can occur with only small changes in allele frequencies if all loci each make only a small contribution to the trait variance.

What effect do small amounts of allele-frequency change have on the genic variance, σ_a^2 ? Letting $p' = p + \Delta p$ denote the frequency after selection, the change in genic variance is

$$\begin{aligned}\Delta\sigma_a^2 &= 2na^2p'(1-p') - 2na^2p(1-p) \\ &= 2na^2\Delta p(1-2p-\Delta p) = a(1-2p-\Delta p)[2na\Delta p] \\ &\simeq a(1-2p)\Delta\mu\end{aligned}$$

Because a is of order $n^{-1/2}$, the change in variance due to changes in allele frequencies scales as $(1/\sqrt{n})$ times the change in the mean (assuming Δp is small). Thus, with a large number of loci, very large changes in the mean can occur without any significant change in the genic variance. The more loci of equal effect underlying a trait, the slower will be the change in σ_a^2 , and hence the longer the selection response will be predictable (Chapter 25). In the limit of an infinite number of loci, there is no selection-induced change in the genic variance ($\Delta\sigma_a^2 = 0$), while arbitrary changes in the mean can occur.

Accounting for Dominance

While our previous focus has been exclusively on alleles with additive effects, dominance is not excluded under an infinitesimal model. The incorporation of dominance, however, requires very delicate conditions for the scaling of allelic effects, so as to bound both the dominance variance and any inbreeding depression. To see this, suppose we have n biallelic loci with no epistasis (the total genotypic value is simply the sum of the individual locus genotypic values), and let the genotypic values at locus i be $0 : a_i + \delta_i : 2a_i$, where the frequency of the increasing allele is p_i . The resulting dominance variance becomes

$$\sigma_D^2 = \sum_{i=1}^n [2p_i(1-p_i)\delta_i]^2$$

For n exchangeable loci, this simplifies to

$$\sigma_D^2 = 4np^2(1-p)^2\delta^2$$

For σ_D^2 to remain bounded as $n \rightarrow \infty$, δ must scale as $n^{-1/2}$, just as we found for a . Thus, if both a and δ scale as $1/\sqrt{n}$, the additive and dominance variances remain bounded as the number of locus goes to infinity.

Now consider the behavior of inbreeding depression, the difference between the mean trait value, μ_f , when population-level inbreeding is f versus that under random mating, μ_0 (LW Chapter 10). Again, assuming that there is no epistasis, from LW Equation 10.3, the inbreeding depression is given by

$$\mu_f - \mu_0 = -2f \sum_{i=1}^n p_i(1-p_i)\delta_i$$

Assuming n loci of equal effect gives

$$\mu_f - \mu_0 = -2nfp(1-p)\delta$$

Because δ scales as $n^{-1/2}$ under the infinitesimal genetics assumption, the amount of inbreeding depression scales as $n \cdot n^{-1/2} = n^{1/2}$ and hence goes to infinity with increasing values of n . Conversely, if we scale δ as order $1/n$, we have bounded inbreeding depression, but the dominance variance is now of order $n/n^2 = 1/n$ and hence is zero in the infinitesimal limit.

Thus, under the exchangeable infinitesimal model, one cannot have both bounded dominance variance and inbreeding depression, a point first made by Robertson and Hill (1983). Of course, a limitation of this argument is our assumption of equal effects over all loci, with all of the δ having the same sign. If we assume that $E[\delta] = 0$, namely, that there is no directional dominance, then we can have bounded dominance variance but no inbreeding depression. To have both dominance variance and inbreeding depression in the infinitesimal limit requires a great deal of delicacy, in that individual allelic effects have to be scaled so that $0 < n E[\delta] < \infty$ as $n \rightarrow \infty$ (there must be finite directional dominance). Related to this point, Wellmann and Bennewitz (2011) showed that the ratio of the squared inbreeding depression to the dominance variance sets a lower bound on the number of underlying loci.

Disequilibrium

While σ_a^2 remains unchanged by selection under the infinitesimal genetics model, selection-induced changes in d can significantly alter the additive genetic variance, σ_A^2 (Chapter 16). We can show this using the same scaling agreements we just employed. Changes in the covariances, C_{ij} , of allelic effects between loci i and j (for $i \neq j$) are roughly of order n^{-2} (Bulmer 1980; Turelli and Barton 1990). Because there are $\sim n^2$ terms contributing to d (Equation 16.1a), the total disequilibrium is of order one ($n^2 \cdot n^{-2}$), and does not necessarily approach zero as the number of loci becomes infinite. The same reasoning holds for changes in the higher-order moments, which are caused by higher-order associations between groups of loci. For the k th-order moment, there are $\sim n^k$ terms in the sum, each scaling as n^{-k} to potentially give a nonzero value in the limit (Turelli and Barton 1990).

THEORETICAL IMPLICATIONS OF THE STANDARD INFINITESIMAL MODEL

The standard (Fisher-Bulmer) infinitesimal model assumes both the infinitesimal *genetics* model and that parent-offspring regressions are linear and homoscedastic. As a result, the *unselected* descendants from a set of parents have a normal distribution of breeding values (and hence, Turelli's use of *Gaussian descendants* for this version of the infinitesimal).

What Generates a Gaussian Distribution Within a Family?

The **central limit theorem** from probability theory—that sums of random variables typically converge to a Gaussian distribution—implies that the distribution of breeding values is Gaussian under the infinitesimal genetics model (Bulmer 1971b; Barton et al. 2017). This Gaussian limit requires the key assumptions that loci are not too tightly linked, mating is random, and there has been no previous selection or any other force generating disequilibrium. If alleles are sufficiently correlated across loci, or if their effects are significantly different (for example, some remain at finite values while the rest become vanishingly small), then convergence to a normal is by no means assured (Lange 1978, 1997; Matthysse et al. 1979; Dawson 1997).

In particular, as we will demonstrate, selection can generate dependencies (linkage disequilibrium [LD]) among sets of three (or more) loci, which can transform a normal distribution into a non-normal one as selection proceeds. However, under the infinitesimal genetics model, there are no changes in allele frequencies, implying that once selection stops

and random mating occurs, any departures from normality (being due to LD) quickly decay. Indeed, Bulmer (1980) showed that the k th-order departure from normality (measured by cumulants, which are introduced later in the chapter) decays by $(1/2)^{k-1}$ in each generation (assuming unlinked loci), so that following t generations of random mating, the k th-order initial departure from normality is scaled by $(1/2)^{t(k-1)}$, which quickly approaches zero. The issue remains as to how much of a departure from normality LD generates and whether this biases infinitesimal-model-based predictions of the selection response. We return to this issue later in the chapter.

A widely used feature of the Fisher-Bulmer infinitesimal model is (for unlinked loci in noninbred parents) a **constant within-family genetic variance**. Specifically, the distribution of breeding values, A_o , in the offspring, conditioned on the breeding values, A_f and A_m , of the parents, is assumed to be normally distributed, with a mean of $(A_f + A_m)/2$ and a variance of $\sigma_a^2/2$ (half the *genic* variance). Thus, we have homoscedasticity with the predictor error variance, $\sigma_a^2/2$, being a constant, independent of the parental values. This constant **Mendelian sampling variance** (or **segregation variance**) is caused by segregation of heterozygous loci in the parents. Provided the loci are unlinked, this feature holds even when gametic-phase disequilibrium is present, as with the independent assortment of heterozygotes, the linkage phase of a parent does not influence gamete frequencies for unlinked loci (Example 16.2). More generally, the segregation variance is given by $\sigma_a^2(1 - \bar{f})/2$, where \bar{f} is the average amount of inbreeding in the two parents (reflecting the decrease in heterozygosity in the parents; Example 16.2). As detailed in Chapter 19, the additive relationship matrix, \mathbf{A} , fully across for relatedness-based changes in σ_a^2 among a collection of individuals in a BLUP analysis.

Under the infinitesimal genetics model and its assumption of no selection-induced allele-frequency change, the genic variance (corrected parental inbreeding) remains constant. However, if the infinitesimal genetic assumption is violated, the even alleles with very small effects eventually will have their frequencies changed by selection. This alters the genic variance, and hence changes the segregation variance. When major genes are present, the segregation variance depends on parental genotypes, which compromises the constant-variance (i.e., genotype-independent) assumption made under the Fisher-Bulmer infinitesimal. Indeed, recall from LW Chapter 8, that such variation of the within-family variance over families is one (albeit weak) test for the presence of a major gene.

Modifications of the Fisher-Bulmer Infinitesimal Model

The rest of this chapter starts to move beyond the standard (Fisher-Bulmer) infinitesimal model. First, by assuming a Gaussian distribution of allelic effects *at each locus*, we can partly account for changes in allele frequencies, and hence changes in σ_a^2 , caused by a finite number of loci and/or genetic drift. This approximation breaks down over time (Chapter 25) and is best regarded as an intermediate-term predictor of response. Next, we allow for linkage. Finally, we examine the selection response when the distribution of genotypic values is no longer normal. None of these approaches fully accounts for allele-frequency change, and they are best considered as predictors for intermediate-term response. The prediction of long-term response requires explicit population-genetic models (Chapters 5, and 25–28).

Finally, a number of authors have suggested finite-locus modifications of infinitesimal-like models, largely in the context of fitting the segregation term in a mixed model when major alleles are also segregating (Cannings et al. 1978; Fernando et al. 1994; Stricker et al. 1995; Lange 1997; Du et al. 1999; Pong-Wong et al. 1999; Goddard 2001). These methods foreshadowed certain aspects of genomic selection, which assigns weights to different chromosomal segments in order to use marker data to predict breeding values (Volume 3). Diffusion approximations (Appendix 1) of finite-locus models were proposed by Miller et al. (2006).

GAUSSIAN CONTINUUM-OF-ALLELES MODELS

Simulation studies (e.g., Bulmer 1974a, 1976; Mueller and James 1983; Sorensen and Hill 1983; Chevalet 1988) have shown that the infinitesimal model gives a reasonably good fit to the change in variance over a few generations of selection when the number of loci is large but finite (provided all alleles have small effects). With a finite number of loci (and hence nonvanishing individual locus effects), some (potentially very small) selection-induced allele-frequency change occurs in each generation. After a sufficient number of generations, the cumulative effect of these changes becomes so large that they cannot be ignored (Chapter 25). Likewise, if the population is finite, genetic drift also changes allele frequencies (Chapter 2). Thus, when either the number of loci, n , or the effective population size, N_e , is finite, we must incorporate changes in the *genic* variance, σ_a^2 , into our model.

Is there an intermediate step between the short-term predictions from the breeder's equation/in infinitesimal model and the unpredictable long-term behavior when significant allele-frequency changes have occurred? In many cases, an affirmative answer is provided by approximations using **continuum-of-alleles models (COA)**. Our focus here is on the Gaussian COA model, with other COA models (such as the house-of-cards, rare alleles, or house-of-Gauss models) examined more fully in Chapter 28. For brevity, for the rest of this chapter, *continuum-of-alleles* refers strictly to the Gaussian COA. This model allows us to partly account for modest changes in allele frequencies due to selection (given a finite number of loci) and genetic drift (due to finite population size). The nice feature about these intermediate-term approximations for response is that they are based entirely on macroscopic parameters, for which there is some hope of estimation.

Infinite-alleles and Continuum-of-alleles Models

The historical roots of the continuum-of-alleles model trace back to the classic paper of Kimura and Crow (1964), which introduced the **infinite-alleles model** (Chapter 2). Before its publication, most population-genetic models typically assumed two (or at most a few) alleles per locus. Kimura and Crow, in the first serious treatment of molecular evolution, noted that with an allele being represented by a long DNA sequence, each new mutation likely creates a new sequence, implying an effectively infinite number of possible alleles. Kimura and Crow's original paper simply dealt with how much variation (measured in terms of heterozygosity) could be maintained by the balance between drift and mutation (Chapter 2), and it was not concerned with allelic effects. Crow and Kimura (1964) and Kimura (1965a) quickly applied this notion of a very large number of alleles per locus to quantitative genetics by considering the distribution of allelic effects at each locus. These Gaussian continuum-of-alleles models were further developed by Latter (1970), Lande (1975, 1977a), and Felsenstein (1977) to consider the amount of variation maintained by mutation-selection balance (Chapter 28). Kimura's (1965a) original analysis revealed that if new mutations have small effects relative to the existing variation at the locus, the distribution of effects (in an infinite population) converges to a normal.

Hence, Gaussian COA models make the assumption that the distribution of additive genetic values *at each locus* is Gaussian (and jointly multivariate normal over a vector of loci). This assumption is strictly correct only if the number of alleles at each locus is infinite, which further implies that there is an infinite population size. This assumption of a *Gaussian distribution of effects at each locus* is much more restrictive than the assumption that the distribution of the *total* genotypic values is normal. The latter follows from the central limit theorem, as the sum of non-normal distributions of single-locus effects converges to a Gaussian, provided that the loci are not overly correlated.

While Gaussian COA models are a very restrictive subset of all possible models that can lead (at their limit) to the infinitesimal, their advantage is that we can assume a *finite number of loci*, and hence partly accommodate allele-frequency change. As discussed in Chapter 28, Gaussian COA models assume that mutational input in any generation is much smaller than the standing additive variation at a locus, or equivalently, that mutation is much stronger

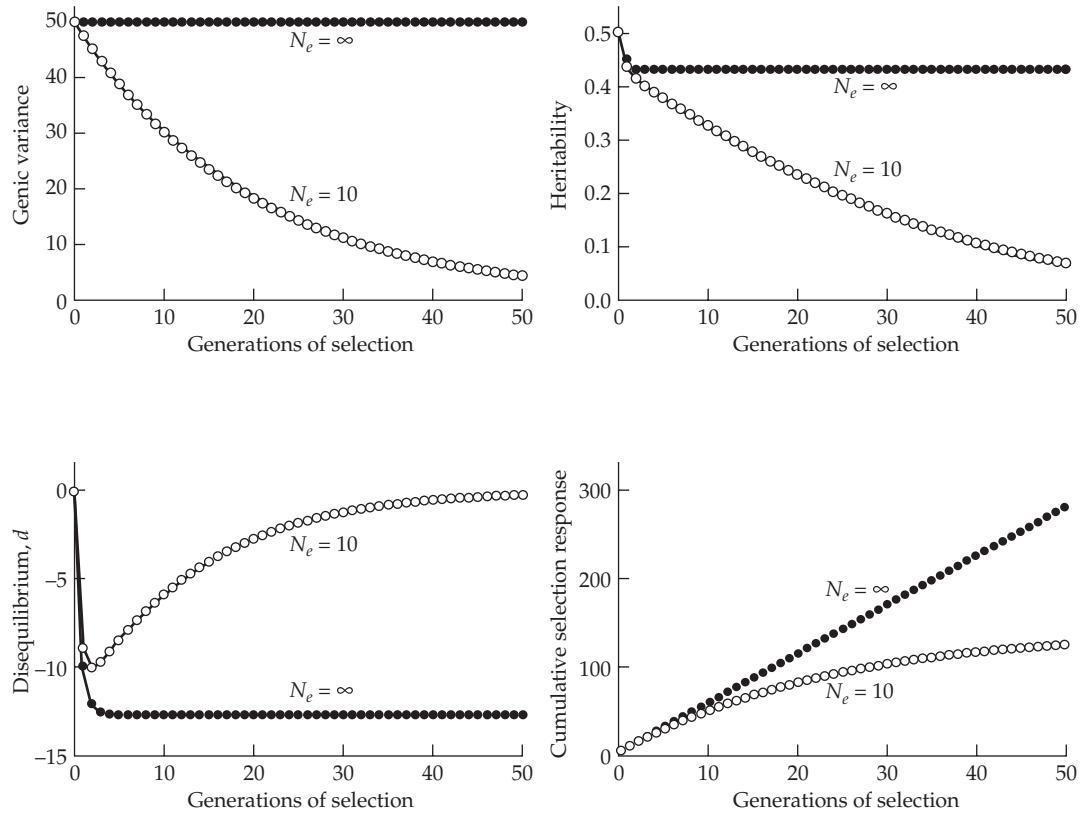

Figure 24.1 The impact of a finite population size, on the genic variance, σ_a^2 (upper left panel), heritability (upper right panel), disequilibrium d (lower left panel), and cumulative selection response (lower right panel). Open circles correspond to $N_e = 10$, and filled circles to the infinitesimal model in the absence of drift ($N_e = \infty$). Details in Example 24.2.

than selection (which allows significant amounts of polymorphism to accumulate at a given locus; Chapter 7). One scenario where biology suggests that the Gaussian model might be approached is in asexual species, where the entire genome is essentially transmitted as a single gene, and hence can have a very large number of possible alleles.

Gaussian COA models attempt to bridge short-term predictors (such as the breeder's and Bulmer equations) that rely on estimable qualities (σ_A^2, h^2) with the long-term predictors of response (Chapters 25 and 26) based on population-genetic models containing quantities that are essentially unestimable. COA models attempt, using estimable quantities, to capture the change in variance from changes in both allele frequencies (and hence changes in σ_a^2) and σ_A^2 from selection-generated disequilibrium (changes in d). Gaussian approximations of the Bulmer equation for the change in variance (Equation 16.7b) under a finite number of loci (n) were introduced by Lande (1975) and Felsenstein (1977, 1979), and Keightley and Hill (1987) further allowed for a finite effective population size (N_e). We consider the effects of drift first. The behavior of these models with mutation is discussed extensively in Chapter 28.

Drift

Assuming that the phenotypic variance after selection has the form $\sigma_{z^*}^2 = (1 - \kappa) \sigma_z^2$ (Equation 16.10a), Keightley and Hill (1987) obtained equations for the change in the additive genic variance, σ_a^2 , and the gametic-phase disequilibrium, d , when the population size is

finite:

$$\Delta \sigma_a^2(t) = -\frac{\sigma_a^2(t)}{2N_e} \quad (24.1a)$$

$$\Delta d(t) = -\frac{1}{2} \left[\left(1 + \frac{1}{N_e}\right) d(t) + \left(1 - \frac{1}{N_e}\right) \kappa h^2(t) \sigma_A^2(t) \right] \quad (24.1b)$$

Note that these expressions were shown previously (Equations 16.9a and 16.9b). As before, $\sigma_A^2(t) = \sigma_a^2(t) + d(t)$ and $h^2(t) = \sigma_A^2(t)/\sigma_z^2(t)$, with $\sigma_z^2(t) = \sigma_A^2(t) + \sigma_E^2$, where $\sigma_E^2 = \sigma_z^2(0) - \sigma_A^2(0)$. As in Chapter 16, the selection response in the mean is given by the breeder's equation, $R(t) = h^2(t)S(t)$. If the population size is at least modest, the correction for drift effects on $d(t)$ is small, as $1 \pm 1/N_e \simeq 1$, and Equation 24.1b essentially becomes the Bulmer equation. Drift effects on the genic variance, however, are quite substantial, as they remove all of the initial genic variance (σ_a^2 , and hence σ_A^2) after sufficient time ($t \simeq 2N_e$ generations, ignoring new mutation). Solving Equation 24.1a yields

$$\sigma_a^2(t) = \left(1 - \frac{1}{2N_e}\right)^t \sigma_a^2(0) \simeq \sigma_a^2(0) \exp\left(-\frac{t}{2N_e}\right) \quad (24.1c)$$

This is simply the standard loss of genetic variation under drift (Chapter 2). When dominance or epistasis is present, the additive variance can actually *increase* (for a while) under inbreeding (Chapter 11), so the assumption of only additive gene action is critical. In the absence of mutation, the response runs out of standing variation in finite populations, as σ_a^2 is driven to zero by drift.

Example 24.2. To see the effects of drift on the infinitesimal model, reconsider Example 16.2 under finite population size. This example assumed that $h^2(0) = 0.5$ and $\sigma_z^2(0) = 100$, implying that $\sigma_A^2(0) = \sigma_a^2 = \sigma_E^2 = 50.00$ (assuming $d(0) = 0$). Truncation selection was applied, with the upper 20% saved (yielding $p = 0.2$, $\kappa = 0.781$, and $\bar{t} = 1.40$). Under the infinitesimal model, the genic variance, σ_a^2 , remains unchanged at its original value of 50, while the additive genetic variance decreases to its equilibrium value of $\tilde{\sigma}_A^2 = 37.46$, and hence $\tilde{h}^2 = 37.46/(37.46 + 50.00) = 0.43$, yielding an asymptotic value of response of $\tilde{R} = \bar{t}\tilde{h}^2\tilde{\sigma}_z = 5.6$ per generation.

Now consider a finite population size with $N_e = 10$, which is close to the effective population sizes of many artificial selection experiments (Chapter 26). Iteration of Equation 24.1 yields the dynamics depicted in Figure 24.1. Drift erodes away the genic variance, decreasing the heritability (and hence response) over time. The population (in the absence of mutation) will eventually run out of variation, reaching a **selection limit** (Chapters 25 and 26). Note the unusual behavior of the disequilibrium, d , which (following an initial drop) increases toward zero over time. This occurs because the genic variance is declining, which limits the amount of disequilibrium that is possible (Equation 24.4).

Drift and a Finite Number of Loci

Under the infinitesimal model, there is no selection-induced change in allele frequencies, leaving the genic variance unchanged by selection. However, when the population size is finite, alleles are subjected to drift, changing allelic frequencies and eventually reducing the genic variance to zero. A second route for allele-frequency change arises when the number of loci, n , is finite. In this case, there are nonzero selective effects on each locus and allele frequencies change (although potentially very slowly; recall from Equation 5.21 that s scales as a/σ_z). Assuming that the potential distribution of genotypic values at *each* locus is Gaussian, continuum-of-alleles (COA) models can account for both finite N_e and n . The

most general result is due to Chevalet (1988, 1994; also see Verrier et al. 1991), where for loci of equal effect and assuming selection of the form such that the phenotypic variance after selection is $\sigma_{z^*}^2 = (1 - \kappa) \sigma_z^2$, we have

$$\Delta \sigma_a^2(t) = - \left[\frac{\sigma_a^2(t)}{2N_e} + \left(1 - \frac{1}{N_e}\right) \frac{\kappa h^2(t) \sigma_A^2(t)}{2n} \right] \quad (24.2a)$$

$$\Delta d(t) = -\frac{1}{2} \left[\left(1 + \frac{1}{N_e}\right) d(t) + \left(1 - \frac{1}{n}\right) \left(1 - \frac{1}{N_e}\right) \kappa h^2(t) \sigma_A^2(t) \right] \quad (24.2b)$$

Provided we are willing to accept the assumption that the distribution of effects at each locus remains normally distributed (a point addressed later), these expressions are iterated to obtain the current values of σ_a^2 and d . Starting from an unselected base population (and hence assuming that $d(0) = 0$), the only genetic parameters required to iterate Equations 24.2a and 24.2b are $\sigma_A^2(0)$, h^2 , n , and N_e , all of which are potentially estimable.

Equations 24.2a and 24.2b highlight the changes that occur when we assume a finite number of loci ($n < \infty$) and/or finite population size ($N_e < \infty$). When both are infinite, we recover the Bulmer equation (16.7b),

$$\Delta \sigma_a^2(t) = 0 \quad \text{and} \quad \Delta d(t) = -\frac{d(t) + \kappa h^2(t) \sigma_A^2(t)}{2} \quad (24.2c)$$

Notice that the additive genic variance, σ_a^2 , remains unchanged (as allele frequencies remain unchanged), while disequilibrium (nonzero d) is generated by selection but decays to zero once selection stops (i.e., when $\kappa = 0$).

While finite n or N_e both result in modifications of the simple Bulmer equation for the dynamics of d , Equation 24.2b shows that these corrections are generally small. However, this is not the case for changes in σ_a^2 . With either finite population size or a finite number of loci, the genic variance decreases in each generation, eventually decaying to zero (in the absence of mutation). The relative importance of drift in comparison to a finite number of loci for changes in σ_a^2 can be compared using Equation 24.2a, which yields

$$\frac{\Delta \sigma_a^2}{2} = \begin{cases} -\frac{\sigma_a^2}{N_e} & \text{for } n = \infty \\ -\frac{\kappa h^2 \sigma_A^2}{n} & \text{for } N_e = \infty \end{cases} \quad (24.2d)$$

Because either directional or stabilizing selection generates negative values of d , we have that $0 < \kappa < 1$ (and hence $\kappa h^2 < 1$), implying that $\sigma_A^2 = \sigma_a^2 + d < \sigma_a^2$, so that $\sigma_a^2 > \sigma_A^2 > \kappa h^2 \sigma_A^2$. Using this inequality in Equation 24.2d shows that for comparable values of N_e and n , drift results in a greater per-generation reduction in σ_a^2 (also see Figure 24.2).

Example 24.3. Suppose the number, n , of loci underlying a trait is finite. Assume the same model as in Example 24.2, but now let $n = 10$ and $N_e = \infty$ (i.e., reversing the values of n and N_e). We will contrast the behavior of this system with that in Example 24.2 ($N_e = 10$, $n = \infty$), and with the standard infinitesimal model ($N_e = n = \infty$). As Figure 24.2 shows, both h^2 and the selection response decrease over time with a finite number of loci, and eventually a selection limit is reached when all of the initial variation is lost. However, these decreases are not nearly as dramatic as those in Example 24.2 (see Figure 24.1). Figure 24.2 shows that the cumulative response for a model with $N_e = n = 10$ is only very slightly less than under drift alone ($N_e = 10$).

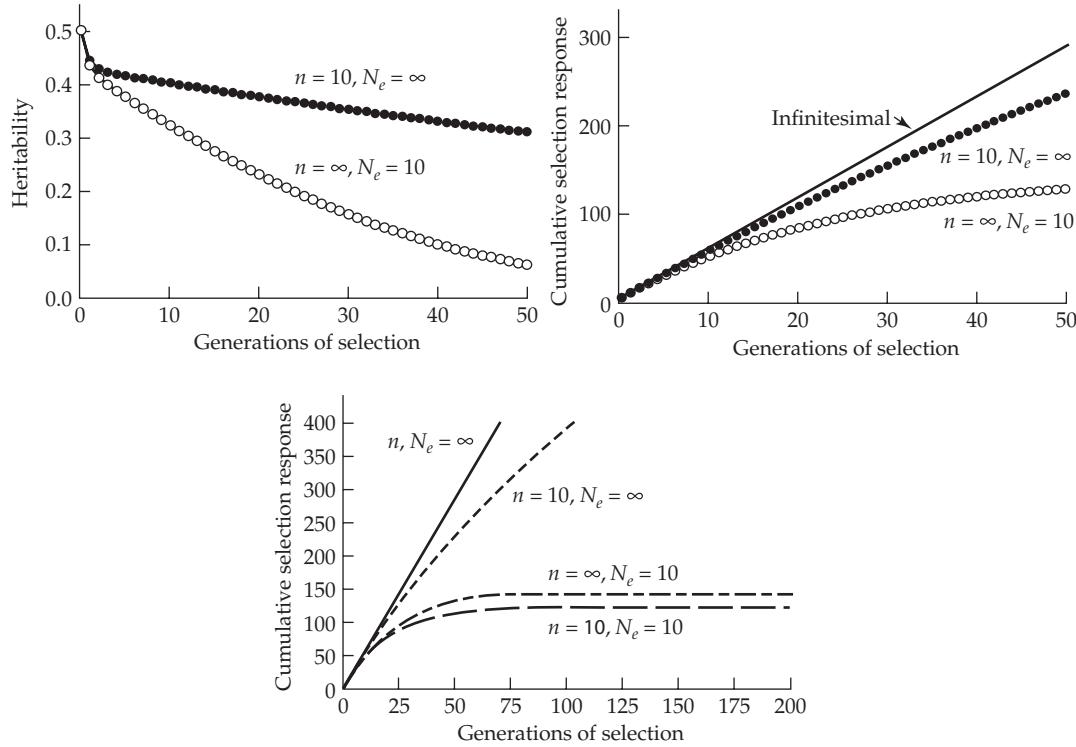

Figure 24.2 The impact of a finite number, n , of loci on heritability and selection response. In both upper panels, the filled circles correspond to the response, with $n = 10$ and $N_e = \infty$, while the open circles correspond to $N_e = 10$ and $n = \infty$. The lower panel displays the cumulative response under four different combinations of N_e and n . Note that the values of $N_e = n = \infty$ corresponds to the standard infinitesimal model.

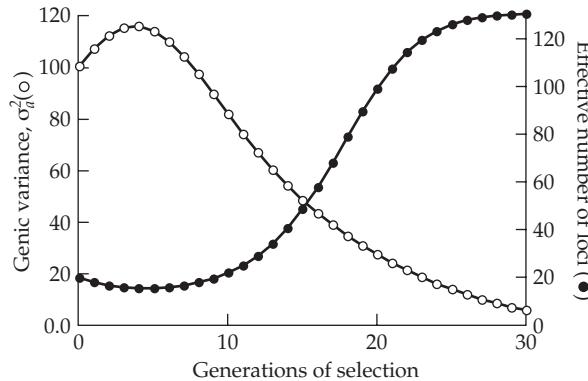

Figure 24.3 The change in the genic variance, σ_a^2 (open circles), and the effective number of loci, n_e (filled circles; see Equation 24.3), for a model with 5 major and 125 minor loci. See Example 24.4 for details.

The Effective Number of Loci, n_e

Chevalet (1994) allowed loci to differ in the amount of genetic variance they contribute, replacing the actual number of loci, n , in Equations 24.2a and 24.2b by the **effective number of loci**, n_e , defined as

$$n_e = \frac{n}{1 + c_v^2} \quad (24.3)$$

where c_v is the coefficient of variation in the genic variance contributed by each locus,

$\sigma(\sigma_{ai}^2) / E[\sigma_{ai}^2]$, with σ_{ai}^2 being the genic variance contributed by locus i . (Note that Equation 24.3 is closely related to the Castle-Wright estimator for the effective number of segregating genes in a line-cross F₂ population; LW Chapter 9.) If all loci contribute the same variance, then $c_v = 0$ and $n_e = n$, while $n_e \ll n$ when $c_v \gg 1$.

Note that n_e changes over time, as allele-frequency changes alter the genic variance contributed by any particular locus. Indeed, loci with the largest genetic variance should show the largest initial response to selection, and also the fastest depletion of locus-specific variance (Chapter 25). In such cases, one can move from a situation where the effective number of loci is quite small (a few loci with large effects, and hence a high value of c_v) to a situation where n_e can be quite large (with the remaining loci all having roughly equal effects, so that c_v is small). Hence, n_e can increase over time, but we also correspondingly expect the total genic variance, σ_a^2 , for the remaining loci to decrease (Figure 24.3).

Example 24.4. As an illustration of how the effective number of loci, n_e , can change over the course of selection, consider an additive model with both major and minor loci underlying a trait under selection. There are five major loci, each with frequency $p = 0.25$ and effect size $a = 5.16$, and 125 minor loci, each with $p = 0.5$ and $a = 0.89$. The resulting initial genic variance is $\sigma_a^2 = 100$ (half of which is from the major genes and half from the minor loci), and we assume an initial heritability of $h^2 = 0.5$ (by setting $\sigma_E^2 = 100$). Finally, assume truncation selection with the uppermost 20% saved (further details for this model are given in Example 25.2). We ignore any effects of disequilibrium, focusing instead on how the genic variance (the open circles in Figure 24.3) and the effective number of loci, n_e (the filled circles) change over time due to allele-frequency changes.

As shown in Figure 24.3, while there are 130 loci in this system, initially the effective number is around 20, due to the large coefficient of variation in the locus-specific genic variances. As selection proceeds, the genic variance initially *increases* as the major alleles increase their frequencies toward 0.5 (where they have maximal additive variance when dominance is absent; LW Figure 4.8). Such an increase in variance is not predicted by Gaussian COA models (which assume a continuous *distribution* of allelic effects at each locus, rather than simply two alleles). Notice that the effective number of loci decreases slightly during this increase in variance, as the c_v increases. As alleles at these major loci become fixed, the total genic variance decreases while the effective number of loci increases (to approximately 125, the number of minor loci), reflecting a decrease in the coefficient of variation (as the remaining loci all have very similar variances).

As Example 24.4 illustrates, a selection response can result in an increase in the additive variance at some point during selection (typically fairly early), as favored alleles at low frequencies increase to intermediate frequencies. Hospital and Chevalet (1996) observed a similar phenomenon in their simulation of linkage, namely, that finite-locus models can also show an increase in additive variation. The distinction is that this increase may come, not rather quickly (as was the case for rare alleles), but only many generations after selection is initiated, reflecting recombination finally generating favorable gametes, which then increase in frequency. They also found that linked systems are vulnerable to lower selection responses due to hitchhiking fixing less favorable alleles, an issue examined further in Chapter 26.

Dynamics: σ_a^2 and d Change on Different Time Scales

Chevalet (1988, 1994) and Gavrilets and Hastings (1994a, 1995) noted that the dynamics of the genic variance and the disequilibrium operate on rather different time scales. The change in d is rather rapid, quickly approaching a **quasi-equilibrium** value (Kimura 1965b),

$$d = -\kappa \left(1 - \frac{1}{n_e}\right) h^2 \sigma_A^2 \quad (24.4)$$

Note from Equation 24.2b that this is simply the amount of new disequilibrium generated by selection (taking $N_e = \infty$). This is not strictly an equilibrium value, as changes in σ_a^2 , which occur over much longer time scales, also change σ_A^2 , albeit much more slowly. As $n_e \rightarrow \infty$, we recover Equation 16.7c (as $\delta(\sigma_z^2) = -\kappa\sigma_z^2$), the equilibrium d value found by Bulmer (which is a true equilibrium, as σ_a^2 does not change under the infinitesimal model). Thus, for a given value of σ_a^2 , there is a quick approach to the equilibrium value of d , which we can very closely approximate by treating the value of σ_a^2 as fixed and applying Equations 16.13a–16.13c.

One direct application of Equation 24.4 involves the distribution of the additive genetic variance within the population. This can be decomposed into that held between families (the difference in family means) and that generated by segregation within each family (Chapter 16). When no disequilibrium is present ($d = 0$), under random mating, each component is $\sigma_A^2/2 = \sigma_a^2/2$. However, with selection, the genetic variance *among* full-sib families is simply half the additive variance following selection, $\sigma_A^2 + d$, which (Equation 24.4) yields

$$\sigma^2(FS) = \frac{\sigma_A^2}{2} \left[1 - \left(1 - \frac{1}{n_e} \right) \kappa h^2 \right] \quad (24.5a)$$

while the within-family (additive genetic) variance is

$$\sigma_A^2(\text{within-family}) = \frac{\sigma_A^2}{2} = \frac{\sigma_A^2}{2} \left[1 + \left(1 - \frac{1}{n_e} \right) \kappa h^2 \right] \quad (24.5b)$$

Equation 24.5b follows by noting that $\sigma_A^2 = \sigma_a^2 + d$, and substituting Equation 24.4 for the value of d .

Gavrilets and Hastings (1994a, 1995) noted that this difference in time scales for changes in d versus σ_a^2 has important implications for the interpretation of experiments using artificial stabilizing selection, where response is measured by a decrease in the phenotypic variance. Simulations, as well as their analysis of two- and n -locus models, showed that while a rapid approach to the quasi-equilibrium d value (Equation 24.4) occurs, the rate of change of allele frequencies can be very slow—on the order of 100 (or more) generations even with strong selection under a two-locus model. As mentioned in Chapter 16, we expect an immediate decrease in the phenotypic variance due to selection generating negative disequilibrium, which reduces σ_A^2 . Selection will also operate to eventually reduce the genic variance, σ_a^2 , resulting in a further decrease in σ_A^2 over that predicted from disequilibrium alone. Gavrilets and Hastings suggested that, given the short time scales of most experiments, if decreases in σ_a^2 occur, these are more likely due to drift than selection. A related point is that an observed reduction in the phenotypic variance is usually assumed to arise solely from a reduction in σ_A^2 . However, as mentioned in Chapter 17, if there is heritable variation in σ_E^2 , the environmental variance is also reduced by stabilizing selection. Thus, selection-driven allele-frequency changes might be involved in an observed reduction in the phenotypic variance, but through changes in σ_E^2 , rather than through σ_a^2 for the trait.

How Robust Is the Gaussian Continuum-of-alleles Model?

As will be fully discussed in Chapter 28, a key determinant of which continuum-of-alleles model is appropriate is the relative strength of selection and mutation at a locus (Table 28.2). The Gaussian model is appropriate when the per-locus mutation rate is far greater than the average strength of selection on a locus (in a large population). In such settings, a given locus is likely to be segregating a large number of alleles, and any new allele adds little to the standing variation. Conversely, other approximations (such as the rare-allele or the house-of-cards models) are more appropriate when selection is much stronger than mutation (i.e., $s \gg \mu$), in which case any given locus will have one dominant allele and a few very rare alleles. Our discussion here assumes that mutation is much stronger than selection.

Under this assumption, if the trait is determined by a modest to large number of loci, all of roughly equal effect and with alleles at intermediate frequencies, then Gaussian COA

models can perform reasonably well, at least over intermediate time scales (Chevalet 1988, 1994). They generally tend to overestimate the cumulative response as generations increase, so that while the decrease in σ_a^2 from selection is partially captured (an improvement over the infinitesimal model), after sufficient time, the COA approximation breaks down.

What are the possible causes for the breakdown of the approximation? A subtle feature of the Gaussian assumption for each locus is the key. The COA approximation generally works well at the start of selection, provided the distributions of genotypic values at each locus are initially *close* to normal. However, as allele-frequency changes drive the individual locus distributions further from normality, the COA approximation breaks down, as loci with alleles at extreme frequencies (near zero or one) can show large departures from normality. A recurrent theme of this chapter is a focus on the skewness and kurtosis of distributions, as these provide very convenient measures of the departure from a normal. Skewness measures departures from symmetry, while kurtosis measures whether the tails of the distribution decline more or less rapidly than under a normal. Both of these statistics (with kurtosis appropriately defined) are zero under a normal, and hence they provide a simple quantification of the departure of a distribution from normality (LW Chapter 2).

What can we say about the skewness and kurtosis for an n -locus biallelic model? Assume n exchangeable loci, each with frequency p of the favorable allele. Zeng (1987) showed that the scaled (to unit variance) coefficients of skewness, k_3 , and kurtosis, k_4 , for the resulting distribution of genotypic values are

$$k_3 = \frac{2p - 1}{\sqrt{2np(1-p)}} \quad \text{and} \quad k_4 = \frac{1 - 2p(1-p)}{2np(1-p)} \quad (24.6)$$

Note that skewness is zero and kurtosis is minimized at intermediate allele frequencies ($p = 1/2$). As allele frequencies become more extreme, so do the skew and kurtosis.

Rare alleles of large effect are especially problematic. Not only do these generate skewness and kurtosis, but as their frequencies increase, so does the genetic variance (Figure 24.3). Lande (1983) and Zhang and Hill (2005a) both noted that natural selection tends to generate a correlation between allelic effect size and frequency, so that alleles of large effect may tend to be rare in natural populations due to pleiotropic deleterious fitness effects. If these rare alleles are captured when a population is sampled to form a laboratory stock for artificial selection, an increase in additive variance is expected during selection. However, if the founding population is under strong drift for a few generations (as with a founding bottleneck), rare alleles can be lost and the COA approximation may be a good predictor of short-term response. This theme of initially rare favorable alleles, and hence an early accelerated response to selection, will be revisited in Chapter 28, as it is central to certain predictions about response in a population under mutation-selection balance.

THE BULMER EFFECT UNDER LINKAGE

Both the standard infinitesimal and Gaussian COA models assume *unlinked* loci. When loci are linked, the contribution from gametic-phase disequilibrium, d , decays by less than half in each generation. This allows higher values to accrue, yielding a larger value of $|d|$ at equilibrium. We examine the impact of linkage under two different settings. First, we consider the Gaussian COA approximation (requiring multivariate normality of the locus-specific distributions of effects), and second, allowing for departures from normality serves as an entry point for our final section on treating non-Gaussian distributions of genetic values.

An Approximate Treatment

An approximate solution for the dynamics of σ_A^2 incorporating linkage was offered by Bulmer (1974a, 1980), whose approach we follow (a more general solution by Turelli and Barton will be considered shortly). Recall from Chapter 16 that C_{ij} denotes the covariance

between allelic effects at loci i and j , meaning that C_{ii} is the genic variance for locus i , while C_{ij} for $i \neq j$ measures the contribution from disequilibrium between i and j . Thus, from Equation 16.1b, $d(t) = 4 \sum_{i < j} C_{ij}(t)$, with the changes in the pairwise covariances describing the change in d . If r_{ij} is the recombination fraction between two loci (we use r_{ij} in place of our more standard c_{ij} used in previous chapters to avoid confusion with C_{ij}), then $(1 - r_{ij}) C_{ij}(t)$ is the contribution passed on to $C_{ij}(t + 1)$. Recalling Equation 16.6, the change in $d(t)$ due to selection when genotypic and phenotypic values are normally distributed is

$$\frac{h^4(t)}{2} \delta(\sigma_{z(t)}^2) = 4 \sum_{i=1}^n \sum_{i < j} \delta C_{ij}(t) \quad (24.7a)$$

where we use both δX and $\delta(X)$ to denote the *within-generation* change in the variable X . In order to approximate δC_{ij} (the change in disequilibrium generated by selection), Bulmer assumed that these changes are the same for each pair of loci (an exchangeable model). For n loci, there are $n(n - 1)/2$ unique pairs, giving the contribution from each pair as

$$4\delta C_{ij}(t) \simeq \frac{h^4(t) \delta(\sigma_{z(t)}^2)}{n(n - 1)} \quad (24.7b)$$

Because the new disequilibrium equals the fraction of the current disequilibrium after recombination plus the fresh disequilibrium generated by selection

$$C_{ij}(t + 1) = (1 - r_{ij}) C_{ij}(t) + \delta C_{ij}(t) \quad (24.7c)$$

This equation is approximate, as the covariance *between* gametes, $C_{i,j}$, is ignored here. Equation 24.11c provides a more exact treatment (as does Example 28.7). Ignoring $C_{i,j}$, Equation 24.7c implies that, at equilibrium, $r_{ij} \tilde{C}_{ij} = \tilde{\delta} C_{ij}$, where the tildes denote equilibrium values. Using Equation 24.7b yields an equilibrium covariance of

$$\tilde{C}_{ij} = \frac{\tilde{h}^4 \tilde{\delta}(\sigma_z^2)}{4n(n - 1)} \frac{1}{r_{ij}} \quad (24.7d)$$

Thus,

$$\tilde{d} = 4 \sum_{i=1}^n \sum_{i < j} \tilde{C}_{ij}(t) = 4 \frac{\tilde{h}^4 \tilde{\delta}(\sigma_z^2)}{4n(n - 1)} \sum_{i=1}^n \sum_{i < j} \frac{1}{r_{ij}} = \frac{1}{2} \tilde{h}^4 \tilde{\delta}(\sigma_z^2) \frac{1}{r_H} \quad (24.8a)$$

where r_H is the harmonic mean of all pairwise recombination distances between loci,

$$r_H = \left(\frac{1}{n(n - 1)/2} \sum_{i=1}^n \sum_{i < j} \frac{1}{r_{ij}} \right)^{-1} \quad (24.8b)$$

The value of r_H varies with both the number of loci and chromosomes, decreasing as the number of loci per chromosome increases. Using simulations of randomly distributed loci, Bulmer (1974a) found that if the haploid chromosome number exceeds 10, r_H will likely be no smaller than 0.4, while in *Drosophila melanogaster*, with its three main chromosomes and lack of recombination in males, r_H is around 0.1 if there are many loci. However, even if only a few loci occur as tightly linked pairs, r_H can be considerably below 0.5, as the harmonic mean disproportionately weights very small values.

Assuming again that the phenotypic variance after selection can be written as $\sigma_{z^*}^2 = (1 - \kappa) \sigma_z^2$, Equation 16.13a can be modified for linkage to give the equilibrium additive genetic variance as $\tilde{\sigma}_A^2 = \sigma_z^2 \gamma$. Letting h^2 and σ_z^2 denote values in the absence of LD (i.e., $d = 0$, implying $h^2 = \sigma_a^2/\sigma_z^2$), then

$$\gamma = r_H \left(\frac{2h^2 - 1 + \sqrt{1 + 2h^2(1 - h^2)\kappa/r_H}}{2r_H + \kappa} \right) \quad (24.9)$$

and the equilibrium heritability, $\tilde{h}^2 = \tilde{\sigma}_A^2/\tilde{\sigma}_z^2 = (\sigma_a^2 + \tilde{d})/(\sigma_z^2 + \tilde{d})$, is given by Equation 16.13c using the value of γ for Equation 24.9. Note that we can express this result in terms of \tilde{d} by noting that $\tilde{\sigma}_A^2 - \sigma_a^2 = \tilde{\sigma}_A^2 - h^2\sigma_z^2 = \tilde{d}$, or that $\tilde{d} = (\gamma - h^2)\sigma_z^2$. The general conclusion from Equation 24.9 is that, for a fixed value of κ , increasing the amount of linkage (e.g., decreasing r_H) increases the absolute value of \tilde{d} (Bulmer 1974a, 1976, 1980).

Finally, turning briefly to disruptive selection (where $\kappa < 0$, and hence $d > 0$), the standard infinitesimal model predicts that \tilde{d} should increase as linkage tightens. As we saw in Chapter 16, with sufficiently strong disruptive selection, namely $\kappa < -r_H/[2h^2(1-h^2)]$, there is no real positive root for γ in Equation 24.9, and the standard infinitesimal model predicts that d , and hence σ_A^2 , increases without limit (Bulmer 1976). With a finite number of loci, this condition implies that selection creates almost complete disequilibrium, so that only a few of the possible gamete types are actually present, namely, most gametes are either $abcd\dots$ or $ABCD\dots$ (Chapter 16).

While the prediction that \tilde{d} increases under disruptive selection as linkage tightens holds for an infinite population, simulations by Sorensen and Hill (1983) found exactly the opposite with small values of N_e , with $|\tilde{d}|$ actually *decreasing* as linkage tightens. They reasoned that this discrepancy arises due to the interaction between a finite number of loci and the finite population sizes used in their simulations. To see this, consider complete linkage. In a finite population, the most extreme gamete observed is affected by sampling, as selection can generate no gamete more extreme than those found in the initial sample (in the absence of recombination). If the number of loci is small, the probability of sampling the most extreme possible gamete is high, but this probability decreases as the number of loci increases. Countering this, as recombination (measured by r_H) or the population size increases, the probability increases that recombination can regenerate more extreme gametes before the relevant loci are fixed by drift or selection. When population size becomes large enough that drift effects are no longer important, \tilde{d} increases with increasing linkage. Interactions of this sort between drift, selection, and recombination are considered in detail in Chapter 26.

Example 24.5. As an example of the consequences of increased linkage, reconsider our analysis of the response under directional selection used in Examples 24.2 and 24.3. Here we assume an infinite number of loci and infinite population size. Substituting into Equation 24.9 to obtain γ and recalling Equations 16.13a–16.13c yields the following metrics of response for different r_H values:

r_H	γ	\tilde{d}	$\tilde{\sigma}_A^2$	\tilde{h}^2	\tilde{R}
0.5	0.37	-12.60	37.40	0.43	5.60
0.4	0.35	-14.50	35.50	0.42	5.37
0.3	0.33	-17.11	32.89	0.40	5.06
0.2	0.29	-20.97	29.03	0.37	4.57
0.1	0.23	-27.49	22.51	0.31	3.70

A value of $r_H = 0.5$ corresponds to free recombination, while $r_H = 0.1$ might be expected in *Drosophila melanogaster*. As expected, decreasing the average amount of recombination between loci increases the effect of linkage disequilibrium, generating more extreme d values, and hence (for directional and stabilizing selection) smaller additive variances, heritabilities, and selection responses. With strong linkage ($r_H = 0.1$), the response is only 66% of that for unlinked loci (3.70 versus 5.60).

A More Careful Treatment

A more rigorous treatment of how selection changes the within-gamete covariances, C_{ij} ,

requires consideration of the (pairwise) **between-gamete covariance**, $C_{i,j}$, as well as higher-order covariance terms that measure the amount of gametic-phase disequilibrium between groups of more than two loci. Here, we introduce some of the notation needed for non-normal distributions of genotypic and phenotypic values, returning to the consequences of relaxing the normality assumption in the next section.

We start by defining the between-gamete covariance,

$$C_{i,j} = \sigma \left(a_{fa}^{(i)}, a_{mo}^{(j)} \right) \quad (24.10)$$

which is the covariance between the effect of an allele at the i th locus in the paternal (fa) gamete and an allele at the j th locus in the maternal (mo) gamete. Under random mating, gametes unite at random, and hence $C_{i,j} = 0$ at the start of each generation. However, selection generates correlations *between* gametes in much the same way that it generates correlations among loci *within* gametes. For example, consider a particular chromosome containing multiple loci influencing a character under stabilizing selection. Initially, there is no correlation between the genetic values of the two copies of this chromosome in an offspring from randomly mated parents. Stabilizing selection changes this initial distribution, favoring adults with intermediate genotypic values. Thus, surviving adults with a large genetic value on one chromosome are expected to have a small value on the other and vice versa, generating negative $C_{i,j}$ (Figure 16.2; Example 28.7). Likewise, positive assortative mating generates positive $C_{i,j}$, while disassortative mating generates negative $C_{i,j}$.

We assume random mating, so that $C_{i,j}(t) = 0$ at the start of each generation. Letting C^* denote the covariance after selection, where

$$C_{ij}^*(t) = C_{ij}(t) + \delta C_{ij}(t) \quad \text{and} \quad C_{i,j}^*(t) = C_{i,j}(t) + \delta C_{i,j}(t) = \delta C_{i,j}(t) \quad (24.11a)$$

Assuming recombination follows selection, then with probability $1 - r_{ij}$, no recombination occurs between i and j and the within-gamete covariance is unchanged. Conversely, with a probability of r_{ij} , recombination occurs and the new covariance depends on the covariance *between* gametes, yielding the result of Lande (1975) and Bulmer (1980) that

$$C_{ij}(t+1) = (1 - r_{ij})C_{ij}^*(t) + r_{ij}C_{i,j}^*(t) \quad (24.11b)$$

Substituting for C^* from Equation 24.11a yields

$$\begin{aligned} C_{ij}(t+1) &= (1 - r_{ij}) [\delta C_{ij}(t) + C_{ij}(t)] + r_{ij} \delta C_{i,j}(t) \\ &= (1 - r_{ij})C_{ij}(t) + \delta C_{ij}(t) - r_{ij} [\delta C_{ij}(t) - \delta C_{i,j}(t)] \end{aligned} \quad (24.11c)$$

Note that we recover Equation 24.7c only if $\delta C_{ij}(t) = \delta C_{i,j}(t)$, meaning that selection changes the within-gamete and between-gamete covariances by the same amount. Turelli and Barton (1990) showed that this occurs if there is either global gametic-phase equilibrium before selection (all groups of loci are in gametic-phase equilibrium) or the distribution of allelic effects over loci is multivariate normal (see Equations 24.13a and 24.13b). Thus, Equation 24.7c follows under Gaussian COA assumptions. However, selection can drive a distribution away from normality, in which case Equation 24.7c may no longer hold.

General expressions for $\delta C_{ij}(t)$ and $\delta C_{i,j}(t)$ were obtained by Turelli and Barton (1990) for the case of no dominance or epistasis. Their expressions involve generalizations of (i) measures of selection to higher moments of a distribution, and (ii) disequilibrium measures to groups of k loci. Starting with (i), recall (Equation 13.27b) that we defined the directional selection gradient, which measures how mean fitness varies with the phenotypic mean, as $\partial \ln \bar{w} / \partial \mu_z$. We can extend this notion to higher moments by considering $\partial \ln \bar{w} / \partial \mu_{k,z}$, where $\mu_{k,z} = E[(z - \mu_z)^k]$ is the k th central moment of the phenotypic distribution (for $k \geq 2$), with $\mu_{2,z} = \sigma_z^2$. If selection is primarily on the mean and variance of the phenotypic

distribution, gradients for the skew and higher moments ($k \geq 3$) will generally be negligible. When phenotypes are normally distributed, the first two gradients are given by

$$\frac{\partial \ln \bar{w}}{\partial \mu_z} = \frac{S}{\sigma_z^2} \quad (24.12a)$$

$$\frac{\partial \ln \bar{w}}{\partial \sigma_z^2} = \frac{\delta(\sigma_z^2) + S^2}{2 \sigma_z^4} \quad (24.12b)$$

(Lande 1976; Lande and Arnold 1983). As will be shown in Chapters 29 and 30, when selection acts only on the mean (such that $\partial \ln \bar{w}/\partial \mu_{k,z} = 0$ for $k \geq 2$), the within-generation change in the phenotype variance will be $\delta(\sigma_z^2) = -S^2$. Hence, $\delta(\sigma_z^2) + S^2$ is the change in variance over that expected due to selection simply on the mean.

Using these extended selection gradients, and ignoring selection acting on the skew and higher moments (i.e., $\partial \ln \bar{w}/\partial \mu_{k,z} = 0$ for $k \geq 3$), Turelli and Barton (1990) found that

$$\delta C_{ij} = \frac{\partial \ln \bar{w}}{\partial \mu_z} \sum_{h=1}^n C_{ijh} + \frac{\partial \ln \bar{w}}{\partial \sigma_z^2} \sum_{h=1}^n \sum_{\ell=1}^n (C_{ijh\ell} - C_{ij} C_{h\ell}) + \dots \quad (24.13a)$$

$$\delta C_{i,j} = \frac{\partial \ln \bar{w}}{\partial \sigma_z^2} 2 \sum_{h=1}^n C_{ih} \sum_{\ell=1}^n C_{j\ell} + \dots \quad (24.13b)$$

where C_{ijh} refers to the third-order covariance between the effects of alleles at loci i , j , and h . If X_i is the additive value of a randomly chosen allele at locus i , and $\mu_i = E(X_i)$ is the average value for this locus, then $C_{ijh} = E[(X_i - \mu_i)(X_j - \mu_j)(X_h - \mu_h)]$. Higher-order covariances are similarly defined. The covariances in Equation 24.13a measure the amount of third-order (C_{ijh}) and fourth-order ($C_{ijh\ell}$) gametic-phase disequilibrium (the departures from random assortment for triplets and quadruplets of loci). If selection on the third (skew) or higher-order moments is significant, then Equations 24.13a and 24.13b need to include covariance terms of order five and higher.

The key point about these equations is that *changes in covariances depend critically on very fine details of the genotypic distribution*, details that are essentially impossible to estimate empirically in realistic situations. Thus, simplifying assumptions are required to proceed further. For example, if the distribution of the vector of individual-locus genotypic values is multivariate normal (which, as previously mentioned, involves the rather strong assumption that allelic effects *at each locus* are normally distributed), Equation 24.13a simplifies greatly, as $C_{ijk} = 0$ and C_{ijkl} can be expressed in terms of second-order covariances ($C_{ijkl} = C_{ij} C_{kl} + C_{ik} C_{jl} + C_{il} C_{jk}$). In this case, $\delta C_{ij} = \delta C_{i,j}$, and combining Equations 24.12b and 24.13b yields

$$\delta C_{i,j}(t) = \delta C_{i,j}(t) \sim \frac{\delta(\sigma_z^2) + S^2}{\sigma_z^4} C_i(t) C_j(t) \quad (24.14a)$$

where $C_i(t) = \sum_j C_{ij}(t)$. Thus, when allelic effects are multivariate normal (normal at each locus and multivariate normal for any subset of loci), Equation 24.11c yields a between-generation change (denoted by Δ , as opposed to a within-generation change, which is denoted by δ) in covariance of

$$\Delta C_{ij}(t+1) = C_{ij}(t+1) - C_{ij}(t) = \frac{\delta(\sigma_z^2) + S^2}{\sigma_z^4} C_i(t) C_j(t) - r_{ij} C_{ij}(t) \quad (24.14b)$$

a result due to Lande (1975, 1977a). Because $2 \sum_i C_i = 2 \sum_{ij} C_{ij} = \sigma_A^2$, and assuming all of the C_i are equivalent, it follows for n loci that $C_i = \sigma_A^2/(2n)$, and Equation 24.14a reduces to

$$\delta C_{ij} \simeq \frac{\sigma_A^4}{4n^2 \sigma_z^4} \left(\delta(\sigma_z^2) + S^2 \right) = \frac{h^4}{4n^2} \left(\delta(\sigma_z^2) + S^2 \right) \quad (24.14c)$$

When $S^2 \ll |\delta(\sigma_z^2)|$ (selection is mainly on the variance), we recover Bulmer's approximation (Equation 24.7b) when the number of loci, n , is large.

RESPONSE UNDER NON-GAUSSIAN DISTRIBUTIONS

The assumption that genotypic values of offspring are described by a linear and homoscedastic regression of the genotypic values of their parents most easily follows if the joint distribution of parental and offspring values is multivariate normal. This assumption, which is the basis for much of the theory of selection response, provides a simple solution to the vexing problem of modeling the transmission of a quantitative trait. The other option is Price's theorem (Equation 6.8), but its composite transmission parameter is very difficult to estimate and depends on the fine details of the underlying genetic architecture.

While changing allele frequencies and the generation of gametic-phase disequilibrium compromise the prediction of response by altering the genetic variance, a more subtle, but no less important, issue is that these changes also compromise predictions by driving the genotypic distribution away from a Gaussian. An active area of research is to both describe how selection can alter a distribution and extend selection theory to arbitrary distributions of genotypic values. While good progress has been made, we warn the reader that this can be a rather intimidating area of the literature. Our purpose here is to simply introduce some of the basic ideas and machinery used, as well as to summarize the major findings.

We start by considering how the distribution of effects at each of the individual loci translates into a distribution of genotypic values. In particular, we examine how within-locus moments of allelic effects translate into moments of the full distribution of genotypic values. While moments are more intuitive measures of the shape of a distribution, the cumulants of the distribution (to be described shortly) are more natural to work with when describing deviations from normality.

Once this basic machinery has been introduced, we will then consider two types of models for the genetics of a trait: (i) a small to modest number of segregating loci, and (ii) a very large number of loci of small effect. With a small number of loci, to an initial approximation, one can ignore effects of gametic-phase disequilibrium and instead focus on the changes in the higher genotypic moments caused by allele-frequency changes. The key result from the analysis of such models is that even single-generation predictions require extensive information about the underlying genetics. In contrast, with a very large number of loci, the (short-term) effects of allele-frequency changes can be essentially ignored, and changes from gametic-phase disequilibrium become critical. The nice (and somewhat surprising) result for this latter class of models is that both the breeder's and Bulmer equations are quite accurate for both directional and strong disruptive selection (Turelli and Barton 1994).

Describing the Genotypic Distribution: Moments

Under our assumption that genotypic and environmental values are additive and independent, $z = G + E$. When environmental values, E , are normally distributed, phenotypes, z , are normally distributed if and only if the genotypic values are Gaussian (i.e., follow a normal distribution). However, the converse is not true—an approximately normal distribution of phenotypes *does not necessarily* imply that genotypic values are Gaussian. While we can test if *phenotypes* are normally distributed, this tells us little about the distribution of *genotypes*. In theory, we can estimate the genotypic distribution by estimating the breeding values for a sample of individuals (LW Chapter 26), but this is generally impractical in most studies (however, see Chapter 20). Further, methods used to estimate breeding values typically *start* with the assumption of normality (Chapters 19 and 20; LW Chapters 26 and 27), and hence bias the distribution of estimated values toward a Gaussian.

Because we assume that there are no genotype \times environment interactions, if the environment remains constant over time, any changes in the phenotypic distribution are entirely due to changes in the genotypic distribution. The moments of a distribution provide a conve-

nient measure to describe its shape, and hence changes in the moments provide descriptions of changes in the shape of the distribution. To see the connection between the moments of the phenotypic and genotypic distributions, note that the phenotypic mean, variance, and skew can be decomposed as $\mu_z = \mu_G$, $\sigma_z^2 = \sigma_G^2 + \sigma_E^2$, and $\mu_{3,z} = \mu_{3,G} + \mu_{3,E}$. Thus, assuming no environmentally induced changes in the moments, changes in any of the first three phenotypic moments will exactly equal the change in the corresponding genotypic moments. Example 24.6 (below) uses cumulants to derive the fourth phenotypic moment, yielding

$$\mu_{4,z} = \mu_{4,G} + \mu_{4,E} + 6\sigma_G^2\sigma_E^2 \quad (24.15)$$

This shows that any changes here can result from either changes in the second (variance) or fourth moments of the genotypic distribution. When E is normal, $\mu_{3,E} = 0$ and $\mu_{4,E} = 3\sigma_E^4$, simplifying these expressions.

How do the moments of G depend on the distribution of allelic effects at individual loci? If n loci control the character, our assumption of complete additivity implies

$$G = \sum_{i=1}^n (X_{fa,i} + X_{mo,i}) \quad (24.16)$$

where $X_{fa,i}$ ($X_{mo,i}$) is the value of the paternal (maternal) allele at the i th locus. Assuming both sexes have the same distribution of allelic effects, the moments of G can be related to moments of the distribution of allelic effects at individual loci by expanding

$$\begin{aligned} \mu_{k,G} &= E([G - \mu_G]^k) \\ &= E\left(\left[\sum_{i=1}^n \{X_{fa,i} + X_{mo,i} - 2E(X_i)\}\right]^k\right) \quad \text{for } k \geq 2 \end{aligned} \quad (24.17)$$

Finally, we assume random mating, so that $X_{fa,i}$ and $X_{mo,i}$ are independent at the start of each generation. Because we assume that the distribution of allelic effects is the same in both sexes, we drop the subscript referring to parental origin.

When considering a particular moment of G , it will be important to distinguish between contributions to that moment from individual loci (**within-locus moments**) and contributions from gametic-phase disequilibrium (**between-locus covariances**). This partitioning, which was used earlier with the additive genetic variance (e.g., Equation 16.2), is extended here to the third and higher genotypic moments. To describe the distribution of effects at locus i , let $\mu_{1,i} = E(X_i) = m_i$ denote the average value of an allele at locus i , and define the k th moment for this locus by $\mu_{k,i} = E([X_i - m_i]^k)$ for $k \geq 2$. After summing over all n loci, we define

$$M_1 = 2 \sum_{i=1}^n \mu_{1,i} \quad (24.18a)$$

$$M_2 = 2 \sum_{i=1}^n \mu_{2,i} \quad (24.18b)$$

$$M_3 = 2 \sum_{i=1}^n \mu_{3,i} \quad (24.18c)$$

as the mean, variance, and skewness, respectively, of the genotypic distribution in terms of the mean, variance, and skew at individual loci (the within-locus moments). Finally, we define the within-locus kurtosis as

$$M_4 = 2 \sum_{i=1}^n (\mu_{4,i} - 3\mu_{2,i}^2) \quad (24.18d)$$

While this may seem odd at first, recall that the fourth and second moments of a normal distribution are related by $\mu_4 = 3\mu_2^2$ (LW Chapter 2). Hence, if the distribution of allelic effects *at each locus* is normal, $M_4 = 0$ and, likewise, $M_3 = 0$ ($\mu_{3,i} = 0$ because a normal random variable does not display skew). On the other hand, nonzero values of M_3 or M_4 imply that G is non-Gaussian and provide a quantitative measure of the departure from normality.

The between-locus contributions from gametic-phase disequilibrium are described by C_{ij} , C_{ijk} , and C_{ijkl} , the covariances between, respectively, groups of two, three, and four loci, as defined previously. Note that with this notation, $C_{ii} = \mu_{2,i}$, $C_{iii} = \mu_{3,i}$ and $C_{iiii} = \mu_{4,i}$, referring to the moments at locus i . If loci are independent (i.e., in gametic-phase equilibrium), then all other combinations involving four (or fewer) loci are zero except C_{iiji} , which equals $C_{ii} \cdot C_{jj} = \mu_{2,i} \cdot \mu_{2,j}$.

Following Turelli and Barton (1990), the genotypic moments can be decomposed into within-locus effects (the M_i from Equation 24.18) due to the moments at individual loci and between-locus effects due to covariances generated by gametic-phase disequilibrium. Remember that we are assuming the simplest case, complete additivity (no dominance or epistasis), so the genotypic distribution G is the distribution of additive genetic (breeding) values (A), namely, the sum of allelic effects over all loci. Expanding Equation 24.17 and taking expectations yields the familiar expressions for the mean and variance

$$\mu_G = 2 \sum_{i=1}^n \mu_{1,i} = M_1 \quad (24.19a)$$

$$\sigma_G^2 = \sigma_A^2 = 2 \sum_{i,j=1}^n C_{ij} = M_2 + 2 \sum_{i=1}^n \sum_{j \neq i}^n C_{ij} \quad (24.19b)$$

where $M_2 = 2 \sum C_{ii}$ corresponds to the genic variance σ_a^2 , and the double sum corresponds to the disequilibrium, d (Equation 16.1b). Similarly, the skew can be partitioned as

$$\mu_{3,G} = 2 \sum_{i,j,k=1}^n C_{ijk} = M_3 + 2 \sum_{i=1}^n \sum_{j,k \neq i}^n C_{ijk} \quad (24.19c)$$

All terms in the second sums of Equations 24.19b and 24.19c are zero when all groups of two and three loci (respectively) are in gametic-phase equilibrium ($C_{ij} = C_{ijk} = 0$). Partitioning the kurtosis requires a little more care. After some simplification (Turelli and Barton 1990), we obtain

$$\mu_{4,G} = 3\sigma_A^4 + M_4 + 2 \sum_{i=1}^n \sum_{j,k,\ell \neq i}^n (C_{ij\ell k} - C_{ij} C_{k\ell} - C_{ik} C_{j\ell} - C_{i\ell} C_{jk}) \quad (24.19d)$$

Again, these fourth- and second-order covariance terms ($C_{ij\ell k}$ and C_{ij} , respectively) are zero when all groups of four loci are in gametic-phase equilibrium. Because $3\sigma_A^4$ is the kurtosis value that is expected when genotypic values are Gaussian-distributed, the last two terms partition any kurtosis in G into the contribution from individual locus kurtosis (M_4) and the contribution generated by gametic-phase disequilibrium between groups of four loci. If the distribution of allelic effects is multivariate normal, then $M_4 = 0$, and each term within the covariance sum is zero as $C_{ij\ell k} = C_{ij} C_{k\ell} + C_{ik} C_{j\ell} + C_{i\ell} C_{jk}$.

Analogous to allele frequencies changing the genic variance, σ_a^2 , and disequilibrium changing the covariances (and hence d), changes in M_3 and M_4 reflect *allele-frequency change*, while changes in the third- and fourth-order covariances reflect *changes from disequilibrium*. These higher-order moments can depart from their expectations under normality by the presence of skewness or kurtosis of allelic effects at the individual loci (generating nonzero M_3 and/or M_4), which can result from allele-frequency changes. Alternatively, even if the within-locus moments are normal ($M_3 = M_4 = 0$), gametic-phase disequilibrium (nonzero

C_{ijk} and/or C_{ijkl}) can introduce skewness and/or kurtosis. When the number of loci is small, the impact of skew or kurtosis at the individual loci can be significant (Equation 24.6), yielding nonzero M_3 and/or M_4 , with the resulting genotypic distribution deviating from normality.

To see these points, first consider the changes due to within-locus moments. If n is the number of loci, then as we saw earlier the effects (*a*) of alleles at individual loci must scale as $1/\sqrt{n}$ in order for the genetic variance to remain bounded, hence C_{ii} terms scale as a^2 or n^{-1} . Summing over all n loci, M_2 will be of order $n \cdot n^{-1} = 1$ and, as required, remains bounded as the number of loci increases. What happens to the skew and kurtosis as n increases? Assuming a is of order $n^{-1/2}$, then $\mu_{3,i}$ will be of order a^3 or $n^{-3/2}$, implying that M_3 is of order $n \cdot n^{-3/2} = n^{-1/2}$ (also see Equation 24.6). Hence, as the number of loci becomes very large, the contribution from skew at individual loci becomes negligible. Likewise, $\mu_{4,i}$ is of order $n^{-4/2}$, implying M_4 is of order $n \cdot n^{-2} = n^{-1}$ (Equation 24.6). Changes in kurtosis generated by within-locus (i.e., allele-frequency) changes become negligible as the number of loci becomes sufficiently large, but this occurs even more rapidly than skew with increasing n .

The behavior of the between-locus contributions (correlations from disequilibrium) as n increases is quite different from that due to within-locus contributions (Turelli and Barton 1990). Under weak selection, Turelli and Barton showed that C_{ijk} is proportional to $C_{ii}C_{jj}C_{kk}$, and of order n^{-3} . However, there are $n(n-1)(n-2) \simeq n^3$ terms involving C_{ijk} in the covariance contribution to skew, so the total contribution is of order one and does not necessarily converge to zero as the number of loci approaches infinity. The same argument holds for the kurtosis and higher-order moments (Turelli and Barton 1990). If the number of loci is very large, the distribution of genotypic values can depart from a Gaussian due to selection generating third- and higher-order covariances between loci, which in turn creates skew and kurtosis in the genotypic distribution. Even if the distribution of genotypes is initially Gaussian, selection generates these higher-order disequilibria, driving it away from normality (Bulmer 1980; Zeng 1987; Turelli and Barton 1990, 1994). Conversely, when selection stops, this disequilibrium quickly decays to zero, restoring the Gaussian.

Describing the Genotypic Distribution: Cumulants and Gram-Charlier Series

While most readers are familiar with moments, an alternate approach to describing the shape of a distribution, and in particular its departures from a Gaussian, is to examine its **cumulants**. These quantities, which arise from the moment-generation function of a probability distribution, offer some advantages over moments, as we will discuss shortly. The first uses of cumulants in examining selection response appears in O'Donald (1972) and Bulmer (1980). Sophisticated (and highly technical) treatments were developed by Bürger (1991a, 1993) and Turelli and Barton (1994). Our aim here is both to give the fearless reader sufficient background to this literature and to show the connection between results derived using moments and those derived using cumulants.

Cumulants (the n th of which we denote by K_n) arise naturally in series approximations of probability distributions, and they can be related to the central moments (μ_n). For example, the first five central moments can be expressed as functions of the cumulants as follows:

$$\mu_1 = K_1, \quad \mu_2 = K_2, \quad \mu_3 = K_3, \quad \mu_4 = K_4 + 3K_2^2, \quad \mu_5 = K_5 + 10K_2K_3$$

(Kendall and Stuart 1977). Hence, the first three cumulants are equal to the mean, variance, and skew, respectively, while the fourth and fifth cumulants are

$$K_4 = \mu_4 - 3\mu_2^2, \quad K_5 = \mu_5 - 10\mu_2\mu_3 \tag{24.20}$$

The major advantage of cumulants over moments is that they are *additive*, so that the n th cumulant of a sum of random variables is simply the sum of the cumulants for each, namely, $K_n(x+y) = K_n(x) + K_n(y)$. This linearity property does not hold for higher-order moments,

which are highly nonlinear functions of the moments of the component distributions. For a normal distribution, cumulants of order three and higher are zero, so nonzero values for these higher-order cumulants provide a convenient measure of departures from normality.

The major disadvantage of using cumulants in place of moments arises when dealing with recombination (Turelli and Barton 1994; Bürger 2000). In such cases, one works with cumulants to compute within-generation changes, converts these to moments for recombination, and then converts the recombinant products back into cumulants.

Finally, cumulants appear in series approximations of arbitrary probability distributions. Consider a standardized random variable, $y = (z - \mu)/\sigma$, which has mean zero and variance one. If the true density function for y is $\phi(y)$, we can approximate it as a unit-normal density function, $\varphi(y)$, plus correction terms. In particular (Johnson and Kotz 1970a; Kendall and Stuart 1977), the **Gram-Charlier series** approximation (here shown to order five) is given by

$$\phi(y) \simeq \varphi(y) \left[1 + \frac{K_3}{6} H_3(y) + \frac{K_4}{24} H_4(y) + \frac{K_5}{120} H_5(y) \right] \quad (24.21a)$$

where $H_k(y)$ denotes the **Chebyshev-Hermite polynomial** of order k , with

$$\begin{aligned} H_3(y) &= y^3 - 3y \\ H_4(y) &= y^4 - 6y^2 + 3 \\ H_5(y) &= y^5 - 10y^3 + 15y \end{aligned} \quad (24.21b)$$

Equation 24.21a shows how the higher-order cumulants (K_3 and above) quantify departures from normality. If all of these are zero, the distribution is Gaussian.

Bulmer (1980), Zeng (1987), and Turelli and Barton (1994) used Gram-Charlier series to examine departures from normality under selection. Further properties of cumulants and Gram-Charlier (and other) series approximations are discussed in Johnson and Kotz (1970a) and Kendall and Stuart (1977). One potentially troublesome issue with Equation 24.21a is that the term in the square brackets can be negative for some y values (and hence not a proper probability distribution) if too low an order of approximation is used.

Example 24.6. Cumulants can be used to easily compute the fourth and fifth central moments of the phenotypic distribution. Here, $z = G + E$, so (Equation 24.20) the fourth moment is

$$\begin{aligned} \mu_{4,z} &= K_{4,z} + 3K_{2,z}^2 \\ &= [K_{4,G} + K_{4,E}] + 3(K_{2,G} + K_{2,E})^2 \\ &= [(\mu_{4,G} - 3\mu_{2,G}^2) + (\mu_{4,E} - 3\mu_{2,E}^2)] + 3(\mu_{2,G} + \mu_{2,E})^2 \\ &= \mu_{4,G} + \mu_{4,E} + 6\sigma_G^2\sigma_E^2 \end{aligned}$$

where the second and third steps, respectively, follow from the additivity property of cumulants ($K_{n,z} = K_{n,G} + K_{n,E}$) and from Equation 24.20, while the final step recovers Equation 24.15. Likewise

$$\begin{aligned} \mu_{5,z} &= K_{5,z} + 10K_{2,z}K_{3,z} \\ &= (K_{5,G} + K_{5,E}) + 10(K_{2,G} + K_{2,E})(K_{3,G} + K_{3,E}) \\ &= (\mu_{5,G} - 10\mu_{2,G}\mu_{3,G}) + (\mu_{5,E} - 10\mu_{2,E}\mu_{3,E}) \\ &\quad + 10(\mu_{2,G} + \mu_{2,E})(\mu_{3,G} + \mu_{3,E}) \\ &= \mu_{5,G} + \mu_{5,E} + 10(\mu_{2,G}\mu_{3,E} + \mu_{2,E}\mu_{3,G}) \end{aligned}$$

These nonlinear expressions for the higher-order moments of a sum of variables are in sharp contrast to the expressions for cumulants, in which $K_{n,z} = K_{n,G} + K_{n,E}$.

Example 24.7. To see the advantage of working with cumulants, consider the fourth cumulant of the genotypic distribution. Equation 24.19d presented a rather complex expression for the fourth moment, but we can use cumulants to easily obtain this result. If the underlying genes are additive across loci (no epistasis), the n th cumulant of the genotypic distribution is the sum of the appropriate cumulants for each of the underlying loci. Following Turelli and Barton (1994)

$$K_{4,G} = \sum_{i,j,k,\ell=1}^n K_{ijkl} = \sum_{i=1}^n K_{iiii} + \sum_{i=1}^n \sum_{j,k,\ell \neq i} K_{ijkl}$$

the sum over K_{iiii} represents the within-locus contributions to the fourth cumulant, while the sums over the other indices are the contributions to K_4 from fourth-order disequilibria between loci. We recover Equation 24.19d by noting that $\mu_{4,G} = K_{4,G} + 3\sigma_A^4$ and substituting

$$M_4 = \sum_{i=1}^n K_{iiii} \quad \text{and} \quad K_{ijkl} = C_{ijkl} - C_{ij}C_{kl} - C_{ik}C_{jl} - C_{il}C_{jk}$$

Application: Departure from Normality Under Truncation Selection

One application of the preceding machinery is to compute the distribution of breeding values following a single generation of truncation selection, assuming that the initial joint distribution of phenotypic and breeding values is multivariate normal. This was examined by Bulmer (1980) and Zeng (1987), and Turelli and Barton (1994) presented a very elegant (and elaborate) analysis for multiple generations. As before, we consider only additive models, so the distribution of genotypic values is also the distribution of breeding values.

First, we assume that there is initial (i.e., existing before selection) normality in phenotypic values, $z \sim N(\mu, \sigma_z^2)$, and compute the cumulants for the resulting distribution of phenotypic values after truncation selection. As before (Chapters 14 and 16), truncation selection saves the uppermost fraction, p , of the population, giving a selection intensity of

$$\bar{\tau} = \frac{\varphi(z_p)}{p}$$

where $\varphi(z_p)$ is the value of a unit-normal density function evaluated at z_p , and z_p satisfies $\Pr(U > z_p) = p$, with U denoting a unit-normal random variable (Equation 14.2b). From Chapters 14 and 16, we already have the first two cumulants following selection as

$$K_{1,z}^* = \mu^* = \mu + \bar{\tau}\sigma_z \quad \text{and} \quad K_{2,z}^* = \sigma_z^{*2} = [1 - \bar{\tau}(\bar{\tau} - z_p)] \sigma_z^2$$

while the next two cumulants are (from Bulmer 1980)

$$K_{3,z}^* = [(\bar{\tau} - z_p)(2\bar{\tau} - z_p) - 1] \bar{\tau} \sigma_z^3 \quad (24.22a)$$

$$K_{4,z}^* = [-6\bar{\tau}(\bar{\tau} - z_p)^2 + (3 - z_p^2)(\bar{\tau} - z_p) + \bar{\tau}] \bar{\tau} \sigma_z^4 \quad (24.22b)$$

Next, we translate these within-generation changes in the *phenotypic* distribution into the within-generation change in the distribution of *breeding values* and then examine how this breeding-value distribution changes (under random mating) during transmission to the next generation. Both steps rely critically on assumptions of normality. If the distribution of breeding and phenotypic values is bivariate normal before selection (as might occur in the initial round of selection, but not necessarily in subsequent rounds), then the regression of breeding values on phenotypic values is linear

$$A = \mu_z + h^2(z - \mu_z) + \epsilon$$

Rao et al. (1968) showed that a single generation of truncation selection does not alter this regression, which leads to our standard results (Chapter 16) for the mean and variance of the breeding values following selection

$$\mu_A^* = \mu_z + h^2 \bar{z} \sigma_z \quad (24.23a)$$

and

$$\sigma_{A*}^2 = \sigma_A^2 [1 - h^2 \bar{z} (\bar{z} - z_p)] \quad (24.23b)$$

Bulmer (1980) showed that when the joint distribution of breeding values and phenotypes is multivariate normal before selection, all higher cumulants follow a very simple relationship

$$K_{i,A}^* = (h^2)^i K_{i,z}^* \quad \text{for } i \geq 3 \quad (24.24a)$$

Assuming unlinked loci, the cumulants for the distribution of breeding values in the next generation become

$$K_{i,A}(t+1) = \left(\frac{1}{2}\right)^{i-1} K_{i,A}^*(t) \quad (24.24b)$$

Hence, the cumulants for the distribution of breeding values at the start of the next generation are related to the cumulants of the postselection phenotypic distribution by

$$K_{i,A}(t+1) = 2 \left(\frac{h^2}{2}\right)^i K_{i,z}^*(t) \quad (24.24c)$$

Notice from Equation 24.22 that after a single generation of selection, $K_{3,A}$ and $K_{4,A}$ will be nonzero, and hence the distribution of breeding values will no longer be normal. At this point, the assumption of bivariate normality no longer holds, and there is no longer a simple relationship between $K_{i,A}^*$ and $K_{i,z}^*$. Thus, we cannot simply iterate this procedure over more than one generation of selection. See Turelli and Barton (1994) for a detailed analysis over multiple generations.

Example 24.8. Suppose truncation selection occurs on a normally distributed trait with an initial mean of $\mu_z = 0$ and variance of $\sigma_z^2 = 100$. Individuals whose phenotypes are in the upper 5% of the distribution are saved, so that $\bar{z} = 2.063$ and $z_p = 1.645$ (Example 14.1). To demonstrate an extreme case, assume that $h^2 = 1$, so that all variance is additive genetic. Applying Equation 24.22a, the resulting third-order cumulant in the phenotypic distribution following selection is

$$\begin{aligned} K_{3,z}^* &= [(\bar{z} - z_p)(2\bar{z} - z_p) - 1] \bar{z} \sigma_z^3 \\ &= [(2.063 - 1.645)(2 \cdot 2.063 - 1.645) - 1] \cdot 2.063 \cdot 100^{3/2} \\ &= 76.45 \end{aligned}$$

Applying Equation 24.24c translates this into the third cumulant in the genotypic distribution in the next generation, yielding

$$K_{3,A}(t+1) = 2 \left(\frac{h^2}{2}\right)^3 K_{3,z}^*(t) = 2 \left(\frac{1}{2}\right)^3 76.45 = 19.11$$

Using the machinery from Chapter 16, for $p = 0.2$, Equation 16.11a yields $\kappa = 0.862$ (i.e., selected individuals have only a fraction, $[1 - 0.862] = 0.138$, of the variance of the preselection population), and Equation 16.12d returns $d(1) = (-\kappa/2)100 = -43.1$. Hence, the

phenotypic variance in the first generation is $\sigma_z^2 = \sigma_A^2(1) = 100 + d(1) = 56.9$. Thus, the scaled skew becomes

$$\gamma_3 = \frac{K_3}{\sigma_A^3} = \frac{19.11}{56.9^{3/2}} = 0.045$$

A similar calculation using Equations 24.22b and 24.24c yields $K_4 = 59.7$ and $\gamma_4 = K_4/56.9^2 = 0.018$. Applying Equation 24.21a, the resulting (fourth-order) Gram-Charlier series approximation for the distribution, $\phi(A)$, of breeding values in generation 1 is

$$\begin{aligned}\phi(A') &\simeq \varphi(A') \left[1 + \frac{0.045}{6} H_3(A') + \frac{0.018}{24} H_4(A') \right] \\ &= \varphi(A') [1 + 0.0075 H_3(A') + 0.00075 H_4(A')]\end{aligned}$$

where $\varphi(x)$ is the normal distribution, the functions $H_i(x)$ are defined by Equation 24.21b, and $A' = A/\sigma_A$ is the standardized breeding value (which, initially, has a mean of zero). For example, consider $A' = 2$, a value two standard deviations away from the mean. Applying Equation 24.21b, $H_3(2) = 2$ and $H_4(2) = -5$, yielding the correction factor for the unit normal density function as

$$1 + 0.0075 H_3(2) + 0.00075 H_4(2) = 1.01125$$

The key point is that the resulting distribution is only very weakly perturbed away from a Gaussian (assuming that $h^2 = 1$ is the most extreme case). For a more typically heritability, say $h^2 = 0.3$, similar calculations yield $\gamma_3 = 0.0039$ and $\gamma_4 = 0.0007$, and

$$\phi(A) \simeq \varphi(A) [1 + 0.00065 H_3(A') + 0.00003 H_4(A')]$$

yielding an even smaller departure from normality (an adjustment factor of 1.00115 for $A' = 2$).

Thus, under the infinitesimal model, the generation of linkage disequilibrium by truncation selection has very little impact on driving the distribution of breeding values away from a Gaussian. While the disequilibrium introduced by truncation selection can indeed drive a distribution of breeding values away from a strict Gaussian, the error in assuming this remains Gaussian is generally small. This point was initially made by Bulmer (1980). The much more extensive analysis by Turelli and Barton (1994) showed that, even in the presence of strong truncation or disruptive selection, the Bulmer equation (Equation 16.7b) can be used with little error. Turelli and Barton's analysis assumed a sufficiently large number of loci so that changes in both the genic variance and locus-specific cumulants of order three or higher can be ignored.

Short-term Response Ignoring Linkage Disequilibrium

With this machinery in hand, we are now ready to examine the response to selection under non-Gaussian genotypic distributions. We first consider the situation in which a small to modest number of loci underlie the character, wherein most of the changes in the higher-order moments are due to changes in allele frequencies, rather than through generation of gametic-phase disequilibrium. Our treatment follows that of Barton and Turelli (1987).

If we are willing to assume additivity across loci and gametic-phase equilibrium, genetic changes in the character will be completely described by the dynamics of allele-frequency changes at each locus. The complete dynamics for a locus with k alleles are described by the $k - 1$ allele-frequency change equations. Alternatively, we could fully describe the dynamics by using equations based on any set of $k - 1$ independent new variables that can be expressed as functions of allele frequencies (this is the standard multivariate transformation problem of vector calculus and requires that the determinant of the Jacobian transformation matrix be nonzero). One such set of new variables involves the first $k - 1$ moments of the allelic distribution. This is the motivation behind Barton and Turelli's (1987) approach, which focuses on *allelic moments*, rather than *allelic frequencies*.

If we ignore gametic-phase disequilibrium, then for n loci with k alleles each, we can completely describe the dynamics by using the first $n(k - 1)$ moments of the genotypic distribution. This same approach can be used when linkage is considered, but in this case the number of equations increases dramatically (scaling as the number of distinct gametic types). While the process of using a new set of variables is exact, it is also just as challenging to solve as the original allele-frequency change equations. The hope, however, is that by considering the first few moments, we can gain considerable insight into the actual dynamics and a better feel for the conditions under which certain approximations work and those under which they break down.

To briefly sketch the approach used by Barton and Turelli, recall Wright's formula for frequency changes with multiple alleles (Equation 5.11a)

$$\Delta p_i = \sum_{j=1}^k G_{ij} \frac{\partial \ln \bar{w}}{\partial p_j} \quad (24.25a)$$

where $G_{ii} = p_i(1 - p_i)/2$ and $G_{ij} = -p_i p_j/2$ (for $i \neq j$). The assumption of linkage equilibrium is needed here, as Wright's formula fails when single-locus fitnesses are background-dependent, which can occur even with constant genotypic fitnesses when linkage disequilibrium is present (see Example 5.7 for details). Now consider a function, $f(p_1, p_2, \dots, p_{k-1})$, that depends on the allele frequencies at this locus, such as a particular moment of the allelic distribution. The change in f due to changes in allele frequencies can be approximated by a second-order Taylor series to yield

$$\Delta f = \sum_{i=1}^k \frac{\partial f}{\partial p_i} \Delta p_i + \frac{1}{2} \sum_{i=1}^k \sum_{j=1}^k \frac{\partial^2 f}{\partial p_j \partial p_i} \Delta p_i \Delta p_j + \dots \quad (24.25b)$$

where this expression ignores higher-order terms of Δp_i . Substituting for Δp_i via Equation 24.25a yields (to first order)

$$\Delta f \simeq \sum_{i=1}^k \frac{\partial f}{\partial p_i} \left(\sum_{j=1}^k G_{ij} \frac{\partial \ln \bar{w}}{\partial p_j} \right) \quad (24.25c)$$

Recall from the chain rule of differentiation that

$$\frac{\partial \ln \bar{w}}{\partial p_j} = \frac{\partial \ln \bar{w}}{\partial f} \frac{\partial f}{\partial p_j}$$

which, upon substitution in Equation 24.52c, yields

$$\Delta f = \frac{\partial \ln \bar{w}}{\partial f} \sum_{i=1}^k \sum_{j=1}^k \frac{\partial f}{\partial p_i} G_{ij} \frac{\partial f}{\partial p_j} \quad (24.25d)$$

This is a *weak-selection approximation*, as it assumes that terms of second order, $(\Delta p_i \Delta p_j)$, and higher can be ignored (if drift is considered, these second-order terms must be included even if selection is weak; see Turelli 1988).

Using this expression yields a set of equations in which changes in a certain moment depend on higher-order moments. After considerable algebra (for details, see Barton and Turelli 1987), the changes in genotypic moments (under the assumptions of complete additivity and gametic-phase equilibrium) can be expressed in matrix form as

$$\Delta_{\mu_G} \simeq \mathbf{M} \nabla \ln \bar{w} \quad (24.26a)$$

where

$$\Delta_{\mu_G} = \begin{bmatrix} \Delta\mu_{1,G} \\ \Delta\mu_{2,G} \\ \Delta\mu_{3,G} \\ \vdots \end{bmatrix} \quad \text{and} \quad \nabla \ln \bar{w} = \begin{bmatrix} \frac{\partial \ln \bar{w}}{\partial \mu_{1,z}} \\ \frac{\partial \ln \bar{w}}{\partial \mu_{2,z}} \\ \frac{\partial \ln \bar{w}}{\partial \mu_{3,z}} \\ \vdots \end{bmatrix} \quad (24.26b)$$

are, respectively, the vectors of changes in the genotypic moments (Δ_{μ_G}) and the vector of partial derivatives of log mean fitness with respect to each moment ($\nabla \ln \bar{w}$), and a matrix of genotypic moments,

$$M = 2 \sum_{i=1}^n \begin{bmatrix} \mu_{2,i} & \mu_{3,i} & (\mu_{4,i} - 3\mu_{2,i}^2) & \cdots \\ \mu_{3,i} & (\mu_{4,i} - \mu_{2,i}^2) & (\mu_{5,i} - 4\mu_{3,i}\mu_{2,i}) & \cdots \\ (\mu_{4,i} - 3\mu_{2,i}^2) & (\mu_{5,i} - 4\mu_{3,i}\mu_{2,i}) & (\mu_{6,i} - \mu_{3,i}^2 - 6\mu_{2,i}\mu_{4,i} + 9\mu_{2,i}^2) & \cdots \\ \vdots & \vdots & \vdots & \ddots \end{bmatrix} \quad (24.26c)$$

The summation symbol used Equation 24.26c indicates that each element on M is twice the sum of a (locus-specific) quantity over all loci. The additional elements of M that are not displayed correspond to selection on the fourth and higher moments (M_{ij} for i and/or $j \geq 4$). The expressions for these terms are more complicated than may be suggested by the simple dots in the matrix due to the nonadditive nature of higher moments. Expressions based on $\partial \ln \bar{w} / \partial K_{i,z}$ (the partial derivative of fitness with respect to the i th cumulant of the phenotypic distribution) have a simpler form due to the additive nature of cumulants (Bürger 1991a, 1993; Turelli and Barton 1994), but retain the undesirable feature that the response of the i th cumulant depends on cumulants of higher order.

In order to close the set of equations given by 24.26a–24.26c, we must impose restrictions on the number of columns in M , which requires assuming that selection mainly occurs on the first few moments. Likewise, the number of rows of M must also be restricted, which implies additional assumptions on the genetic moments. Examples 24.9 and 24.11 discuss the two most common assumptions to accomplish these goals, namely the Gaussian and rare-alleles models.

In cases where the first three phenotypic moments account for the majority of selection, the expected single-generation change in mean becomes

$$\Delta\mu_z \simeq \sigma_A^2 \frac{\partial \ln \bar{w}}{\partial \mu_z} + \mu_{3,G} \frac{\partial \ln \bar{w}}{\partial \mu_{2,z}} + \kappa_4 \sigma_A^4 \frac{\partial \ln \bar{w}}{\partial \mu_{3,z}} \quad (24.27)$$

where $\kappa_4 = (\mu_{4,G} - 3\sigma_A^4)/\sigma_A^4$ is the scaled coefficient of kurtosis (Frank and Slakkin 1990 obtained the same result, for the special case of stabilizing selection using the Price equation; Chapter 6). If the distribution of G is Gaussian, then $\mu_{3,z} = \kappa_4 = 0$, and we recover the selection gradient version of the breeder's equation (Equation 13.27a). Under more general distributions, predicting changes in even the simplest genotypic moment, the mean, requires a detailed knowledge of both higher-order allelic moments ($\mu_{k,i}$) and the nature of selection on these higher-order moments ($\partial \ln \bar{w} / \partial \mu_{k,z}$). In order to proceed further, we have to make additional assumptions about the distribution of allelic effects at *individual loci*.

If the phenotypes are approximately normally distributed (but allelic effects at individual loci are not necessarily Gaussian), the mean and variance terms of the selection gradient vector generally will dominate. Recalling Equations 24.12 and 24.18, Equation 24.26a re-

duces to

$$\begin{bmatrix} \Delta\mu_{1,G} \\ \Delta\mu_{2,G} \\ \Delta\mu_{3,G} \\ \vdots \end{bmatrix} = \begin{bmatrix} \sigma_A^2 & M_3 & & \\ M_3 & M_4 & & \\ M_4 & 2 \sum_i (\mu_{5,i} - 4\mu_{3,i}\mu_{2,i}) & & \\ \vdots & \vdots & \ddots & \end{bmatrix} \begin{bmatrix} S \\ \frac{S}{\sigma_z^2} \\ \frac{\delta(\sigma_z^2) + S^2}{2\sigma_z^4} \end{bmatrix}$$

If we consider only the first three genotypic moments, then

$$\Delta\mu_G \simeq h^2 S + \left(\frac{\delta(\sigma_z^2) + S^2}{2\sigma_z^4} \right) M_3 \quad (24.28a)$$

$$\Delta\sigma_A^2 \simeq \frac{S}{\sigma_z^2} M_3 + \left(\frac{\delta(\sigma_z^2) + S^2}{2\sigma_z^4} \right) M_4 \quad (24.28b)$$

$$\Delta\mu_{3,G} \simeq \frac{S}{\sigma_z^2} M_4 + \left(\frac{\delta(\sigma_z^2) + S^2}{2\sigma_z^4} \right) \sum_{i=1}^n (\mu_{5,i} - 4\mu_{3,i}\mu_{2,i}) \quad (24.28c)$$

where M_3 and M_4 are as defined by Equations 24.18c and 24.18d. As is discussed in Chapters 29 and 30, when selection acts only on the mean ($\partial \ln \bar{w} / \partial \mu_{k,z} = 0$ for $k \geq 2$), $\delta(\sigma_z^2) = -S^2$, meaning that the first term in each of these three equations accounts for the effect of selection to change the mean and the second term accounts for the effect of selection acting directly on the variance (selection is based, in part, on an individual's squared deviation from the mean, $[z - \mu]^2$). We previously obtained Equation 24.28a by an alternative approach (Equation 5.27b). When the genotypic distribution is skewed ($M_3 \neq 0$), the single-generation change in the mean also depends on the nature of selection on the variance (O'Donald 1968, 1972; Bulmer 1980; Gillespie 1984a; Barton and Turelli 1987; Mitchell-Olds and Shaw 1987). Further, even if skew is initially absent, Equation 24.28c shows that if the kurtosis of the genotypic distribution differs from that expected for a Gaussian ($M_4 \neq 0$), selection that is strictly on the mean generates skew. Thus, even ignoring the effects of gametic-phase disequilibrium, selection on the mean generates skew when the genotypic distribution displays kurtosis.

Whether allele-frequency change at the individual loci or gametic-phase disequilibrium among loci is more important for producing departures from normality depends on whether there are alleles of modest to large effects. When alleles of major effect are present, locus-specific selection coefficients (e.g., Equation 5.21) can be sufficiently large that significant allele-frequency change can quickly occur, which has a far great effect on departures from normality than does selection-generated disequilibrium (Turelli and Barton 1990). Conversely, when all alleles have small effects (and hence selection is extremely weak on any single locus), then over modest time scales, departure from normality is largely due to selection generating third- (and higher-) order disequilibrium. Thus, when the number of loci is small, the error created by using Equation 24.26a (which assumes gametic-phase equilibrium) should be small. As the number of (equivalent) loci increases, within-locus effects make a smaller and smaller contribution, with departures from normality caused by disequilibrium eventually dominating any small departures caused by allele frequency change.

Gaussian Versus Rare-alleles Approximations

In order to have Equation 24.26a form a closed set of equations, additional assumptions are needed, both on the nature of selection (columns of M) and on the underlying genetics (rows of M). If phenotypes are (and remain) normally distributed, then one needs to only consider selection on the mean and variance, as these define all other moments. More generally, if selection is sufficiently weak, then any selection function can be well approximated by a quadratic Taylor series, which again only involves the first two moments.

Two different assumptions about the genotypic distribution have been used to reduce Equation 24.26a to the first three moments. The first is to assume that distributions start (and remain) Gaussian (Example 24.9). The second is the **rare-alleles model**, which assumes loci are very near fixation (Example 24.11). This model is very closely related to an important approximation (Turelli's 1984 house-of-cards) which appears in Chapter 28 and which assumes that the effect of a new mutation is large relative to the amount of standing variation at a locus, which is equivalent to assuming that selection is much stronger than mutation.

Example 24.9. If we assume that the Gaussian approximation holds, the distribution of allelic effects at each locus will be normal. In this case, all odd central moments at each locus are zero ($\mu_{2k+1} = 0$) and all even moments are related to the second moment by $\mu_{2k} = \mu_2^k (2k)!/(2^k k!)$ (Kendall and Stewart 1977). For example, $\mu_4 = 3\mu_2^2$, implying that $\mu_4 - \mu_2^2 = 2\mu_2^2$. Assuming that most of selection is on the mean and variance, we can neglect the third- and higher-order selection gradients. In this case, \mathbf{M} (Equation 24.26c) reduces to a 2×2 matrix

$$\mathbf{M} = \begin{pmatrix} 2 \sum_{i=1}^n \mu_{2,i} & 0 \\ 0 & 4 \sum_{i=1}^n \mu_{2,i}^2 \end{pmatrix} = \begin{pmatrix} \sigma_A^2 & 0 \\ 0 & \frac{\sigma_A^4}{n_e} \end{pmatrix} \quad (24.29a)$$

where

$$n_e = \frac{\sigma_A^4}{4 \sum_i \mu_{2,i}^2} \quad (24.29b)$$

is equivalent to Chevalet's (1994) effective number of loci (Equation 24.3); see Example 24.10. The expected response in the genotypic mean and variance then becomes

$$\begin{pmatrix} \Delta\mu \\ \Delta\sigma_A^2 \end{pmatrix} \approx \begin{pmatrix} \sigma_A^2 & 0 \\ 0 & \sigma_A^4/n_e \end{pmatrix} \begin{pmatrix} \frac{\partial \ln \bar{w}}{\partial \mu_z} \\ \frac{\partial \ln \bar{w}}{\partial \sigma_z^2} \end{pmatrix} = \begin{pmatrix} \sigma_A^2 \frac{\partial \ln \bar{w}}{\partial \mu_z} \\ \frac{\sigma_A^4}{n_e} \frac{\partial \ln \bar{w}}{\partial \sigma_z^2} \end{pmatrix} \quad (24.30a)$$

If the phenotypic distribution is *exactly* normal, all moments can be expressed in terms of the mean and variance, only gradients measuring selection on the mean and variance will appear, and these equations will be exact. Recalling Equations 24.12a and 24.12b yields

$$\Delta\mu \simeq h^2 S \quad (24.30b)$$

and

$$\Delta\sigma_A^2 \simeq \frac{h^4}{2n_e} \left(\delta(\sigma_z^2) + S^2 \right) \quad (24.30c)$$

Thus, the expected change in the mean follows the breeder's equation and short-term changes in variance (from allele-frequency change) are expected to be small when the value of n_e is modest to large. We remind the reader that this analysis ignores the effects of gametic-phase disequilibrium.

Because the locus-specific variances, $\mu_{2,i}$, change as allele frequencies change, predicting changes in variance over several generations, even under these simplifying assumptions, still requires a detailed knowledge about the distribution of allelic effects at *individual loci*. Thus, while short-term changes in the mean can be predicted without detailed knowledge of the underlying genetics (only σ_A^2 is required), changes in variance cannot (unless an estimate of $\sum \mu_{2,i}^2$ or n_e can be obtained). Further, as allele frequencies change, so does n_e , and Example 24.4 showed just how unpredictable such changes can be.

Finally, let's attempt to connect these results for the change in the genic variance, $\Delta\sigma_A^2 = \Delta\sigma_a^2$ (as we ignore any disequilibrium), with those obtained under the continuum-of-alleles (COA) approximation (Equation 24.2a). If the within-generation change in the phenotypic

variance is $\delta(\sigma_z^2) = -\kappa\sigma_z^2$, then the Gaussian COA approximation for the change in genic variance (Equation 24.2a, ignoring drift by taking $N_e = \infty$) becomes

$$\Delta\sigma_a^2 = -\frac{\kappa h^2 \sigma_A^2}{2n_e} \quad (24.30d)$$

By contrast, because $\kappa h^4 \sigma_z^2 = \kappa h^2 \sigma_A^2$, Equation 24.30c yields an allelic-moment approximation of

$$\Delta\sigma_a^2 \simeq \frac{h^4}{2n_e} \left(\delta(\sigma_z^2) + S^2 \right) = -\frac{\kappa h^2 \sigma_A^2}{2n_e} + \frac{h^4 S^2}{2n_e} \quad (24.30e)$$

Thus, the allelic-moment approximation has a positive term lacking in the COA approximation, and hence predicts a smaller change in σ_a^2 when $\kappa > 0$ (i.e., when selection reduces the phenotypic variance; Chapter 16). Nick Barton (pers. comm., 2014) suggested that this discrepancy between approximations arises because the selection-gradient approach relies on a weak selection assumption, so terms of order S^2 are not accurately predicted.

Example 24.10. Here we show that n_e , as defined in the previous example, is equivalent to Chevalet's (1994) n_e (Equation 24.3). This simply clears up a technical detail, and it can be skipped by the casual reader. Specifically, we need to show that

$$n_e = \frac{n}{1 + c_v^2} = \frac{\sigma_A^4}{4 \sum_i \mu_{2,i}^2}$$

where c_v is the coefficient of variation in the genic variance contributed by each locus. Because $\mu_{2,i}$ is the variance of allelic effects at locus i , the genic variance contributed by locus i is $2\mu_{2,i}$ (as there are two alleles per locus). If we recall that the coefficient of variation is defined as the standard deviation divided by the mean

$$1 + c_v^2 = 1 + \left(\frac{\sigma(2\mu_{2,i})}{E[2\mu_{2,i}]} \right)^2 = \frac{E[2\mu_{2,i}]^2 + \sigma^2(2\mu_{2,i})}{E[2\mu_{2,i}]^2} \quad (24.31a)$$

Recalling that $\sigma^2(x) = E[x^2] - E[x]^2$, we have

$$\sigma^2(2\mu_{2,i}) = E[(2\mu_{2,i})^2] - E[2\mu_{2,i}]^2 = \left[\frac{1}{n} \sum_{i=1}^n (2\mu_{2,i})^2 \right] - E[2\mu_{2,i}]^2 \quad (24.31b)$$

which rearranges to

$$E[2\mu_{2,i}]^2 + \sigma^2(2\mu_{2,i}) = \frac{1}{n} \sum_{i=1}^n (2\mu_{2,i})^2 \quad (24.31c)$$

If we sum the genic variances, $2\mu_{2,i} = \sigma_{a,i}^2$, at each locus we get the total additive genic variance, σ_a^2 . Because we are ignoring disequilibrium (i.e., assuming that $d = 0$), we have the result that $\sigma_a^2 = \sigma_A^2$, or that

$$\sigma_A^2 = \sum_{i=1}^n 2\mu_{2,i} = n E[2\mu_{2,i}], \quad \text{or that} \quad E[2\mu_{2,i}]^2 = \frac{\sigma_A^4}{n^2} \quad (24.31d)$$

First substituting Equation 24.31b into 24.31a and then using Equation 24.31d yields

$$1 + c_v^2 = \frac{E[2\mu_{2,i}]^2 + \sigma^2(2\mu_{2,i})}{E[2\mu_{2,i}]^2} = \frac{(1/n) \sum_{i=1}^n (2\mu_{2,i})^2}{\sigma_A^4 / n^2} = \frac{4n \sum_{i=1}^n \mu_{2,i}^2}{\sigma_A^4}$$

Thus,

$$n_e = \frac{n}{1 + c_v^2} = \frac{n \sigma_A^4}{4n \sum_{i=1}^n \mu_{2,i}^2} = \frac{\sigma_A^4}{4 \sum_{i=1}^n \mu_{2,i}^2}$$

demonstrating the equivalence of n_e as defined by Equation 24.29b with that given by Equation 24.3.

Example 24.11. An important construct used in the analysis of population-genetic models for the maintenance of quantitative-trait variation (Chapter 28) is the **rare-alleles model** of Barton and Turelli (1987). This assumes that loci are very near fixation, which occurs when the strength of selection is much greater than the strength of mutation. Here we show that under this assumption, allelic moments are proportional to the rare-allele frequencies, meaning that products of moments can be ignored and higher-order moments can be expressed in terms of lower-order ones.

To see how this approximation arises, consider the simplest case of a biallelic locus (i), where the common allele has an effect of 0, while the rare allele ($p_i \simeq 0$) has an additive effect of a_i . The resulting mean is $\mu_{1,i} \simeq 2a_i p_i$ and because p_i is assumed small, quadratic and higher terms in p_i are ignored in higher moments. For example, the $(2k)$ th moment becomes

$$\mu_{2k,i} = (a_i - \mu_{1,i})^{2k} p_i + (0 - \mu_{1,i})^{2k} (1 - p_i) \simeq a_i^{2k} p_i \quad (24.32a)$$

The last step follows because $\mu_{1,i}^k$ is of order p_i^k and is ignored (for $k \geq 2$). Thus, higher-order moments are related,

$$\mu_{4,i} \simeq a_i^4 p_i = a_i^2 (a_i^2 p_i) = \xi_i \mu_{2,i}$$

For now, we set $\xi_i = a_i^2$ as this, or a closely related term, appears in the expression for all higher-order moments. Likewise, products of moments are of quadratic- or higher-order in p_i , and thus are ignored. For example, $\mu_{4,i} - \mu_{2,i}^2 \simeq \mu_{4,i} = \xi_i \mu_{2,i}$, as $\mu_{2,i}^2$ is of order p_i^2 . Turelli (1984) showed that these moment relationships also hold under his house-of-cards assumption that selection at a locus is much stronger than mutation (and hence most alleles are rare and deleterious), but now with $\xi_i = \sigma_{\alpha_i}^2$, the variance in the effects of new mutations at locus i , replacing a_i^2 (which follows from the fact that $E[\alpha_i^2] = \sigma_{\alpha_i}^2 + (E[\alpha_i])^2 = \sigma_{\alpha_i}^2$, as $E[\alpha_i] = 0$). Assuming n equivalent loci (hence, $\xi = \xi_i$), under the rare-alleles or house-of-cards assumption, the moments matrix, \mathbf{M} , from Equation 24.26c simplifies to

$$\begin{pmatrix} \Delta\mu \\ \Delta\sigma_A^2 \\ \Delta\mu_{3,G} \end{pmatrix} \simeq \begin{pmatrix} \sigma_A^2 & M_3 & \xi\sigma_A^2 \\ M_3 & \xi\sigma_A^2 & \xi M_3 \\ \xi\sigma_A^2 & \xi M_3 & \xi^2\sigma_A^2 \end{pmatrix} \begin{pmatrix} \frac{\partial \ln \bar{w}}{\partial \mu} \\ \frac{\partial \ln \bar{w}}{\partial \sigma_z^2} \\ \frac{\partial \ln \bar{w}}{\partial \mu_{3,z}} \end{pmatrix} \quad (24.32b)$$

Notice that $\Delta\mu_{3,G} = \xi\Delta\mu_{1,G}$, thus directly coupling changes in the mean and skew. If we assume no initial skew (and no selection on skew), Equation 24.32b further reduces to

$$\begin{pmatrix} \Delta\mu \\ \Delta\sigma_A^2 \end{pmatrix} \simeq \begin{pmatrix} \sigma_A^2 & 0 \\ 0 & \xi\sigma_A^2 \end{pmatrix} \begin{pmatrix} \frac{\partial \ln \bar{w}}{\partial \mu_z} \\ \frac{\partial \ln \bar{w}}{\partial \sigma_z^2} \end{pmatrix} = \begin{pmatrix} \sigma_A^2 \frac{\partial \ln \bar{w}}{\partial \mu_z} \\ \xi\sigma_A^2 \frac{\partial \ln \bar{w}}{\partial \sigma_z^2} \end{pmatrix} \quad (24.32c)$$

Comparing these results with Example 24.9 (the Gaussian approximation) shows that the expected change in the mean (in the absence of skew) is identical in both the rare alleles and Gaussian-approximation models. Under the Gaussian, the change in the variance is given by σ_A^4/n_e times the fitness gradient with respect to the phenotypic variance, while under the rare alleles model, the quantity $\xi\sigma_A^2$ is multiplied by the gradient. Under the rare alleles (and house-of-cards) models, the assumption is that the variance at a locus is small relative to the input from new mutation, implying that $\xi = \sigma_{\alpha_i}^2 \gg \sigma_A^2/n_e$, and thus $\xi\sigma_A^2 \gg \sigma_A^4/n_e$, predicting a much larger change in the variance than under the Gaussian. We will return to this important point in Chapter 28.

A second critical difference between the rare-alleles and Gaussian-approximation models can be seen from Equation 24.28a. This shows that selection on the variance only influences

the response in the mean when there is skew in the breeding value distribution ($M_3 \neq 0$), which does not occur under the Gaussian approximation (although selection-induced third-order LD can create it from an initially Gaussian model). Conversely, the rare-alleles model can easily have skew, thus coupling changes in the mean with selection on the variance.

A final important point is that if the rare-alleles model is a good approximation of reality, then most genetic variation is additive. Even when significant interactions (dominance and epistasis) are present, most genetic variation loads onto the additive component in cases where all but a few of the multilocus genotypes under consideration are rare (Crow 2008; Hill et al. 2008; Mäki-Tanila and Hill 2014). One simple way to see this point is to consider a fully dominant, but rare, allele. In this case, the frequency of dominant homozygotes is extremely small, so that the additive effect of the allele is given almost entirely by the genotypic values of the recessive homozygote and the heterozygote, thus loading most of the effects into the additive component. With multilocus genotypes, most combinations of genotypes are so rare that they have little impact on the least-squares regressions that determine additive effects. For example, consider a highly nonlinear relationship between genotypes and trait value. If only a few of the genotypes are common, then most of the regression is determined by just a few points, meaning that a linear regression (and hence additive effects) is likely to account for a significant fraction of the variance.

Short-term Response Ignoring Allele-frequency Change

The last section considered one class of approximations for the short-term selection response for non-Gaussian distributions of genotypic values, focusing solely on allele-frequency changes. Here we consider the converse approximation: a large enough number of loci (all of small effect) that allele-frequency change (over the time span of interest) can be ignored, with the change in genotypic moments thus attributable entirely to selection-generated disequilibrium. Our discussion departs from the standard infinitesimal model in that we no longer make any Gaussian assumptions.

Turelli and Barton (1990, 1994) extended basic moments analysis (Equation 24.26a) to allow for gametic-phase disequilibrium, by considering both within-locus moment changes due to allele-frequency changes (M_{ii}) and between-locus contributions generated by disequilibrium ($M_{ij}, i \neq j$). Their 1994 paper is the more general of the two, with the analysis based on the cumulants of the distribution. While the mean, variance, and skew are equivalent to the first three cumulants, cumulants of order four and higher provide much more compact expressions than using moments, due to the additivity of cumulants versus the nonlinear nature of higher-order moments.

In parallel with their moments analysis, Turelli and Barton defined the gradients of selection associated with the i th cumulant of the phenotypic distribution $K_{z,i}$ by

$$L_i = \frac{\partial \ln(\bar{W})}{\partial K_{z,i}} \quad (24.33a)$$

L_1 and L_2 correspond to selection on the mean and variance, while L_i for $i \geq 3$ represents selection that drives the distribution away from normality (as cumulants of order three and higher are zero for a Gaussian). Turelli and Barton presented general expressions for the change in all cumulants of the distribution. In particular, for a large number of loci, they show that if the majority of selection is on the first four cumulants of the distribution, the changes in the mean and variance are given by

$$\Delta\mu = \sigma_A^2 L_1 + K_{G,3} L_2 + K_{G,4} L_3 + K_{G,5} L_4 \quad (24.33b)$$

$$\begin{aligned} \Delta\sigma_A^2 = & \frac{\sigma_A^2 - \sigma_A^2}{2} - \frac{(\Delta\mu)^2}{2} + \frac{K_{G,3}}{2} L_1 + \left(\sigma_A^4 + \frac{K_{G,4}}{2} \right) L_2 \\ & + \left(3\sigma_A^2 K_{G,3} + \frac{K_{G,5}}{2} \right) L_3 + \left(3K_{G,3}^2 + 4\sigma_A^2 K_{G,4} + \frac{K_{G,6}}{2} \right) L_4 \end{aligned} \quad (24.33c)$$

where $K_{G,i}$ denotes the i th cumulant of the genotypic distribution. Note that for Equation 24.33b if some cumulants of order three or higher are nonzero, selection on higher-order cumulants of the phentoypic distribution (i.e., L_3 or $L_4 \neq 0$) also results in a change in the mean. Further, note the appearance of the *genic* variance σ_a^2 in Equation 24.33c. We are assuming (at least over our time scale) that allele-frequency change can be ignored and hence σ_a^2 is a constant. All changes in the variance (and higher-order moments or cumulants) are thus assumed to arise entirely from selection generated-disequilibrium.

Example 24.12. As an application of these results, when phenotypes are normally distributed, Equations 24.12a and 24.12b yield

$$L_1 = \frac{S}{\sigma_z^2} \quad \text{and} \quad L_2 = \frac{\delta(\sigma_z^2) + S^2}{2\sigma_z^4} \quad \text{with} \quad L_i = 0 \quad \text{for } i \geq 3$$

If the genotypic values also follow a normal distribution, then $K_{G,i} = 0$ for $i \geq 3$. In this case, Equation 24.33b reduces to

$$\Delta\mu = \sigma_A^2 \frac{S}{\sigma_z^2} = h^2 S$$

which recovers the breeder's equation. If we recall that $\sigma_A^2 = \sigma_a^2 + d$, using the preceding expressions reduces Equation 24.33c to

$$\begin{aligned} \Delta\sigma_A^2 &= \frac{\sigma_a^2 - \sigma_A^2}{2} - \frac{(\Delta\mu)^2}{2} + \frac{0}{2}L_1 + \left(\sigma_A^4 + \frac{0}{2}\right)L_2 \\ &\quad + \left(3\sigma_A^2 \cdot 0 + \frac{0}{2}\right) \cdot 0 + \left(0^2 + 4\sigma_A^2 \cdot 0 + \frac{0}{2}\right) \cdot 0 \\ &= \frac{\sigma_a^2 - \sigma_A^2}{2} - \frac{(h^2 S)^2}{2} + \sigma_A^4 \left(\frac{\delta(\sigma_z^2) + S^2}{2\sigma_z^4}\right) \\ &= -\frac{d}{2} + \frac{h^4}{2} \delta(\sigma_z^2) \end{aligned}$$

which recovers Bulmer's equation. Notice that there is no change in the genic variance, as we assume there are very large number of loci of small effect.

Turelli and Barton (1994) examined the effects of both strong truncation (directional) selection and strong disruptive selection on Gaussian (infinitesimal and COA) models when the number of loci is large. They found that while strong truncation selection does indeed generate nonzero cumulants of order three and higher (and hence departures from normality), these departures are generally quite small (e.g., Example 24.8). As a result, the breeder's equation with the variance changes predicted from the Bulmer equation (Equation 16.7b) gives quite accurate results for the predicted change in the mean and variance. Hence, the effects of disequilibrium in this case are essentially accounted for by considering only the second-order disequilibrium, which is done in the basic Bulmer model. Barton and Turelli found that the distribution of genotypic values is highly non-normal under strong disruptive selection, with a significant fourth cumulant (kurtosis) being generated by significant fourth-order disequilibrium (generating correlations between groups of four loci). Surprisingly, even in this case the change in variance is still well predicted by the Bulmer equation.

Effects of Linkage

As might be expected, when these results are generalized to allow for arbitrary linkage (as opposed to the previous expressions, which assume unlinked loci), they become rather complex, even when we assume that there is no allele-frequency change (Turelli and Barton 1990, 1994; Bürger 2000). However, when selection is weak, we can include linkage into an approximation for the asymptotic response for a generalized infinitesimal model that makes no assumptions about the distribution of genotypic values (Turelli and Barton 1990). In particular, Turelli and Barton showed under weak selection that higher-order genotypic moments can be expressed in terms of the initial additive variance in the absence of gametic-phase disequilibrium (the genic variance, σ_a^2 , which is assumed to be constant). Using this result, the asymptotic response to selection can be found to be approximately

$$\Delta\mu_z \simeq \sigma_a^2 \left(\frac{\partial \ln \bar{W}}{\partial \mu_z} \right) + \frac{\sigma_a^4}{r_{H_2}} \left(\frac{\partial \ln \bar{w}}{\partial \mu_z} \cdot \frac{\partial \ln \bar{w}}{\partial \sigma_z^2} \right) + \frac{3\sigma_a^6}{2r_{H_3}} \left(\frac{\partial \ln \bar{w}}{\partial \sigma_z^2} \cdot \frac{\partial \ln \bar{w}}{\partial \mu_{z,3}} \right) \quad (24.34)$$

where r_{H_2} and r_{H_3} are the harmonic mean recombination rates (weighted by the allelic contributions at each locus) between pairs and triplets of loci (Turelli and Barton 1990). At equilibrium, the higher-order genotypic moments are constant, as allele frequencies do not change and, with constant selection, covariances between loci approach equilibrium values. Under these conditions, the expected change in the mean following t generations of selection is just t times Equation 24.34.

Recalling Equations 24.12a and 24.12b (the fitness gradients for the mean and variance of a normally distributed trait), if phenotypes are approximately normal, the asymptotic rate of response further reduces to

$$\Delta\mu_z \simeq \frac{\sigma_a^2}{\tilde{\sigma}_z^2} \left[S + \sigma_a^2 \frac{\tilde{\delta}(\sigma_z^2) + S^2}{2\tilde{\sigma}_z^2} \left(\frac{S}{r_{H_2}} + \frac{3\sigma_a^2}{2r_{H_3}} \frac{\partial \ln \bar{w}}{\partial \mu_{3,z}} \right) \right] \quad (24.35)$$

where $\tilde{\sigma}_z^2$ is the equilibrium phenotypic variance and $\tilde{\delta}(\sigma_z^2)$ is the equilibrium within-generation change in phenotypic variance due to selection. This generalizes Bulmer's results (Chapter 16), which correct the breeder's equation for changes in the variance due to pairwise disequilibrium. Equation 24.35 demonstrates that further corrections are required to account for the third- (and higher-order) disequilibrium generated by selection.

SUMMARY: WHERE DOES ALL THIS MODELING LEAVE US?

Predicting selection response is complicated. Even in the ideal setting where the breeder's equation holds exactly, drift and segregation generate a *variance* in response about the expected value (Chapter 18). Thus, any specific *realization* of the selection response will be randomly distributed about its expected value, and hence be less predictable than suggested by the deterministic result for the expected response. Further, even when the initial parent-offspring regression is linear and homoscedastic, there is still a large number of confounding factors for even the single-generation response (Table 13.2). Despite these concerns, short-term prediction of the response to artificial selection is reasonable for many traits (Chapter 18), but far less so for natural selection, in part due to uncertainty as to the target(s) of selection (Chapter 20). In contrast, the prediction of long-term response is an unobtainable goal unless one essentially knows all of the very fine (microscopic) genetic details of a trait, *including* the distribution of allelic effects and frequencies.

As we have seen here and elsewhere (Chapters 5 and 16), selection compromises the simple breeder's equation, $R = h^2S$, prediction in two different ways. First, when some of the underlying loci harbor alleles of modest to large effect, this can generate locus-specific selection coefficients sufficiently large to significantly change allele frequencies over short time scales (Equations 5.3 and 5.21). Such changes alter the base-population heritability in

ways that are not predictable from observable macroscopic features (such as the initial additive variance). Rather, the dynamics of selection response depend on very fine (microscopic) details of the trait's genetic architecture. A more subtle consequence of allele-frequency change is that it can drive a genotypic distribution away from normality by generating locus-specific skewness and kurtosis. This results in nonlinear and heteroscedastic parent-offspring regressions, and hence potential failure of the breeder's equation, even when correctly updated values of h^2 are used.

Dealing with the second consequence of selection, generation of linkage (or, more correctly, gametic-phase) disequilibrium, is often much more manageable than accounting for changes in allele frequencies. Indeed, in the absence of allele-frequency change, changes in LD are temporary, and decay away under random mating following the cessation of selection. Further, unless linkage is very tight or there are genes of very large effect, changes in LD occur on a much faster time scale than do allele-frequency changes. When the trait is controlled by a large number of loci, each of small effect, allele-frequency change is negligible over short time scales. However, selection-induced correlations (even among unlinked loci) change not only the genetic variance (Chapter 16), but can also generate skewness and kurtosis via the creation of third- and fourth-order disequilibrium. While these two latter effects drive a genotypic distribution away from normality, this effect is often modest and does not greatly compromise predictions of response. Further, as we saw in Chapter 16, the Bulmer equation accounts for changes in variances from disequilibrium using easily observed parameters. In the words of Turelli and Barton (1990), "Though our work shows that the distribution of breeding values for an additive polygenic character is unlikely to be precisely Gaussian, we expect that the Gaussian approximation suffices for predicting short-term selection response in all but the most extreme cases."

Allele-frequency change is the more pernicious feature of selection (relative to disequilibrium), but (for short time scales) it is restricted to traits whose underlying genetic architectures harbor one or more alleles of large effect. Chapters 25 and 26 examine the long-term consequences of allele-frequency change, while the additional role of mutation when directional and stabilizing selection is occurring is examined in Chapters 26 and 28, respectively.

25

Long-term Response: 1. Deterministic Aspects

The depletion of the variance by fixation of favored alleles is compensated by bringing previously rare alleles into the range where they contribute substantially to the response. Crow (2010)

Previous chapters assumed that the genetic variances for traits under selection either remain constant or can be predicted solely from their base-population values. Under the infinitesimal model, selection does not alter allele frequencies (Chapters 13, 16, and 24), and hence the genic variance, σ_a^2 , remains unchanged, while the additive variance, $\sigma_A^2 = \sigma_a^2 + d$, changes (from selection-induced disequilibrium, d) in a predictable way (Chapter 16). With finite population size, allele frequencies are changed by drift, but again in predictable ways under an additive model (Chapters 16 and 24). If allele-frequency change is entirely due to drift, the expectation is that the amount of change is *independent* of allelic-effect size. However, with selection-induced changes, we expect alleles with larger effects to experience greater allele-frequency change. In such cases, while short-term response can be reasonably predicted from the base-population variance components alone, long-term response depends on the underlying, and generally unknown, genetic architecture (number of genes, allelic effects and frequencies). Our discussion of long-term response, which spans the next four chapters, is divided into three major topics: (i) deterministic changes in very large populations (the focus of this chapter), (ii) the special features that emerge due to drift (Chapter 26), and (iii) the long-term consequences of mutational input (Chapters 26–28). Our focus over the next two chapters is directional selection. The long-term consequences of stabilizing selection are considered in Chapter 28.

We start by examining an idealized model where an initially linear response declines smoothly to an asymptotic **selection limit** as the additive-genetic variation from the initial (or **base**) population becomes exhausted. We will show more formally that while populations with the same variance components show essentially the same short-term response, their long-term responses can be very different, depending on their underlying genetic architectures. We then develop the deterministic theory for allele-frequency change under long-term response in order to quantify the expected time for a certain amount of response and the ultimate selection limit (using only the initial variation). While these models cannot be applied to most real populations (as they require detailed information on the joint distribution of allele frequencies and effects at each locus underlying the trait), they provide an important framework for examining empirical results. Next, we examine response with a major gene and background polygenes. We conclude by reviewing a few generalizations that emerge from long-term artificial selection experiments and examine the nature of the (apparent) selection limit, if present, in these experiments.

IDEALIZED LONG-TERM RESPONSE IN A LARGE POPULATION

The general pattern expected in the long-term response to directional selection is roughly as follows: in the absence of segregating major alleles, additive variance (and hence the selection response) is roughly constant over the first few generations, yielding a nearly linear response (Figure 25.1). As discussed in Chapters 16 and 24, there is an initial reduction

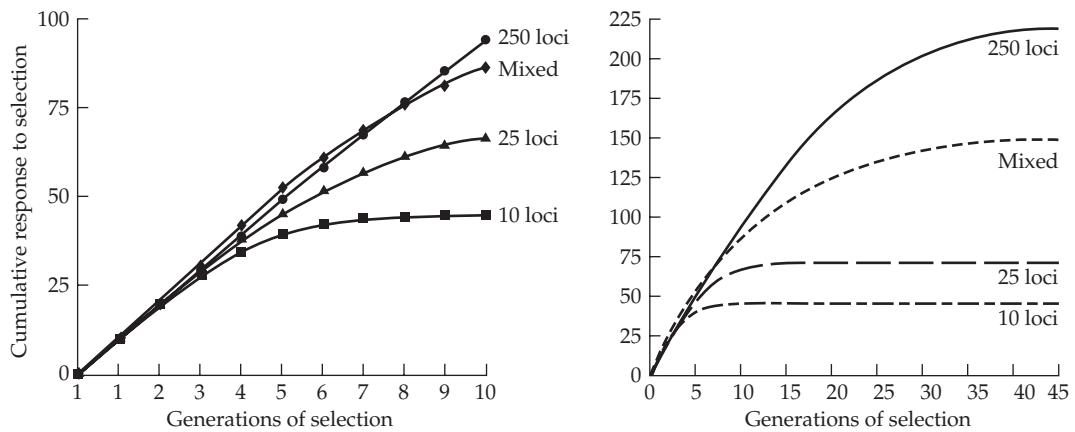

Figure 25.1 Examples of the expected response to selection, here assuming truncation selection (with the upper 20% saved) and n identical diallelic loci (each with genotypic values of $0 : a : 2a$, and a favorable allele frequency of p). We further assume that there is no epistasis and ignore any effects of gametic-phase disequilibrium. All populations start with $\sigma_A^2(0) = 100$ and $\sigma_E^2 = 100$, so $h^2(0) = 0.5$. Curves are plotted for models with 10, 25, and 250 equivalent loci, each with initial allele frequency $p = 0.5$ and a values of 4.47, 2.82, and 0.89, respectively. A mixed genetic model is also shown, which consists of 5 identical major loci ($p = 0.25$ and $a = 5.16$) and 125 identical minor loci ($p = 0.5$ and $a = 0.89$); as a consequence of these starting values, the major and minor loci contribute equally to the initial additive-genetic variance. **Left:** Short-term response over the first 10 generations. **Right:** Response over the first 40 generations. Note that the total response increases with the number of loci. In the infinitesimal-model limit, the response remains linear over all generations (after correcting for the slight decrease over the first few generations from linkage disequilibrium; see Example 16.3).

in the additive variance due to the generation of gametic-phase disequilibrium, but this is generally small unless directional selection on the trait is strong, heritability is high, and the number of underlying loci is large. As generations proceed, sufficient allele-frequency change accrues to significantly alter genetic variances, and in particular the genic variance, σ_a^2 . At this point, the additive-genetic variance can either increase or decrease, depending on the starting distribution of allelic frequencies and effects. However, assuming no input of new variation (from mutation or migration), the additive variance generated from the initial variation in the base population eventually declines. Ultimately, a **selection limit** or **plateau** is reached, potentially reflecting the removal of all additive-genetic variance at the underlying loci, either by fixation of all segregating alleles at a locus or the absence of additive variance at those loci that are still segregating (e.g., the presence of overdominant alleles for the character under selection). This expectation follows from an important corollary of Fisher's fundamental theorem (Chapter 6), namely that, in the absence of new inputs, selection is expected to eventually remove all additive genetic variation in fitness.

If loci with both major and minor alleles influence the character under selection, an initial rapid response can result from large changes in allele frequencies at major loci, provided these alleles are initially not rare. This burst of response is followed by a much longer period of slower response due to allele-frequency changes at loci having smaller effects and major alleles that were initially very rare or partly recessive. Such differences in rates of response can make it difficult to determine whether a selection limit has actually been reached. As the genetic variation in the base population becomes fully exhausted, the effects of new mutations will drive any continued response, which is examined in Chapter 26.

Figure 25.1 illustrates differences in the long-term selection response for four hypothetical populations with the same initial heritability but different underlying genetic architectures. All show essentially the same response over the first few generations. By generation 5,

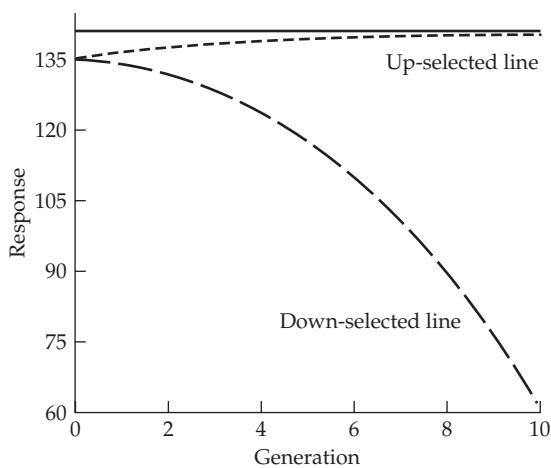

Figure 25.2 With strong directional dominance, an apparent selection limit can result when favored alleles are dominant, because selection is only acting against the increasingly rare recessive homozygotes. Here the genotypes have values of $0 : 2a : 2a$, and we ignore epistasis and gametic-phase disequilibrium. The population consists of 25 identical loci, with $a = 2.82$ and initial dominant-allele frequency of $p = 0.8$. We assume truncation selection with the upper (or lower) 20% of the population being saved. If all loci are fixed for the favored allele, the selection limit is $2 \cdot 2.82 \cdot 25 = 141$ (indicated by the horizontal line). There is little response to upward selection and the population appears at a selection limit, even though there was considerable genetic variation in the base population, as shown by the rapid response of the down-selected line.

however, selection has changed allele frequencies in the 10- and 25-locus populations enough to reduce the response, while the 250-locus population shows a roughly constant response through 20–25 generations. The mixed population (5 major loci, each with an initial frequency of the favored allele of $p = 0.25$, and 125 minor loci, each with $p = 0.5$) shows an enhanced response relative to the others in generations 3–7. This results from an increase in heritability, as the frequencies of alleles with large effects increase from 0.25 to 0.50, increasing the additive variance contributed by these loci (LW Figure 4.8). If rare recessives are present, there can be a considerable time lag until the enhanced response appears (Figure 25.10B). For all models, the time for allele-frequency change scales as $1/s$ (Equations 5.3d–5.3f), with s scaling with the allelic-effect size (Equation 5.21). Hence, as a rough approximation, if the effect size is halved, the same amount of allele-frequency change will take twice as long.

If alleles favored by selection are dominant, response slows considerably as they become common, reflecting the rarity of homozygous recessives. In such cases, the response can be so slow that the population appears to be at a limit. However, as Figure 25.2 demonstrates, reverse selection can result in a fairly rapid response, indicating the presence of substantial additive-genetic variation. As was mentioned in Chapter 18, divergent selection in this case generates a significant asymmetric response. This apparent limit due to the very slow removal of recessives can be partly overcome by inbreeding. By increasing the frequency of homozygotes relative to a random-mating population, inbreeding greatly improves the efficiency of selection, allowing favorable dominant alleles to be more rapidly fixed.

Example 25.1. Falconer (1971) examined an apparent limit in a mouse line selected for increased litter size. Four sublines were created from this plateaued line and subjected to inbreeding and selection. Selection on a new line formed by crossing these inbred-selected lines

gave an improvement of 1.5 mice per litter over the original limit. Falconer's interpretation was that many recessive alleles decreasing litter size were segregating in the apparently plateaued line, some of which were lost during inbreeding within sublines. Crossing the inbred-selected lines generated a population segregating fewer recessives (i.e., fixed for more of the favorable dominant alleles), thus facilitating the total response. Several other selection experiments in mice also found segregating recessives in populations near apparent selection limits. For litter size, Eklund and Bradford (1977) found that inbreeding and selection increased the response. However, Al-Murrani and Roberts (1974) found that while a population that had plateaued for increased body weight was also segregating a number of recessives, their loss was expected to yield only a trivial increase in body weight, and no increase was detected using Falconer's inbred-selection method.

DETERMINISTIC SINGLE-LOCUS THEORY

The contribution to the selection limit from a single locus and the half-life associated with this contribution depend on a variety of genetic parameters: initial allele frequencies, the dominance relationship among alleles, and allelic-effect sizes. This section quantifies how these factors influence long-term response for a diallelic locus in the absence of drift, mutation, and epistasis. This basic model provides insight into the dynamics of response and serves as the foundation for theories incorporating drift and mutation (Chapters 26 and 28).

Expected Contribution From a Single Locus

We start with the expected total contribution from a given diallelic locus. Let B be the allele favored by directional selection, where the genotypes $bb : Bb : BB$ have genotypic values of $0 : a(1 + k) : 2a$. Assuming genotypes are in Hardy-Weinberg equilibrium, the contribution to the mean character value from this locus is a function of p (the frequency of B), namely,

$$m(p) = 2ap [1 + (1 - p)k] \quad (25.1a)$$

Provided there is no epistasis, gametic-phase disequilibrium will have no influence on this contribution to the mean. The total contribution from this locus if B is fixed, given that it starts at an initial frequency of p_0 , is

$$m(1) - m(p_0) = 2a - 2ap_0 [1 + (1 - p_0)k] = 2a(1 - p_0)(1 - p_0k) \quad (25.1b)$$

Figure 25.3 plots the total contribution when allele B is either additive ($k = 0$), dominant ($k = 1$), or recessive ($k = -1$). The total response from this locus is largest when B is recessive and rare, and smallest when B is dominant and common. With overdominance ($k > 1$), the maximum value for $m(p)$ occurs at at $p = \hat{p}$, where

$$\hat{p} = \frac{1+k}{2k} \quad (25.1c)$$

which is obtained by taking the derivative of $m(p)$ with respect to p and solving for zero. With an overdominant locus underlying the trait, when $p_0 > \hat{p}$, directional selection on the trait results in p decreasing to \hat{p} , while if $p_0 < \hat{p}$, then p increases to \hat{p} . In either case, the final contribution from this locus is

$$m(\hat{p}) - m(p_0) \quad (25.1d)$$

Finally, the allele frequency, p_β , at which a preset fraction, β , of the total contribution occurs is also of interest. This is determined by solving the quadratic equation

$$m(p_\beta) - m(p_0) = \beta [m(1) - m(p_0)] \quad (25.1e)$$

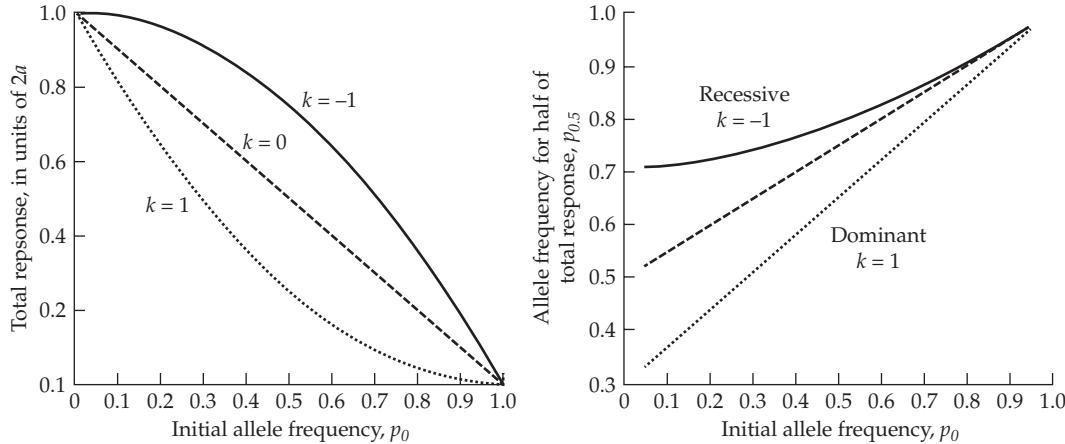

Figure 25.3 **Left:** The contribution to total response from a diallelic locus assuming allele B , starting at frequency p_0 , is eventually fixed. The genotypes $BB : Bb : bb$ have values of $2a : a(1+k) : 0$. The three curves correspond to B being additive ($k = 0$), dominant ($k = 1$), and recessive ($k = -1$). The smallest contribution is made by dominant alleles at high frequencies, and the largest from recessive alleles at low frequencies. **Right:** The allele frequency, $p_{0.5}$, at which half the total response contributed by a locus occurs, as a function of its initial frequency, p_0 .

Table 25.1 Total contribution to the selection limit and the allele frequency, $p_{0.5}$, at which half this response occurs for a diallelic locus when allele B has an initial frequency of p_0 .

	Total Contribution	$p_{0.5}$
B additive ($k = 0$)	$2a(1 - p_0)$	$(1 + p_0)/2$
B dominant ($k = 1$)	$2a(1 - p_0)^2$	$1 - \sqrt{[1 - p_0(2 - p_0)]/2}$
B recessive ($k = -1$)	$2a(1 - p_0^2)$	$\sqrt{(1 + p_0^2)/2}$

for p_β , with $m(1)$ is replaced by $m(\hat{p})$ when $k > 1$. A case of particular interest is $p_{0.5}$, the frequency at which half of the expected response occurs ($\beta = 1/2$). Expressions for $p_{0.5}$ as a function of initial allele frequency are given in Table 25.1 and plotted in Figure 25.3. Observe that rare recessives have to increase substantially in frequency to yield half their ultimate response (e.g., for $k = -1$, $p_{0.5} \simeq 0.71$ when $p_0 = 0.1$).

Dudley's Estimators of a , n , and p_0

In a similar fashion to the Wright-Castle estimator for the number of loci (LW Chapter 9), if we are willing to make the assumption of the exchangeable model (all loci are additive with the same effects and initial frequencies; Chapter 24), we can estimate a , n , and p_0 from data on selection limits. Under this model, Equation 25.1b gives the expected total response ($R_c(\infty)$, which we will simply write here as R) of $2na(1 - p_0)$, while the starting additive variance is $2na^2p_0(1 - p_0)$. Using these expressions yields Robertson's (1970a) result for the total response, scaled by the square root of the initial additive variance, as

$$\frac{R}{\sigma_A} = \frac{2na(1 - p_0)}{\sqrt{2na^2p_0(1 - p_0)}} = \sqrt{\frac{2n(1 - p_0)}{p_0}} \quad (25.2a)$$

Dudley (1977) noted that, in a divergence selection experiment (Chapter 18), Equation 25.2a yields the limit, R_H , for response in the high direction, while

$$\frac{R_L}{\sigma_A} = \frac{2nap_0}{\sqrt{2na^2p_0(1 - p_0)}} = \sqrt{\frac{2np_0}{1 - p_0}} \quad (25.2b)$$

yields the limit to response in the low direction. Taking the ratio of these two limits yields

$$\frac{R_H}{R_L} = \frac{\sqrt{2n(1-p_0)/p_0}}{\sqrt{2np_0/(1-p_0)}} = \frac{1-p_0}{p_0} \quad (25.2c)$$

Equation 25.2c rearranges to suggest an estimate of p_0 , with

$$\hat{p}_0 = \frac{1}{R_H/R_L + 1} \quad (25.2d)$$

Next, because $R_H R_L = 4n^2 a^2 p_0 (1-p_0)$, it follows that $R_H R_L / \sigma_A^2 = 2n$, which suggests an estimator for the number of loci

$$\hat{n} = \frac{1}{2} \frac{R_H R_L}{\sigma_A^2} \quad (25.2e)$$

Finally, a little algebra recovers an estimate of the allelic effect, namely,

$$\hat{a} = \sigma_A^2 \left(\frac{1}{R_H} + \frac{1}{R_L} \right) \quad (25.2f)$$

These estimates of the genetic architecture of a trait should be regarded as extremely crude (at best), but they nonetheless provide potential insight. One of the many caveats in applying these results is that the selected populations must be at their respective limits, which can be hard to access. Operationally, the limits could be estimated from curve-fitting of the data, a topic that will be discussed shortly.

Dynamics of Allele-frequency Change

To obtain approximate expressions for the actual dynamics of the selection response in the mean, we need to follow allele-frequency changes over time. Recall from Equation 5.21 that if a character is normally distributed, then the change in the frequency of allele B is $\Delta p \simeq \bar{i}(\alpha/\sigma_z) p$, where p and α are, respectively, the frequency and average excess of B . This is a weak-selection approximation, as it assumes that $|\bar{i}\alpha/\sigma_z| \ll 1$. It also assumes that the effects of epistasis, gametic-phase disequilibrium, and genotype \times environment interactions are negligible. Assuming random mating, the average effect of an allele equals its average excess, and LW Equation 4.15a gives $\alpha = (1-p)a[1+k(1-2p)]$. Substituting yields

$$\Delta p \simeq \frac{a\bar{i}}{\sigma_z} p(1-p)[1+k(1-2p)] \quad (25.3)$$

Recall that this is correct only to linear order (terms of a^2 and higher order are ignored; see Equation 5.27a). Thus, there are potential pitfalls in applying Equation 25.3 when $\bar{i} \simeq 0$. One important example of this latter situation is strict stabilizing selection, where $\bar{i} = 0$ but allele frequencies can still change due to selection on the phenotypic variance of the character, which enters as quadratic terms, a^2 (e.g., Equation 5.6f).

Example 25.2. The idealized response curves in Figure 25.1 were generated using Equation 25.3 to compute the expected allele-frequency change at each locus, assuming there is no gametic-phase disequilibrium. We assumed complete additivity ($k = 0$ and no epistasis), that $\sigma_E^2 = 100$, and n identical loci underlying the character. Equation 25.3 yields

$$\Delta p_t = \frac{a\bar{i}p_t(1-p_t)}{\sigma_z(t)} = \frac{a\bar{i}p_t(1-p_t)}{\sqrt{\sigma_A^2(t) + \sigma_E^2}} \simeq \frac{a\bar{i}p_t(1-p_t)}{\sqrt{2na^2p_t(1-p_t) + 100}}$$

Strictly speaking, the last expression is an approximation, albeit a close one, as $2na^2p_t(1-p_t)$ is the *genic* variance, $\sigma_a^2(t)$, at generation t , while the *additive genetic* variance equals the *genic*

variance plus the disequilibrium contribution, $\sigma_A^2(t) = \sigma_a^2(t) + d(t)$, as discussed in Chapters 16 and 24. Iteration generates the response curves shown in the figure.

Recall that the results for the single-locus selection response in Chapter 5 used the fitness parameterization where the genotypes $bb : Bb : BB$ have fitnesses $1 : 1 + s(1 + h) : 1 + 2s$. For weak selection (e.g., $|s|, |sh| \ll 1$), this model gives the change in the frequency of B as

$$\Delta p \simeq s p (1 - p) [1 + h (1 - 2p)]$$

which follows from Equation 5.1c upon noting that $1/\bar{W} = 1 + O(s, sh)$, namely, one plus terms of order s and sh . Upon matching terms with Equation 25.3, we find that a QTL under directional selection has approximate selection parameters of

$$s = \frac{a}{\sigma_z} \bar{t} \quad \text{and} \quad h = k \quad (25.4)$$

Thus, as an initial approximation, the dynamics for a QTL with a small effect on a character under directional selection follow those of a locus under these constant fitnesses. If there is gametic-phase disequilibrium or epistasis, single-locus fitnesses change as the background genotype changes (Example 5.7). However, in the absence of these complications, fitnesses still change as the phenotypic variance, σ_z^2 , changes. As other loci become fixed due to selection and drift, σ_z^2 generally decreases as the genetic variance decreases, which in turn increases s . Unless heritability is large, this effect is usually small. For example, assuming that all of the genetic variance is additive, then if $h^2 = 0.1$, the phenotypic standard deviation when all loci are fixed is 95% ($\sqrt{0.9}$) of its initial value (inflating s by 5%), while for $h^2 = 0.25$ and 0.5, s can be inflated by 15% and 43%, respectively. This decrease in the phenotypic variance can be countered if σ_E^2 increases as genotypes become more homozygous (LW Chapter 6) or if there has been selection to increase σ_E^2 (Chapter 17). It is worth stressing that these results are for a trait under directional selection. The dynamics for a locus for a trait under stabilizing selection are quite different (Example 5.6; Chapter 28).

We can use these results to compute the expected time to achieve a fraction of the response contributed by a locus in an infinite population. When selection is weak ($|s|, |hs| \ll 1$), Equation 5.3c gives the expected time for a favorable allele, B , to reach a frequency of p , given it starts at a frequency of p_0 , for the general fitness model $1 : 1+s(1+h) : 1+2s$. Equation 5.3d gives the expected time (in generations) when B is additive ($h = 0$), Equation 5.3e when B is recessive ($h = -1$), and Equation 5.3f when B is dominant ($h = 1$). These expressions, together with Equations 25.1e and 25.4, allow us to obtain approximate expressions for the expected time until a fraction, β , of the total contribution from a single locus occurs (namely, the expected time to reach frequency p_β). Note that the rate of allele-frequency change scales as $s^{-1} = (\bar{t} a / \sigma_z)^{-1}$, meaning that the smaller is the allelic effect, the slower is the expected response time. Substituting $p_{0.5}$ for p_β gives the expected half-life of response associated with the locus under consideration (Figure 25.4). The half-life for rare recessives can be quite long, while the half-life of response for dominant loci *increases* with allele frequency when B is common (although in such cases, the additional gain made by fixing B is typically very small; see Figure 25.3).

These results ignore the effects of gametic-phase disequilibrium. Negative disequilibrium generated by directional selection reduces the average effect of an allele (plus alleles are associated with an excess of minus alleles at other loci, and vice versa, reducing allelic effects relative to a population in gametic-phase equilibrium). This results in a slower change in allele frequency. Hence, the half-lives plotted in Figure 25.4 are slight underestimates. In addition, for major alleles, our assumption that $|a|/\sigma_z$ and $|ak|/\sigma_z$ are small no longer holds, and the previous expressions for change in allele frequency and expected time to reach a given frequency can be poor approximations. More accurate versions for cases where major alleles are present were given by Latter (1965a) and Frankham and Nurthen (1981).

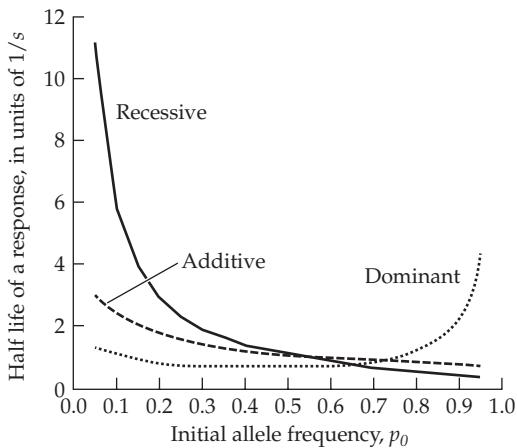

Figure 25.4 The expected times for a diallelic locus to contribute half of its total response, assuming the favored allele, B , is eventually fixed. These curves are obtained by substituting $p_{0.5}$ from Table 25.1 into the appropriate version of Equation 5.3. Note that times for half-life scale as $s^{-1} = (\bar{t} a / \sigma_z)^{-1}$ generations.

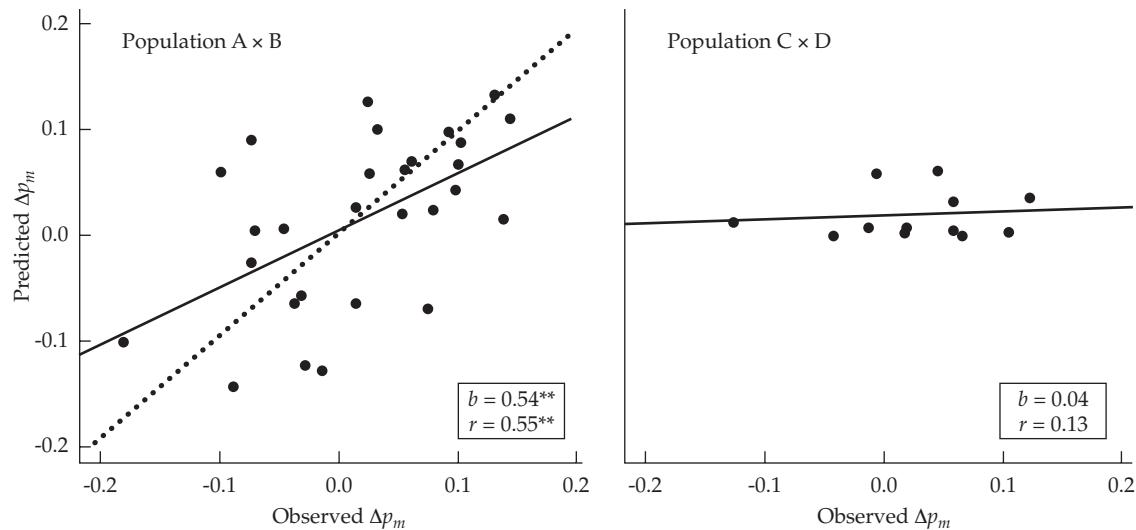

Figure 25.5 Correlation between observed and predicted (from estimated QTL effect size) changes in marker allele frequencies in two inbred-line crosses ($A \times B$ and $C \times D$) of maize subsequently subjected to seven cycles of selection. **Left:** QTL effect size was a fairly good predictor in the $A \times B$ selected lines ($r = 0.55$). The expectation is a line with a slope of $b = 1$ (observed = predicted; the dotted line), while the solid line is the best-fitting regression, with a slope of $b = 0.54$. While significantly different from 0 (showing a positive association between observed and predicted values), the predicted allele-frequency change is *less* than the observed allele-frequency change. **Right:** No significant association between the observed and predicted allele-frequency change was seen in the $C \times D$ selected lines ($r = 0.13$, ns). Further details are provided in Example 25.2. (After Falke et al. 2007.)

Example 25.3. An ingenious experiment examining the fit between estimated QTL effects and their projected allele-frequency changes under selection was performed by Falke et al. (2007). By making crosses between inbred lines, the frequency of all segregating alleles in the F_1 is $1/2$. Assuming only additive effects, for $p = 1/2$, Equation 25.3 reduces to $\Delta p = a \bar{t} / (4\sigma_z)$. Further, the expected frequency change at a marker allele linked to n QTLs is

$$\Delta p_m = \frac{\bar{t}}{4\sigma_z} \sum_{i=1}^n a_i(1 - 2c_i) \quad (25.5)$$

where c_i is the recombination frequency between the i th-marker and the QTL (this expression is only approximate, as it ignores LD among the linked QTLs and quickly breaks down if more than a couple of QTL are linked to the marker).

Falke et al. examined two sets of crosses involving European flint maize. The A × B cross used roughly 270 F_{2:3} lines (selfed F₂ lines) for QTL mapping and was subjected to four cycles of selection, while the C × D cross used roughly 130 F_{3:4} (selfed F₃ lines) for QTL mapping and was subjected to seven cycles of selection. As Figure 25.5 shows, while the QTL effect was a modest predictor of change in marker allele frequency in the A × B cross ($r = 0.55$), the slope of the regression of predicted on observed change was roughly 0.5, implying that the observed marker allele frequency change exceeded the predicted value by roughly two-fold. The association was nonsignificant in the C × D cross ($r = 0.13$).

While the lack of fit should not be surprising given that Equation 25.5 is an approximation, the direction was unexpected. One would expect Equation 25.5 to *overpredict* (predict a greater change than was seen), rather than underpredict, the allele-frequency change. Overprediction is expected from either the Beavis effects (overestimation of the effect sizes of detected QTLs when power is low; LW Chapter 15; also see Göring et al. 2001; Xu 2003; Goddard et al. 2009) or from the generation of negative linkage disequilibrium among selected loci (Chapter 16), which reduces the selection response below the value predicted by Equation 25.5.

Example 25.4. As an example of the consequences for the limit, R , and half-life, $t_{0.5}$, as the number of loci increases, consider the exchangeable model with n completely identical additive loci (in the absence of mutational input). Suppose populations with different numbers of loci underlying the character all start with the same initial variances ($\sigma_A^2(0) = 100$ and $\sigma_z^2(0) = 200$) and with an initial frequency of $p_0 = 0.5$. To hold initial additive-genetic variance constant as n increases, the allelic effect, a , must decrease as the number of loci increases. If we ignore gametic-phase disequilibrium, then $\sigma_A^2(0) = 2na^2p_0(1 - p_0) = na^2/2 = 100$, implying $a = 10\sqrt{2/n}$. From Table 25.1, the selection limit becomes $2na(1 - 1/2) = na = 10\sqrt{2n}$. With $p_0 = 1/2$, Table 25.1 gives $p_{0.5} = [1 + (1/2)]/2 = 3/4$. Substituting these values into Equation 5.3d yields the expected time, $t_{0.5}$, for this amount of allele-frequency change (from 0.5 to 0.75, or $t_{0.75,0.5}$ in the notation of Equation 5.3d) as

$$t_{0.5} = t_{0.75,0.5} \simeq \frac{1}{s} \ln \left(\frac{(3/4)(1 - [1/2])}{[1/2](1 - [3/4])} \right) = \left(\frac{\sigma_z}{a\bar{t}} \right) \ln(3) = \frac{\sqrt{n}}{\bar{t}} \ln(3)$$

The resulting values of these various quantities for 5 to 500 loci become

n	a	R	$R/\sigma_z(0)$	$t_{0.5} \cdot \bar{t}$
5	6.32	31.6	2.2	2.5
10	4.47	44.7	3.2	3.5
25	2.82	70.7	5.0	5.5
50	2.00	100.0	7.1	7.8
100	1.41	141.4	10.0	11.0
250	0.89	223.6	15.8	17.4
500	0.63	316.2	22.4	24.6

At the selection limit, the mean phenotype is usually more extreme than any phenotype observed in the initial base population ($R > 3\sigma_z$). For example, when $n = 25$, the total response is 5 phenotypic standard deviations. For $U \sim N(0, 1)$, $\Pr(U > 5) = 2.87 \cdot 10^{-7}$. Hence, on average, $2.87 \cdot 10^{-7} \cdot 10^6 = 0.287$ such extreme individuals are expected in a base population sample of size 10^6 . From the zero term of the Poisson, the probability that no such individuals are seen in such a sample is $e^{-0.287} = 0.75$. Hence, the limiting mean exceeds any phenotype likely to be found in the initial population. This is not surprising, as

the probability of observing the most extreme genotype (BB at all loci) in the base population is $(1/4)^{25} \simeq 10^{-15}$

MAJOR GENES VERSUS POLYGENIC RESPONSE: THEORY

As highlighted by Example 24.4 and Figure 25.1, the presence of a major gene or genes can change the dynamics of response. A hotly debated issue in quantitative genetics and evolutionary biology is whether selection response is largely due to major genes or polygenes. At present, the data are still murky and likely biased. Before reviewing the evidence, we first consider Lande's theoretical work on conditions for major gene versus polygenic response (Lande 1983). Apparently unaware of Lande's work, plant and animal breeders have also conducted small-scale simulations on this issue (Sehested and Mao 1992; Cox 1995). A related topic, selection when a known major gene is included in an index of selection (e.g., Pong-Wong and Woolliams 1998), is a special case of marker-assisted selection and is covered in Volume 3.

Lande's Model: Response With a Major Gene in an Infinitesimal Background

Lande (1983) assumed a single major gene and an infinitesimal background of polygenes, and his concern was how often a selection response (such as an adaptation by natural selection) is primarily due to a single (or a very few) major genes versus being polygenic. Because genes with major effects on a trait often have deleterious effects on overall fitness (Wright 1977; Lande 1983; Kemper et al. 2012), Lande allowed for such pleiotropic fitness effects acting on the major locus in addition to its influence on the trait under phenotypic selection. The basic parameters of his model are given in Table 25.2. For each of the three major-locus genotypes, the distribution of phenotypic values is assumed to be normal with a mean of $\mu + \alpha_i$ and a variance of σ^2 . Part of this variance, $h^2\sigma^2$, is from the additive-genetic variance of background polygenes, where h^2 is the polygenic heritability. As the expression for the trait mean in Table 25.2 suggests, the dynamics of the mean jointly depend on the change in frequency of the major allele (Δp) and the change in the mean ($\Delta\mu$) of the background polygenes (also see Equation 25.8e). While both p and μ change over time, to avoid excessive notation we suppress the subscript for generation on each.

Consider the change in the major allele-frequency, p , first. Using the mean and marginal fitnesses from Table 25.2, Wright's formula (Equation 5.5b) yields the expected change as

$$\begin{aligned}\Delta p &= \frac{p(1-p)}{2\bar{W}} \frac{\partial \bar{W}}{\partial p} \\ &= \frac{p(1-p)}{\bar{W}} [(p-1)\bar{W}_0 + (1-2p)(1-s_1)\bar{W}_1 + p(1-s_2)\bar{W}_2]\end{aligned}\quad (25.6)$$

with the second step following upon differentiation of the mean fitness. Note that the \bar{W}_i are not constants, but rather change with the polygenic mean, μ , whose expected change follows from the Lande equation (13.27a)

$$\Delta\mu = h^2\sigma^2 \frac{\partial \ln(\bar{W})}{\partial \mu} = \frac{h^2\sigma^2}{\bar{W}} \frac{\partial \bar{W}}{\partial \mu}\quad (25.7a)$$

Taking the derivative of \bar{W} with respect to μ returns

$$\Delta\mu = \frac{h^2\sigma^2}{\bar{W}} \left[(1-p)^2 \frac{\partial \bar{W}_0}{\partial \mu} + 2p(1-p)(1-s_1) \frac{\partial \bar{W}_1}{\partial \mu} + p^2(1-s_2) \frac{\partial \bar{W}_2}{\partial \mu} \right]\quad (25.7b)$$

To evaluate the derivatives of the marginal fitnesses of the major locus, first note that the normal density function is given by

$$\varphi(z, \mu, \sigma^2) = \frac{1}{\sqrt{2\pi\sigma^2}} \cdot \exp \left[-\frac{(z-\mu)^2}{2\sigma^2} \right]$$

Table 25.2 Lande's (1983) model for simultaneous selection on a major locus and background polygenes. The distribution of phenotypic values for each major-locus genotype is assumed to be normal, with variance σ^2 . The distribution of background polygenic values around each major genotype is normal with variance $h^2\sigma^2$. Here $\varphi(z, \mu, \sigma^2)$ denotes the density function for a normal random variable with mean μ and variance σ^2 , and $w(z)$ is the expected fitness associated with phenotype z .

	Major-locus genotype		
	bb	Bb	BB
Frequency	$(1-p)^2$	$2p(1-p)$	p^2
Mean phenotype	μ	$\mu + \alpha_1$	$\mu + \alpha_2$
Natural selection	1	$1 - s_1$	$1 - s_2$
Mean fitness	\overline{W}_0	$(1 - s_1)\overline{W}_1$	$(1 - s_2)\overline{W}_2$

$$\overline{W}_i = \int w(z) \varphi(z, \mu + \alpha_i, \sigma^2) dz \quad \text{for } i = 0, 1, 2$$

Mean fitness:

$$\begin{aligned} \overline{W} &= (1-p)^2 W_{bb} + 2p(1-p)W_{Bb} + p^2 W_{BB} \\ &= (1-p)^2 \overline{W}_0 + 2p(1-p)(1-s_1)\overline{W}_1 + p^2(1-s_2)\overline{W}_2 \end{aligned}$$

Mean phenotype:

$$\bar{z} = \mu (1 + 2\alpha_1 p(1-p) + \alpha_2 p^2)$$

To obtain the required derivatives of $\varphi(z, \mu, \sigma^2)$, recall from the chain rule of differentiation that

$$\frac{\partial \exp[f(x)]}{\partial x} = \frac{\partial [f(x)]}{\partial x} \cdot \exp[f(x)]$$

yielding

$$\frac{\partial \varphi(z, \mu + \alpha_i, \sigma^2)}{\partial \mu} = \frac{z - (\mu + \alpha_i)}{\sigma^2} \varphi(z, \mu + \alpha_i, \sigma^2) \quad (25.8a)$$

Hence,

$$\begin{aligned} \frac{\partial \overline{W}_i}{\partial \mu} &= \int w(z) \frac{\partial \varphi(z, \mu + \alpha_i, \sigma^2)}{\partial \mu} dz \\ &= \frac{1}{\sigma^2} \left[\int z w(z) \varphi(z, \mu + \alpha_i, \sigma^2) dz - (\mu + \alpha_i) \int w(z) \varphi(z, \mu + \alpha_i, \sigma^2) dz \right] \\ &= \frac{1}{\sigma^2} \left[\int z w(z) p_i(z) dz - (\mu + \alpha_i) \overline{W}_i \right] = \frac{\overline{W}_i}{\sigma^2} S_i \end{aligned} \quad (25.8b)$$

where

$$S_i = \int z w(z) \frac{p_i(z)}{\overline{W}_i} dz - (\mu + \alpha_i) \quad (25.8c)$$

is the selection differential acting on the major-locus genotype, i . This equivalence follows from the fact that the integral represents the mean value for major-locus genotype i following selection (μ_{s_i}), the second term is the mean for i before selection (μ_i), and $S_i = \mu_{s_i} - \mu_i$. From Equations 25.7b and 25.8b, the expected change in the polygenic mean becomes

$$\Delta\mu = h^2 \left[(1-p)^2 \frac{\overline{W}_0}{\overline{W}} S_0 + 2p(1-p)(1-s_1) \frac{\overline{W}_1}{\overline{W}} S_1 + p^2(1-s_2) \frac{\overline{W}_2}{\overline{W}} S_2 \right] \quad (25.8d)$$

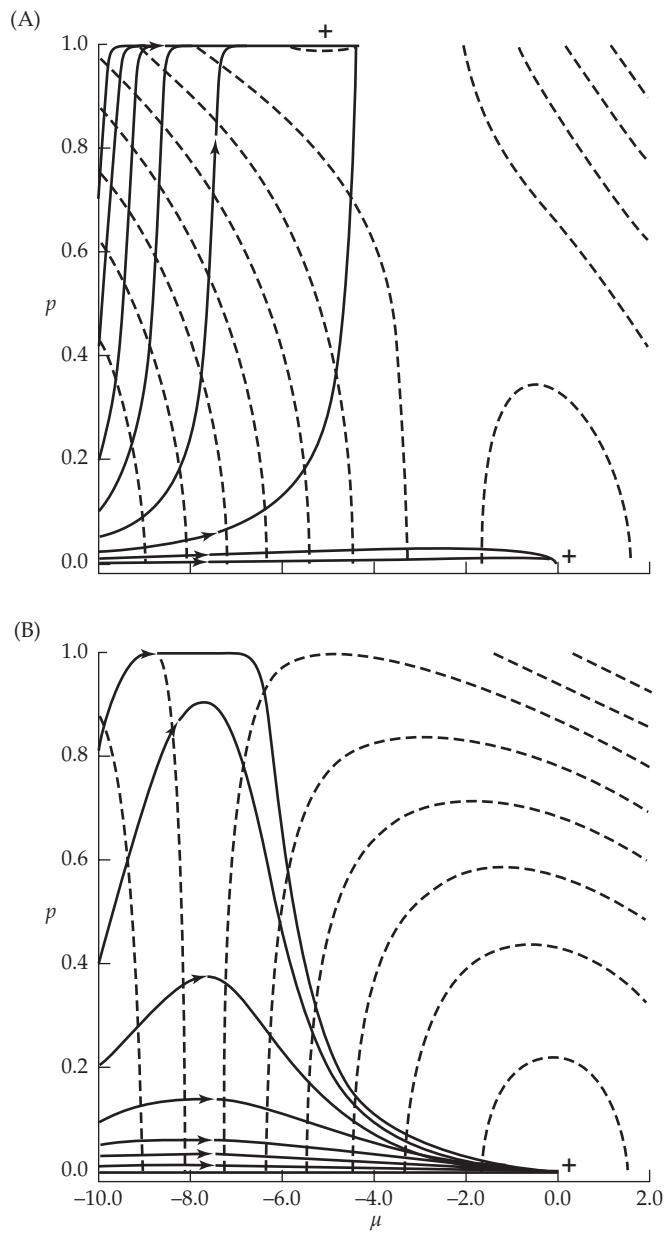

Figure 25.6 Lande's analysis of selection toward a new optimum when a major gene and polygenes are present. In both examples, the population initially starts 10 units below the new optimum value (zero), and the favored major-gene homozygote adds a value of 5. Dashed lines represent contours of equal fitness in the (p, μ) space, while the arrowed solid lines represent the allele-frequency trajectories of the major gene. **A:** The favored homozygote has a pleiotropic disadvantage of $s = 0.02$. Here there are two peaks on the (p, μ) fitness surface, on the lower right ($p = 0, \mu = 0$) and in the upper middle ($p = 1, \mu = -5$). If the initial frequency of the major allele is above 0.025, the major allele is fixed, while it is lost if the initial frequency is below this critical frequency. **B:** The favored homozygote has a pleiotropic disadvantage of $s = 0.40$. There is a single peak on the fitness surface ($p = 0, \mu = 0$), and although p may initially increase in frequency, it will always be lost, with the ultimate response being entirely polygenic. A significant fraction of the initial response can be through the major gene, but eventually this is replaced by the polygenic component. As polygenic response drives the population mean toward the optimum, the pleiotropic disadvantage of the major allele eventually exceeds its fitness advantage from selection on the trait, resulting in its eventual loss. (After Lande 1983.)

From Table 25.2, the new mean becomes

$$\bar{z} = (\mu + \Delta\mu) \left[1 + 2\alpha_1(p + \Delta p)(1 - p - \Delta p) + \alpha_2(p + \Delta p)^2 \right] \quad (25.8e)$$

Note that while changes in p influence changes in μ , and vice-versa, Lande assumed that the infinitesimal variance, σ^2 , and heritability, h^2 , remain unchanged over time (ignoring the Bulmer effect). By using the machinery from Chapter 16, we could modify these expressions to allow for the changes caused by selection generating gametic-phase disequilibrium.

Lande provides extensive analysis of his model in several settings, two of which we will consider. The first is the evolution toward a new optimum. Suppose the optimal phenotype suddenly shifts (for example, due to a major environmental change). In such cases, if the frequency of the major allele is sufficiently rare relative to the strength of selection on the trait (and also relative to the strength of pleiotropic selection against the major allele), it will be lost and the response will be entirely polygenic. As Figure 25.6 illustrates, the dynamics can be complex in this case. The key to understanding this frequency-dependent behavior is to recall the dynamics of an underdominant locus (Figure 5.1). Here, there is an unstable internal equilibrium, with the allele becoming fixed provided it starts above this value, and otherwise being lost.

Two additional remarks concerning Lande's examples displayed in Figure 25.6 are in order. First, because B is strictly deleterious before the shift in optimum, its initial frequency is expected to be low. For example, for an additive allele with mutation rate ν , $p \simeq 2\nu/s$ (Equation 7.6b). While most of the trajectories in Figure 25.6A show fixations, almost all populations would be expected to start with the frequency of B below the 0.025 initial allele-frequency threshold for fixation (the initial frequency is below this value when $2\nu/0.02 < 0.025$, or when $\nu < 0.00025$). Second, this is a deterministic analysis, which has implications for Figure 25.6B. Notice that the trajectory for an allele starting at frequency 0.8 approaches one before eventually declining to zero. As polygenic response moves the trait mean toward the optimum, the deleterious pleiotropic effects of this allele become greater than its favorable effect on the trait, resulting in the major allele becoming selected against, and eventually removed. In a finite population, selection may initially drive the major-allele frequency sufficiently close to one for drift to fix B before polygenic response negates its favorable effect on the trait. In such cases, a major gene response will be seen.

Lande's analysis of directional selection used an exponential model of trait fitness, $w(z) \propto \exp(\beta z)$, which reduces to a simple linear fitness function, $w(z) \simeq 1 + \beta z$, for weak selection ($|\beta z| \ll 1$). Lande showed that under exponential fitnesses, his model is nicely behaved, with the polygenic mean evolving at a constant rate

$$\Delta\mu = \sigma_A^2 \beta \quad (25.9a)$$

while the relationships between the major-locus genotypic fitnesses remain constant, with

$$\frac{\overline{W}_i}{\overline{W}_0} = e^{\beta\alpha_i} \quad \text{for } i = 1, 2 \quad (25.9b)$$

The resulting relative fitnesses of the three major locus genotypes become

$$W_{bb} = 1 \quad W_{Bb} = (1 - s_1) e^{\beta\alpha_1} \quad W_{BB} = (1 - s_2) e^{\beta\alpha_2} \quad (25.9c)$$

Because these are constants, the machinery of Chapter 5 quickly informs us as to the fate of the major gene. Selection maintains both alleles as a stable polymorphism when $W_{Bb} > W_{BB}, W_{bb}$. There is an unstable internal equilibrium when $W_{Bb} < W_{BB}, W_{bb}$, with B being lost if sufficiently rare (frequency below the equilibrium value), and otherwise being fixed. Finally, if $W_{bb} < W_{Bb} \leq W_{BB}$ or $W_{bb} \leq W_{Bb} < W_{BB}$, then the major allele is fixed (under our assumption, in this chapter, of no drift).

The simple fate of the major allele is not a complete analysis of the full dynamics of this system, as even if the allele is fixed, its contribution could be far outstripped by the polygenic response. Lande examined this possibility by letting α represent the difference between the two major-locus homozygotes and assuming that B is initially rare. He then compared the expected amount of time for a B allele (starting at frequency $p_0 \ll 0.5$) to increase to the point where the response from the locus is half its potential response, $\alpha/2$. This is accomplished by using Equation 25.1e to find the critical frequency, and then applying the appropriate version of Equation 5.3 to obtain the required time for this amount of allele-frequency change. If the polygenic response over this amount of time exceeds $\alpha/2$, the response is primarily polygenic, even if B is fixed. For weak exponential selection (Equation 25.9c), the resulting initial frequencies above which the major gene exceeds the polygenic response are approximately

$$p_0 > \begin{cases} 2/b & \text{recessive} \\ e^{-b/4} & \text{additive} \\ e^{-b/2} & \text{dominant} \end{cases} \quad \text{where } b = \left(1 - \frac{s}{\beta \alpha}\right) \frac{\alpha^2}{\sigma_A^2} \quad (25.9d)$$

where, before, β is the strength of directional selection on the trait.

Much of this discussion is framed by the assumption that genes that have a large effect on a trait generally have deleterious effects in natural populations. However, as Orr and Coyne (1992) pointed out, if genes with a small effect on the character also have similarly small (and negative) effects on fitness, their advantage over a major locus largely (or completely) disappears. However, if the potential pool of alleles of small effects is large, it will become enriched by natural selection for those alleles with nearly neutral pleiotropic fitness effects.

Gomulkiewicz et al. (2010) reached a somewhat different conclusion from Lande's suggestion that major genes generally require very strong selection on a trait in order to account for the majority of response. They focused on the time required for a population that has invaded a harsh new environment (equivalent to a major environmental shift) to evolve persistence. This is a different scenario from that envisioned by Lande, who focused on the genetic composition once an adaptation had occurred (the equilibrium value following a shift). One of the major points from Gomulkiewicz can be seen in Figure 25.6B. Here, a major allele can substantially increase in frequency, but at some point it is overtaken by polygenic response, and ultimately lost. Gomulkiewicz noted that such a situation may be critical for a population to evolve persistence in a harsh new environment. Even though the major gene is eventually lost, the population runs a risk of extinction if this allele is not initially present. Thus, by shifting the focus toward the dynamics during adaptation, rather than on the equilibrium values, a potentially different view of the relative importance of major and minor genes arises. Important roles of major genes may therefore be overlooked if one only focuses on the alleles that are ultimately fixed.

Finally, while the importance of deleterious pleiotropic fitness effects has been framed as a constraining force for major alleles, Otto (2004) showed that the presence of pleiotropy may impact small-effect alleles as well, which returns us to the point made earlier by Orr and Coyne (1992).

Example 25.5. Lande's method of analysis can be used with other fitness functions. For example, suppose the trait of interest is subjected to truncation selection, with only individuals above the threshold value, T , being allowed to reproduce. In this case

$$W(z) = \begin{cases} 1 & \text{for } z \geq T \\ 0 & \text{for } z < T \end{cases}$$

The marginal fitnesses become

$$\overline{W}_i = \int_T^\infty \varphi(z, \mu + \alpha_i, \sigma^2) dz = \Pr \left[U > \left(T^* - \frac{\alpha_i}{\sigma} \right) \right]$$

where $T^* = (T - \mu)/\sigma$ is the current (standardized) truncation value given μ , and U is a unit normal random variable. We usually analyze truncation selection in terms of the fraction, q , of individuals that are allowed to reproduce, rather than the threshold value, T , especially because T changes as the population mean increases. In our case, these are connected by

$$\begin{aligned}\bar{W} = q &= (1-p)^2 \Pr(U > T^*) + 2p(1-p)(1-s_1) \Pr\left[U > \left(T^* - \frac{\alpha_1}{\sigma}\right)\right] \\ &\quad + p^2(1-s_2) \Pr\left[U > \left(T^* - \frac{\alpha_2}{\sigma}\right)\right]\end{aligned}$$

This expression for mean fitness is simply the probability of being above the threshold given a particular major-locus genotype, weighted by the frequencies of these genotypes. For a particular q value and the current μ and p values, one can numerically solve the these equation for T^* . Likewise, from LW Equation 2.14, the mean of genotype i following selection becomes

$$\mu_{s_i} = \mu_i + \sigma \frac{\varphi(T, \mu + \alpha_i, \sigma^2)}{\Pr[U > (T^* - \alpha_i/\sigma)]}$$

implying a directional selection differential of

$$S_i = \mu_{s_i} - \mu_i = \sigma \frac{\varphi(T, \mu + \alpha_i, \sigma^2)}{\Pr[U > (T^* - \alpha_i/\sigma)]}$$

To proceed with the analysis of the model dynamics, for a given (p, μ) vector, we first find T^* to obtain the specified strength of truncation selection, q , and then compute the \bar{W}_i for Equation 25.6 and S_i for Equation 25.8d to update the p and μ values. Example 25.10 uses these results to obtain the equilibrium frequency of a major gene that is lethal as a homozygote, but improves the trait as a heterozygote.

MAJOR GENES VERSUS POLYGENIC RESPONSE: DATA

A long-running debate in evolutionary biology, dating back to the rediscovery of Mendel, is whether the majority of adaptations are due to a few alleles with large effects or to the accumulation of small changes over a large number of loci. Before the modern evolutionary synthesis, geneticists (the Mendelians) felt that macromutations drove evolution, while supporters of Darwin (the Biometricians) felt that evolution was driven by selection acting on numerous factors of small effect. These differing views (and more importantly, their vocal supporters and opponents) delayed the merging of modern genetics with Darwin's theory of evolution. Fisher's (1918) paper, founding quantitative genetics, was a watershed event in helping to fuse these two schools (see Provine 1971 for a historical overview of the Mendelian-Biometrician debate). This same debate, in slightly different forms, resurfaced in the 1940s with Goldschmidt's (1940) idea of **hopeful monsters** (single mutations with a large effect driving major evolutionary changes) and also in the late 1970s to early 1980s with the debate surrounding **punctuated equilibrium** (the causes of long periods of evolutionary stasis, punctuated by rapid change, in the fossil record; see Eldredge and Gould 1972; Charlesworth et al. 1982).

Major Genes Appear to Be Important in Response to Anthropogenically Induced Selection

One of Lande's (1983) conclusions was that sufficiently strong selection is required for a major-gene response when polygenic variation is available. One situation where strong selection is often assumed to occur involves the response of wild populations to **anthropogenically induced selection**, namely, a major (and sudden) environmental change induced by human activity. This could be in the form of toxins (pesticides, herbicides, pollutants) or other side effects of human activity, such as industrial melanism (Lees 1981).

In the pesticide and herbicide literature, a commonly expressed theme echoing Lande's theoretical predictions is that relatively weak selection (as might be expected to occur in laboratory settings, where at least a small percentage of the population is allowed to reproduce) leads to a polygenic response, whereas very strong selection (e.g., in a newly sprayed field where nearly everything is killed) leads to major-gene resistance (Greaves et al 1977; Clarke and McKenzie 1987; Macnair 1991; McKenzie et al. 1992; McKenzie 2000). However, a survey by Groeters and Tabashnik (2000) found that the strength of selection on insecticide resistance varies greatly in the field and overlaps the intensities used in laboratory experiments. Further, major-gene responses are not uncommon in the laboratory.

A relevant example involves resistance to Bt toxin (*Bacillus thuringiensis* Cry1Ac toxin), an organic insecticide widely used in both sprayed fields and as the foundation for some transgenic crops (e.g., Bt corn). Bt resistance is often due to recessive mutations in the same gene independently arising over different pest species. For example, independent mutations in a 12-cadherin-domain protein gene confer resistance in laboratory-selected strains from three very distantly related moth species, as well as in field populations of a fourth species (Zhang et al. 2012). Likewise, Baxter et al. (2011) found that independent recessive mutations in a different gene (the membrane transporter ABCC2) confers resistance in two very distant moth species.

In contrast to these finding of mainly recessive Bt-resistance alleles, Zhang et al. detected nonrecessive cadherin alleles in a Chinese population of cotton bollworms (*Helicoverpa armigera*). This observation has important biocontrol implications, because the strategy used to retard the evolution of Bt resistance is to plant refuge rows of non-Bt crops (Gould 1988; Tabashnik et al. 2008). Under the assumption that resistance is recessive, crosses of resistant homozygotes and susceptibles are expected to result in susceptible heterozygous offspring, which are killed when their larvae feed on Bt crops. This strategy fails if the response is either polygenic or due to nonrecessive major genes, as resistant alleles can then spread.

If the strength of selection is not the key factor explaining the difference between field (usually major genes) and lab (mainly polygenic) responses, then what is? One likely explanation is simply population size. Major alleles, especially those involved in detoxification, likely have deleterious side effects in toxin-free environments, and are thus expected to occur at very low frequencies in a population. As rare alleles are mainly present as heterozygotes (with frequency $\sim 2p$), the probability that a random sample of n individuals chosen to create a laboratory stock for selection does not contain the allele is $(1 - 2p)^n$. For $n = 1000$ and $p = 0.001$, this is 0.14. Using a more realistic founder stock of 100, this increases to 0.82. Even if such a mutation is present, it will likely be in just a few copies and can easily be lost early in an experiment by drift, even with strong selection. These arguments illustrate that the interaction of drift and mutation is often critical in determining the nature of the selection response, especially in smaller laboratory populations (Chapter 26).

Finally, the finding that major genes appear to be commonly involved in Bt resistance in laboratory populations might be explained by the fact that many of these mutations appear to be knockouts. One might expect a rather large mutational target size for loss-of-function mutations, meaning they might appear at a modest rate in laboratory populations.

What is the Genetic Architecture of Response in Long-term Selection Experiments?

With the advent of dense molecular markers and subsequent whole-genome sequencing, we have a new set of tools to examine the genetic makeup of long-term response (Stapley et al. 2010; Burke 2012). One approach is to use QTL mapping with large sample sizes to both detect alleles of small effect and avoid the overestimation of effects when power is low (the Beavis effect; LW Chapter 15). While a large number of studies crossing divergent lines have been performed (LW Chapter 15), we restrict attention to those crosses between lines generated by persistent selection in opposite directions. For these crosses, the general picture emerging is that much, if not most, of the selection response is often due to QTLs of small effect.

Perhaps the most careful studies involve the Illinois long-term selection experiment,

which (as we will detail shortly) has been going on for over a century (Figure 25.9). The F_1 progeny crosses between 70th-generation high vs. low oil lines and high vs. low oil protein lines were randomly mated for 7–10 generations before QTL mapping (the advanced inter-cross, or AIC, design; LW Chapter 15). Such a design allows recombination to randomize even closely linked QTLs (the effect is a 7- to 10-fold map expansion relative to the F_2). Over 50 QTLs were detected, each with small, and additive, effects (Laurie et al. 2004; Clark et al 2006; Dudley et al. 2007). A similar finding is seen in chicken lines divergently selected for 50 generations (resulting in a nine-fold difference in body weight), which revealed mainly small-effect QTLs underlying the response (Jacobsson et al. 2005; Wahlberg et al. 2008).

Results from mouse lines have been more mixed. The majority of the roughly 40 QTLs detected in a cross from a 27-generation line selected for weight gain with a random control had effects of 1–3%, although a few had effects of around 5% (Allan et al. 2005). Moody et al. (1999) found QTLs with effects of ~3–4% in an analysis of lines divergently selected for energy balance for 16 generations. In contrast, Hovat et al. (2000) found that just four QTLs could account for most of the response in obesity in lines subjected to 53 generations of divergent selection. One caveat about these mouse results is that typically F_2 , rather than AIC, designs were used. This can result in significant overestimates of QTL effects due to linkage of multiple QTLs. Typically, such large QTL peaks fractionate upon finer mapping (reviewed by Flint and Mackay 2009; Mackay et al. 2009).

A second class of approaches is to search for signatures of selection in the genomes of individuals sampled near the end of a long-term selection experiment, either from the fixation of alternate alleles in divergent lines (essentially a localized F_{ST} measure; e.g., Johansson et al. 2010) or by more classic hard-sweep tests (e.g., Chan et al. 2012). In addition to estimating the number of genomic regions under apparent selection, the machinery of Chapters 8 and 9 could also be used to estimate selection coefficients (and hence effect sizes). However, as discussed in Chapter 8, these approaches are strongly biased toward detecting alleles of large effect, and hence involve hard sweeps as opposed to either soft sweeps (existing variation) or polygenic sweeps (small changes at a number of loci). As mentioned previously, this bias toward detecting major genes is somewhat countered by a bias *against* them by the founding of most experimental populations. The expectation is that alleles of large effect are at low frequencies in natural populations, and thus are unlikely to be routinely captured in the small to modest population samples used to found most laboratory populations.

What is clear from the existing data is that massive responses in long-term experiments can be entirely due to genes of small effect (Teotónio et al. 2009; Burke et al. 2010; Johansson et al. 2010; Parts et al. 2011; Turner et al. 2011; Zhou et al. 2011; Chan et al. 2012; Beissinger et al. 2014). What is unclear is the extent to which these results from long-term laboratory experiments with strong and constant artificial selection on a single trait translate to natural or domesticated populations undergoing mild (and likely constantly shifting) selection.

Finally, the results from examining adaptations (often inferred from species differences) in natural populations are also mixed. Hilu (1983) and Gottlieb (1984, 1985) suggested that major genes have played very important roles in species differences between plants (many of which are, presumably, adaptive), but Coyne and Lande (1985) disputed this view. A literature review by Orr and Coyne (1992) found that support for the polygenic model (i.e., that most adaptations are due to many genes of small effect) is also inconclusive. There may also be a publication bias as many of these examples are color traits, which are often controlled by just a few genes and lead to differences that are visually obvious, and thus more easily detected (and therefore studied). Clearly, this is an area of active ongoing research, and we will return to a different aspect of the question, **adaptive walks** (the successive fixation of multiple mutations during adaptation), in Chapter 27.

AN OVERVIEW OF LONG-TERM SELECTION EXPERIMENTS

The above theory suggests that populations under selection should show a reasonably

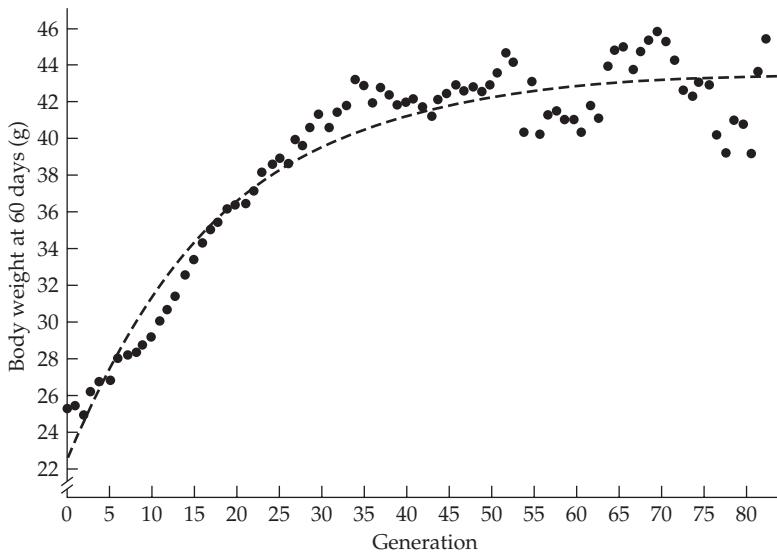

Figure 25.7 Bünger and Herrendörfer's (1994) fit of an exponential regression to the long-term selection experiment of Goodale on mouse weight at 60 days (Goodale 1938; Wilson et al. 1971). The estimated selection limit was 43.5 grams (for a total response of 21.3 grams), with a half-life of 12 generations. The plotted curve regresses the cumulative response as a function of generation number. When the regression is instead plotted as a function of the cumulative selection differential (as opposed to generations), the estimated total response was 17.5 grams.

smooth response (albeit often with considerable sampling noise; Chapter 18), which is initially linear, but eventually (in the absence of new mutations) asymptotes to a selection limit as base-population genetic variance becomes exhausted. Unfortunately, this simple picture is very often wrong. Selection response can be rather erratic, showing periods of acceleration even after many generations of selection, and limits often occur in spite of significant additive variance in the character under artificial selection. Before reviewing the experimental data, a few remarks on estimating the actual limit and duration of response are in order.

Estimating Selection Limits and Half-lives

Because the selection limit is approached asymptotically, the typical measure of duration is the **half-life** of response—the time for half the response to occur. As was the case for short-term response (Chapters 18 and 19), this parameter is generally estimated by curve-fitting, and in doing so accommodating the inherent sampling noise in selection response data (Chapter 18). Given that the response curve is nonlinear, a number of authors have used quadratic regressions, taking the maximum of the regression as the limit (James 1965; Eisen 1972; Rutledge et al. 1973). Grassini et al. (2013) used a piecewise approach, breaking the response into either two distinct linear regressions or a quadratic regression segment followed by a constant value (the latter is used to represent the plateau).

A more natural approach is to use **exponential regressions**, where the cumulative response at generation t is given by $R_c(t) = a + ce^{-bt}$ (more formally this is a **negative-exponential regression**). A number of variant expressions based on this approach appear in the literature (James 1965; Frahm and Kojima 1966; Harris 1982; Herrendörfer and Bünger 1988; Bünger and Herrendörfer 1994; Árnason 2001). The motivation for using exponential regressions is two-fold. First, these curves naturally generate an asymptotically maximum value (a), while quadratic regressions do not. Second, if the fraction of additive variance

that is retained is just a constant amount, $(1 - \alpha)$, of the previous generation (as would occur under drift with the infinitesimal model; e.g., Equation 26.15a), this leads to a cumulative response of the form

$$R_c(t) = \beta(1 - [1 - \alpha]^t) \simeq \beta(1 - e^{-t\alpha}) \quad (25.10a)$$

This motivated Herrendörfer and Bünger (1988) and Bünger and Herrendörfer (1994) to suggest using an exponential regression of the form

$$R_c(t) = a[1 - \exp(-bt/a)] \quad (25.10b)$$

where a is the selection limit and b is the maximum rate of response (i.e., the response in the first generation). Figure 25.7 shows an application of this method, while optimal experimental design issues were examined by Rudolph and Herrendörfer (1995).

An interesting application of such estimated limits was presented by Árnason (2001). A fitted exponential regression for the racing speed of standardbred trotters in Sweden suggested that the limiting trotting time is around 68 sec/km. In the 1950s, the fastest times were just under 80 sec/km, reaching around 73 sec/km in the mid-1990s, which is slightly more than half of the expected total response of a limiting decrease of 12 sec/km (80–68, starting from the 1950 benchmark).

Using the fitted curve given by Equation 25.10b, the resulting half-life of the cumulative response becomes

$$t_{0.5} = -a \cdot \ln(0.5)/b \quad (25.10c)$$

Assuming constant selection, the tangent of the response curve, $R_c(t)$, at a particular generation provides an estimate of the rate of response in that generation (Frahm and Kojima 1966; Herrendörfer and Bünger 1988). Assuming that $R_c(t)$ is well approximated by an exponential regression, this is given by the derivative of Equation 25.10b, evaluated at the generation of interest, yielding

$$\frac{\partial R_c(t)}{\partial t} = b \cdot \exp(-bt/a) \quad (25.10d)$$

As was the case for linear regressions of short-term response, one decision is whether to regress cumulative response on number of generations or on the cumulative selection differential (Chapter 18). Under the breeder's equation, the short-term response is linear with respect to the cumulative selection differential, $R_c(t) = h^2 S_c(t)$ (see Chapter 18). For long-term response, if the expectation is a constant decline in additive variation each generation, then regression on number of generations is more logical, *provided* that the assumptions of a constant selection differential and a constant decline in variance are appropriate.

A second, more subtle issue, which also arose in Chapter 18, is the nature of the residual variance structure. One standard approach for curve-fitting is ordinary least-squares (OLS), which involves finding the parameter values for Equation 25.10b that minimize the sum of squared residuals, $\sum e_i^2 = \mathbf{e}^T \mathbf{e}$, where the i th residual, $e_i = R_c(t_i) - \hat{R}_c(t_i)$, is the difference between the i th observed and predicted values for a given candidate regression model. OLS regression assumes homoscedasticity, with $\sigma^2(e_i) = \sigma_e^2$ for all i , and that residuals are uncorrelated, $\sigma(e_i, e_j) = 0$ for $i \neq j$. As with short-term response, the presence of drift compromises both of these assumptions. As was done in Chapter 18 to accommodate this concern, curves should be fitted using generalized least-squares, where parameters are chosen to minimize the quadratic product $\mathbf{e}^T \mathbf{V}^{-1} \mathbf{e}$, where \mathbf{V} is the variance-covariance matrix for the residuals (Equation 18.15c).

Other candidate response curves have also been proposed, which also attempt to capture the asymptotic approach to a limit expected for an idealized long-term response. Wiser et al. (2013) suggested a **hyperbolic function**, with

$$R_c(t) = \frac{a t}{t + b} \quad (25.11a)$$

Here, the cumulative response approaches a limiting value of a , with a half-life of $t_{0.5} = b$.

Table 25.3 Estimates of the selection limit and half-life based on 22 generations of selection for increased 12-day litter weight in mice. *Selection limit* refers to response in grams as a deviation from the control, and half-life is given in generations. The quadratic and exponential models explain the same amount of variation ($r^2 = 0.81$ for both models) and cannot be discriminated on this basis. (Data for line W_3 from Eisen 1972.)

Estimate	Model	
Selection limit	Quadratic	5.79 ± 0.84
	Exponential	8.19 ± 0.29
Half-life	Quadratic	8.58
	Exponential	12.48

A much more intriguing function for very long-term selection data is a **power curve**, where

$$R_c(t) = b t^a \quad \text{for } a < 1 \quad (25.11b)$$

which has the feature that while the rate of response decelerates over time ($\partial^2 \mu(t)/\partial t^2 < 0$ for $a < 1$), there is no upper limit. The power curve provided a better fit than the hyperbolic for data on the response over 50,000 generations of selection for fitness in *Escherichia coli* (Wiser et al. 2013), suggesting that slowly diminishing returns, rather than an approach to a true selection limit, is a better description of their data. A concern with all of these models is that the selection limit is *extrapolated* from the data. As Table 25.3 shows, different models can yields essentially the same fit of the data but very different estimates of the limit and half-life.

Some final cautionary notes are in order. First, scale effects (LW Chapter 11) can be important. Many continuously distributed characters have zero as a lower limit, and hence on a linear scale they always have a lower limit. This is not true on a log scale. Similarly, if we model a binary trait as resulting from the transformation of an underlying continuous variable (the liability), we should work with response as measured on the liability scale (see Chapter 14 and LW Chapters 11 and 25).

Finally, the entire issue of selection limits due to the exhaustion of additive-genetic variation is complicated by mutation. Most “long-term” experiments are long-term only from the viewpoint of the experimenter, rarely spanning more than 50 generations. As is discussed in Chapters 26 and 28, over longer time scales, mutational input becomes very important and observed limits can be artifacts of the relatively short time scales being used.

General Features of Long-term Selection Experiments

As Figure 25.8 illustrates, long-term selection experiments display a wide range of behaviors. Fortunately, a few generalizations do emerge:

1. *Selection routinely results in mean phenotypes that are far outside the range seen in the base population.* At the selection limit, the mean phenotype is usually many standard deviations away from the initial mean.
2. *Response can be very uneven.* Bursts of accelerated response after many generations of selection can be seen, and the additive-genetic and phenotypic variances can increase during part of the response.
3. *Reproductive fitness usually declines as selection proceeds.*
4. *Most laboratory populations approach a selection limit.* As discussed in Chapter 26, an apparent selection limit may simply be an artifact of the short time scale (and hence insufficient time for significant mutational input) and small population sizes of most experiments. However, this is not always the case (Figure 25.9).

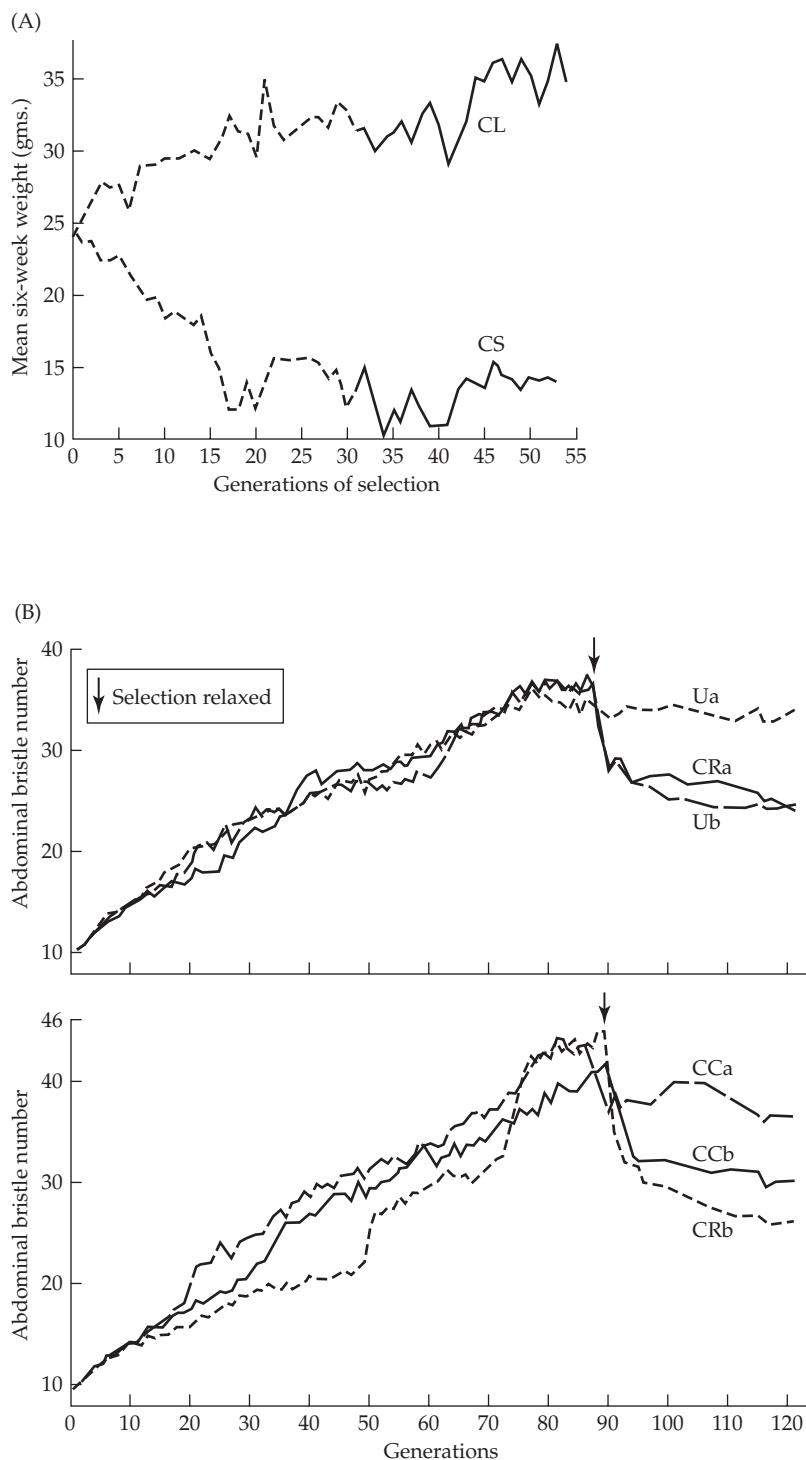

Figure 25.8 A few of the nonstandard behaviors observed in long-term selection experiments. **A:** Delayed accelerated response during selection for increased six-week body weight in mice. An apparent limit of 31 grams had been reached in the up-selected line (CL) by generation 15. A second burst of response occurred around generation 43, with the mean weight increasing to around 35 grams (Roberts 1966). **B:** Selection for increased abdominal bristle number in *Drosophila*. At generation 90, selection was relaxed and most lines showed a considerable (but not complete) erosion of response. The presence of segregating lethals accounts for some of this erosion. Also note the bursts of response for line CRb (the short-dashed curve in the lower panel) around generations 50 and 75 (Yoo 1980a).

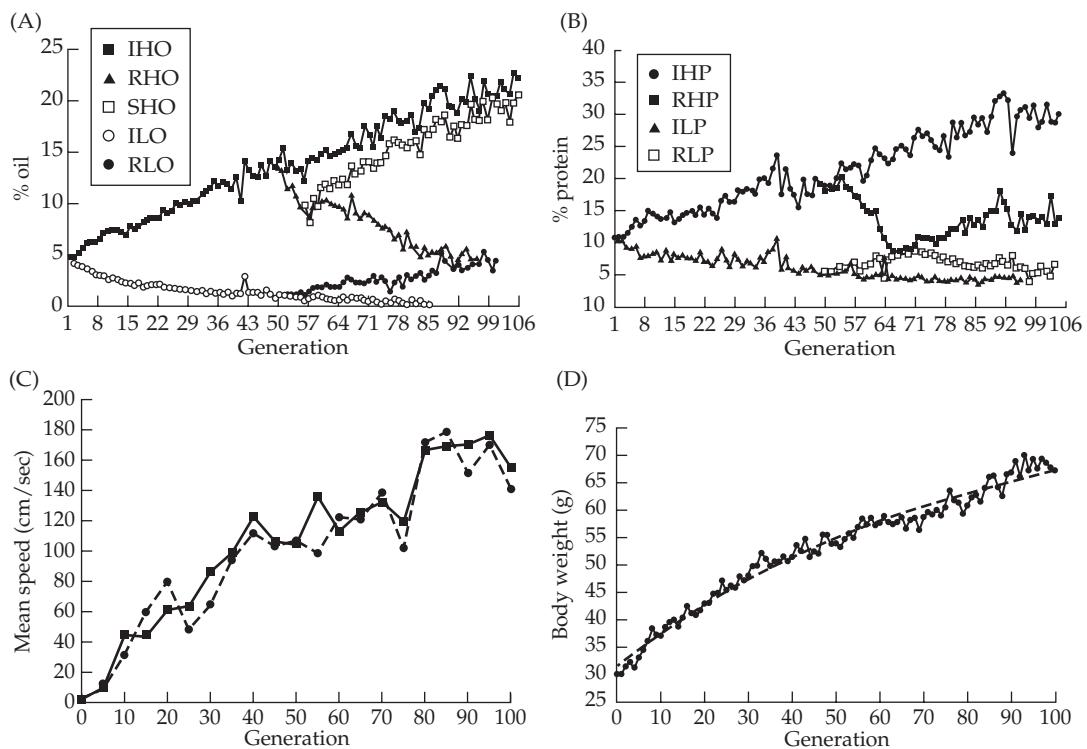

Figure 25.9 Example of long-term selection experiments showing no apparent selection limits. The top two panels are from the Illinois long-term selection experiment on oil and protein content in maize. **A:** Response over 106 generations of selection for increased or decreased oil percentage. Lines IHO and ILO (Illinois high and low oil) are up- and down-selected, while lines RHO and RIL are lines of IHO and ILO subjected to reversed selection around generation 50. Line SHO (switchover high oil) is an up-selected line using RHO. The responses in RHO, RLO, and SHO indicate significant additive variance present in the population when these new lines were formed. (After Dudley 2007.) **B:** Response over 106 generations of selection for changes in the percentage of protein. Lines IHP and ILP were up- and down-selected, while lines RHP and RLP are the result of reverse selection starting around generation 50. Again, the responses of RHP and RLP indicates significant additive variance. (After Dudley 2007.) **C:** One hundred generations of response for increased flight speed in *Drosophila melanogaster*. Two replicate lines showed very similar response. (After Weber 1996.) **D:** Response in the Dummerstorff long-term mouse lines, which were subjected to continuous selection for 42-day weight. Conducted over 160 generations, this is the longest continuous selection experiment in mammals (Renne et al. 2013). (After Bünger et al. 2001.)

5. Considerable additive variance in the trait under artificial selection often exists at an apparent selection limit (Table 25.4).

It is important to recognize that long-term selection experiments are a biased sample of organisms and traits. Controlled selection experiments in multicellular organisms exceeding 20 generations are largely restricted to *Drosophila*, *Tribolium*, mice, and maize. Whether the genetic architectures of these organisms (and the easy-to-score traits used in experiments) are representative of typical characters in natural populations is unclear, although there is no serious reason to suspect that they are not. Another caveat in extrapolating from these model experimental systems to natural and domesticated populations is that the strength of continuous selection on a single character is likely much higher in artificial selection experiments. In addition, under natural selection, and in most breeding programs, selection operates on a suite of characters, so that for a given overall strength of selection, the fraction imparted on a particular trait likely decreases as the number of traits under

selection increases. Further, the amount of natural selection on any particular character likely fluctuates over time. Conversely, laboratory experiments on artificial selection generally focus on a single character and involve strong and consistent selection, usually in highly controlled environments.

The Nature of Selection Limits

What is the nature of selection limits observed in artificial selection experiments? In particular, is there any genetic variation present at an apparent limit, and if so, is any of it additive? Correlations between relatives can be used to characterize the nature of residual variation. One caveat to this approach is that selection can generate strong gametic-phase disequilibrium, complicating standard methods for estimating components of variance (Robertson 1977b). However, changing selection schemes and inbreeding offer two simple approaches for characterizing the nature of any residual genetic variation. If additive variance is present, the line should respond to **reversed selection** (subjecting the line to selection in the opposite direction, e.g., Figures 25.9A and 25.9B). A decay in the mean of a plateaued line after selection is relaxed also indicates the possibility of additive variance in the selected trait (Figure 25.8B), although epistasis or maternal effects can also result in slippage of the mean (see Chapter 15). If nonadditive variance is present, the line can show inbreeding depression, with the mean changing as the line is inbred. The *absence* of inbreeding depression, however, does not imply a lack of nonadditive genetic variation, as directional dominance, and not simply the presence of σ_D^2 , is required for inbreeding depression (LW Chapter 10).

Table 25.4 highlights some of the causes of selection limits observed in long-term artificial selection experiments. This is by no means a comprehensive listing. The general conclusion is that significant additive-genetic variance in the selected character is often present at an apparent limit. This is rather surprising given that most experiments have such small effective population sizes that drift is expected to remove most variation (Chapters 3 and 26).

One celebrated apparent selection limit is racing performance in thoroughbred horses, where the winning times in classic English races have not fallen substantially over the past 50 years (Gaffney and Cunningham 1998; Hill 1998). To be fair, this is a nonstandard trait, namely, the best single performance within a set of individuals and not their mean performance. However, if mean times have responded to selection, we also expect these outlier times (the best of a dozen or so) to fall as well. One possibility is that while means have fallen, so too has the genetic variance, potentially keeping low outliers (i.e., faster speeds) at a roughly constant value. Gaffney and Cunningham (1998) found ample additive variance in a strong correlate of performance, handicap weight, which Hill predicted should result in a mean improvement of roughly 0.1% per year. A more recent analysis by Wilson and Rambaut (2008) on the genetics of lifetime earning of racing horses (again correlated with speed) found that while roughly 90% of the variation was environmental (diet, trainer, etc.), there was a significant heritable component that should respond to selection.

Some long-term experiments have yet to reach their limit (Figure 25.9). The most iconic of these is the **Illinois long-term corn selection experiment**, started by the agricultural chemist Cyril Hopkins in 1896 and currently ongoing (Hopkins 1899; Smith 1908). The results after 76, 90, 100, and 106 generations of selection were summarized by Dudley (1977), Dudley and Lambert (1992, 2004), Moose et al. (2004), and Dudley (2007). As shown in Figure 25.9A, a fairly constant response for increased oil content is seen over 90 generations with no apparent selection limit, with a total cumulative response of $22\sigma_A$. Selection for low oil was stopped after 87 generations due to the difficulty of selecting among individuals with close to 0% oil. While a limit appears to have been reached, this is due to a scale effect, as oil percentage is bounded below by zero. Selection for protein shows a similar pattern to that for oil (Figure 25.9B), with the up-selection line (IHO) currently showing a cumulative increase of $26\sigma_A$ after generation 90 with no apparent limit, and the down-selected lines showing an apparent plateau, again likely due to scale effects. The interesting, and far-reaching, intellectual legacy of this experiment was nicely summarized by Goldman (2004).

Table 25.4 Nature of the selection limit observed in various laboratory selection experiments.

Reduced thorax length in <i>D. melanogaster</i> F. W. Robertson 1955	Apparent exhaustion of all genetic variation: no further change under inbreeding, no response to reversed selection.
Increased body weight in mice Falconer and King 1953 Roberts 1966	Exhaustion of σ_A^2 : no response to reversed selection.
Egg production in <i>D. melanogaster</i> Brown and Bell 1961, 1980	Exhaustion of σ_A^2 : significant nonadditive genetic variance present at selection limit. Lethals and sterility factors negligible.
Wing length in <i>D. melanogaster</i> Reeve and Robertson 1953	Significant σ_A^2 at limit: complicated interaction due to segregating lethals and an overdominant gene influencing wing length.
Reduced body weight in mice Falconer 1955 Roberts 1966	Opposing natural selection: response to reversed selection, mean slippage upon relaxation of selection. Likely due to reduction in viability.
Abdominal bristles in <i>D. melanogaster</i> Clayton and Robertson 1957 Yoo 1980b	Segregating lethals: major gene increases bristle number as a heterozygote, lethal as a homozygote.
Pupal weight in <i>Tribolium castaneum</i> Enfield 1980	Opposing natural selection: significant σ_A^2 at limit, large decay in response with relaxed selection. Sterility reduced and fertility improved in relaxed lines.
Shank length in chickens Lerner and Dempster 1951	Opposing natural selection: shank length negatively correlated with hatchability.
Litter weight in mice Eisen 1972	Negative genetic correlation between direct and maternal effects.
Increased body weight in mice Wilson et al. 1971	Negative correlation between weight and litter size.
Increased litter size in mice Falconer 1971	Apparent limit due to slow changes in the frequency of dominant alleles.

A few other classical experiments continue to show selection response without an apparent limit. The **Dummerstorf long-term** selection lines (started in Dummerstorf, Germany) are the mammalian counterpart to the Illinois maize lines. Selecting for mouse weight at 42 days, this experiment has run for over 160 generations, making it the longest continuous selection experiment in mammals (Bünger et al. 2001). As shown in Figure 25.9D, it has not yet reached a limit. Another long-term mouse experiment is the work of Holt et al. (2005), who selected for litter size for over 122 generations, but with the selected population experiencing at least two waves of migration of new genetic material to break the selection limit. **Weber's long-term selection experiment for flight speed** in *Drosophila* involves over 600 generations of continuous selection (Weber 1996, 2004). Figure 25.9C shows no apparent limit after 100 generations, while by generation 300, the response was slowing down, but still continuing (Figure 26.4). Unpublished results by Weber (pers. comm.) indicate that the line was still responding after 640 generations of selection. The champion of continuous long-term studies is **Lenski's long-term evolution experiment (LTEE)** using the bacterium *Escherichia coli*, which continues to respond to selection for increased fitness after over 50,000 generations (Lenski et al. 1991; Lenski and Travisano 1994; Barrick et al. 2009; Wiser et al. 2013). The roles of both finite population size (larger populations have larger limits) and new mutation input are critical to the ongoing selection response in any very long-term

experiments, and we examine this further in Chapter 26.

Fortunately, limits appear to be rare in many selection programs for important commercial traits in domesticated animals (Fredeen 1984; Hunton 1984; Kennedy 1984). This is perhaps not surprising given that breeders are constantly shifting the suite of characters under artificial selection, as well as searching out new sources of genetic material. A more dubious possibility is that, while not currently at a limit, breeders are quickly approaching one (e.g., Grassini et al. 2013).

Several strategies can be used to break an apparent selection limit and allow for further response. Relaxing selection for several generations followed by directional selection can break a limit caused by strong gametic-phase disequilibrium between segregating loci. Likewise, if the limit results from a balance between natural and artificial selection, increasing the amount of artificial selection can result in further response. If the limit is caused by a lack of genetic variation, crossing different lines can introduce additional variation. Over longer time scales, a limit can be exceeded simply by waiting for new mutational input, either to increase additive variance or by generating alleles that improve the artificially selected trait but with less deleterious pleiotropic effects on fitness (Chapters 26 and 28). A final approach is selection in a new environment, which can often exploit genetic variation that is not usable in the current environment. For example, Abplanalp (1962) was able to improve a chicken line, which was apparently at a plateau for increased egg number, by selecting in a different environment (females being subjected to one day without food every two weeks).

A final comment on the nature of limits, which is discussed in much greater detail in Volume 3, is essentially an extension of the concept of a lack of further selection response because of a trade-off between natural and artificial selection. In natural populations, where the target of selection is some multivariate phenotype (say an index of trait values), one can easily have very little or no additive variation in the index (and hence, selection response at a limit), yet still have ample additive variation in each of the component traits. If the focus is on a single character in nature or even some smaller subset of the traits making up the index upon which natural selection is operating, one could easily observe ample selection on the trait and the presence of ample additive variation for that trait, yet no selection response (Blows and Hoffmann 2005; Blows and Walsh 2009; Walsh and Blows 2009; Chapter 20). As stressed in Volume 3, treating multivariate selection as a series of univariate responses is extremely misleading.

INCREASES IN VARIANCES AND ACCELERATED RESPONSES

Contrary to the expectations of idealized long-term response, phenotypic and additive genetic variance can *increase* during the course of selection, often resulting in bursts of response (Figure 25.8B). As we detail here, a variety of different conditions can lead to such a burst in response, emphasizing just how unpredictable long-term responses can be.

Rare Alleles

One obvious source for increases in variance is the increase of favorable rare alleles under selection. For an additive locus, σ_A^2 is maximized at $p = 1/2$ (LW Figure 4.8). Thus, additive loci with favorable alleles below 50% show an increase in additive variance as the allele frequency approaches one-half, after which σ_A^2 starts to decline to zero as the alleles becomes fixed. If the allele is rare and also of large effect, the result can be an increase in response many generations after the start of selection (Figure 25.10). The magnitude of this effect depends on both the initial frequency of the allele and its effect size. Alleles of large effect are subjected to stronger selection, and hence show more rapid increases in allele frequencies and larger effects on response. As Figure 25.11 illustrates, if there is a distribution of allele frequencies (and allelic-effect sizes) at the underlying loci, then different alleles are increasing at different rates, which can result in a very erratic pattern of response. This is especially true when the allele frequencies follow the Watterson distribution (Chapter 2), the distribution of allele

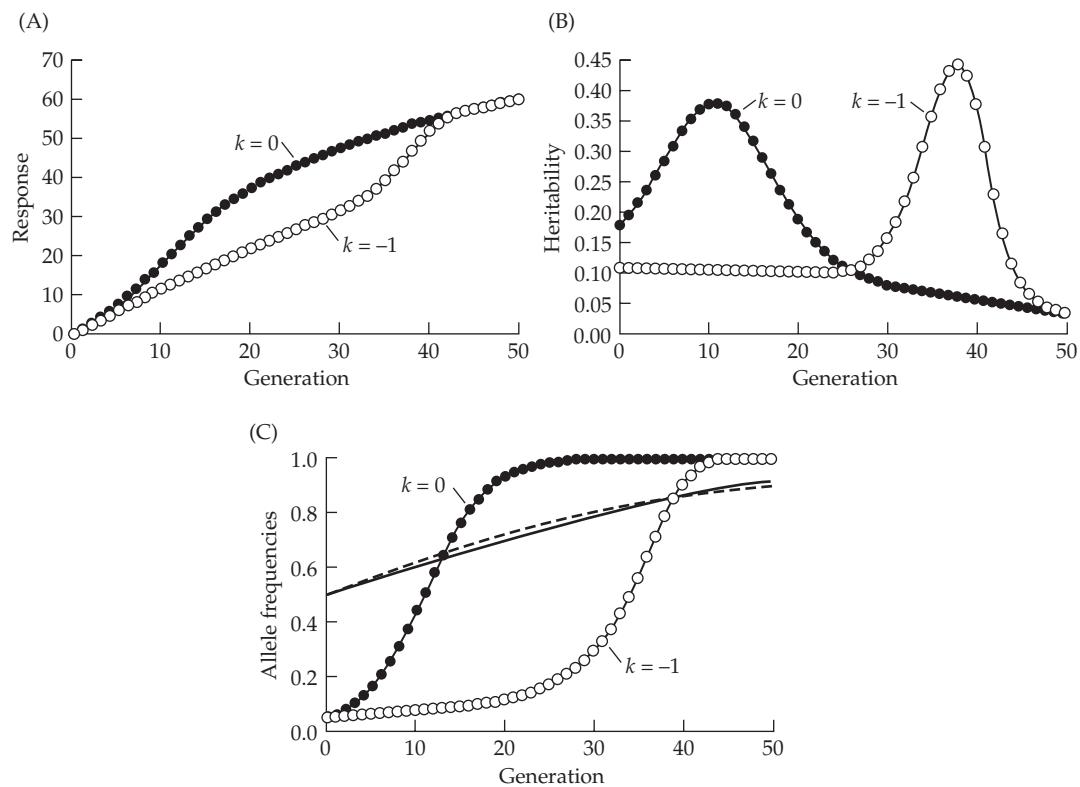

Figure 25.10 Examples of a delayed accelerated response due to the increase of an initially rare allele of major effect. The character is determined by a polygenic background (100 completely additive dialleic loci, with $a = 0.5$ and $p = 0.5$, so that the initial additive variance contributed by the polygenic background is $\sigma_A^2 = 12.5$) plus a major allele that is initially at low frequency ($a = 10$ and $p = 0.05$). We assume that the favored allele at the major locus is either additive ($k = 0$; contributing an initial additive variance of 9.5) or recessive ($k = -1$; contributing an initial additive variance of 0.095). **A:** Response under the recessive model shows an accelerated response around generation 35, while the additive major gene results in an acceleration around generation 10. **B:** Heritabilities clearly show the basis for this acceleration. **C:** Changes in the major-allele frequency show the much longer time required for the recessive major allele to increase in frequency. Note that the change in the polygenic frequencies (the middle two curves; solid for $k = 0$ and dashed for $k = -1$) are almost the same under the two different major-locus dominance values.

frequencies expected under drift-mutation balance, wherein most minor alleles are rather rare. The effects of natural selection may further exaggerate this distribution. If alleles of large effect also tend to be slightly deleterious, then these frequencies may be even lower than expected under the Watterson distribution, with a negative correlation between frequency and effect size (e.g., Figure 28.5).

Major Mutations

Major alleles can arise by mutation while selection is ongoing, creating bursts of response throughout the course of the experiment. An example of this appeared in an experiment by Yoo (1980a), who selected for increased abdominal bristles in *Drosophila* for over 80 generations (Figure 25.8B). Five of the six replicate lines showed various periods of accelerated response after 20 generations of selection. Yoo was able to correlate many of these bursts with the appearance of new alleles that had major effects on bristle number as heterozygotes but were lethal as homozygotes.

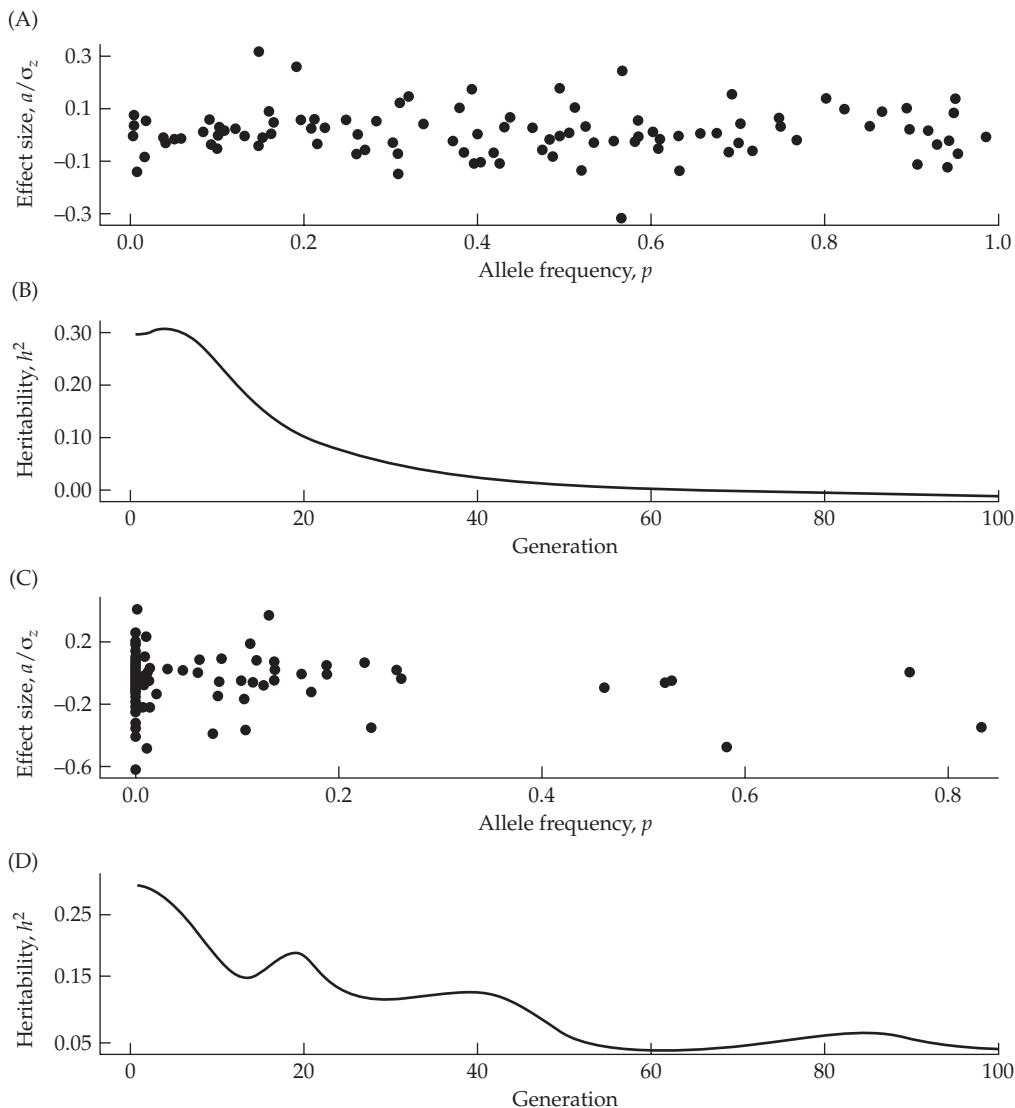

Figure 25.11 The impact of a distribution of initial allele frequencies and effects on the long-term response to directional truncation selection on a trait in an infinite population. The model simulated here assumes 100 underlying loci, that are unlinked and with completely additive effects within and among loci (no dominance or epistasis). Linkage disequilibrium is ignored, with Equation 25.3 iterated to generate the dynamics (see Example 25.2). Allelic effects were randomly sampled from an exponential distribution reflected about zero (effects were equally likely to be positive or negative). Initial allele frequencies were either sampled from uniform or Watterson (Equation 2.34a) distributions, with randomly assigned allelic effects. Given the initial distribution of allele frequencies and effects, a base-population additive variance, $\sigma_A^2(0)$, was computed, and σ_E^2 was set at $(7/3) \cdot \sigma_A^2(0)$ to give the trait a starting heritability of 30% (a typical value for many traits). Results from two realizations are presented here. The joint distribution of initial frequencies and their standardized effects, a/σ_z , is plotted for a given realization from the uniform (A) and Watterson (C) distributions. As (B) shows, under a uniform distribution of starting allele frequencies at the underlying loci, the temporal change in the heritability was generally well-behaved over the course of selection (here, a slight initial increase, followed by a nearly monotonic decrease). Conversely, (D) shows that change in the heritability under an initial Watterson distribution was highly erratic. While the specific realization shown here for the Watterson distribution was typical for a number of simulations, even more erratic patterns (i.e., heritabilities rapidly increasing after many generations of selection) were seen in some realizations. In experimental populations, drift and founder-sampling would obscure these patterns.

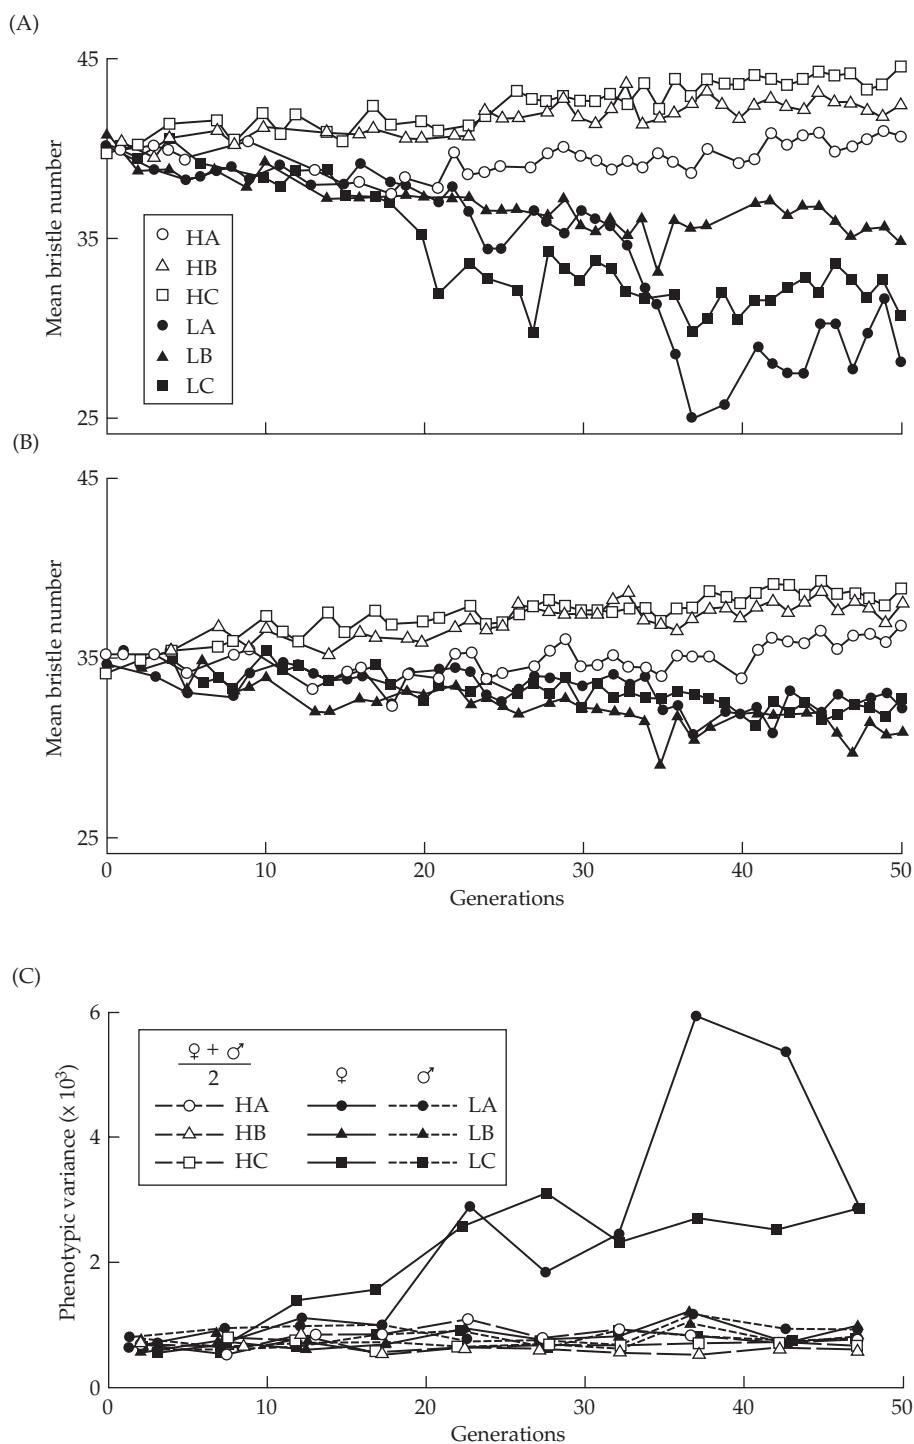

Figure 25.12 The response to selection in *Drosophila melanogaster* for high and low abdominal bristle numbers. While equal amounts of selection was applied to both sexes, results are separated by sex-specific response. **A:** Response in females. **B:** Response in males. While two of the down-selected lines (LA and LC) show bursts of response in females, no such response is seen in the males from these lines. **C:** The phenotypic variances for these lines. The figure plots the average of the male- and female-specific variances for all three high-selected lines (which showed no sex-specific differences over the response), while sex-specific differences were seen in two of the low-selected lines. Note that the variance increased only in females from the two lines showing a burst of response. (After Frankham et al. 1980.)

A second example of a mutation-induced burst of response in *Drosophila* bristle number was seen by Frankham's group (Frankham et al. 1978, 1980; Frankham 1988), which examined selection responses in lines initially containing very little variation. In two of their down-selected lines, females (but not males) showed a burst of response (Figure 25.12). This burst was accompanied by an increase in the phenotypic variance and heritability in females, but not in males. Females also showed reduced fitness, as indicated by a male-biased sex ratio in these lines. These effects were attributable to the appearance of *bobbed* mutants at the ribosomal gene cluster, a deficiency in the number of rRNA genes. The *bobbed* mutants arose on the X-chromosome rRNA cluster, while the Y-chromosome rRNA cluster remained normal, accounting for the sex-limited nature of the response. These mutants were generated by unequal crossingover within the rRNA gene cluster during the course of the selection experiment.

These examples involve mutations of major effects, with an almost immediate impact. The implications of ongoing mutations of minor effects are considered in Chapter 26.

Scale and Environmental Impacts on Variances

Scale effects can also result in increases in genetic variances and selection responses, for example, when the variance increases with the mean (LW Chapter 11). A possible example of this is Enfield's (1972) selection experiments for increased pupal weight in *Tribolium*. Both the additive-genetic and total phenotypic variance increased over time, while heritability remained roughly constant (meaning that response was fairly constant). Comstock and Enfield (1981) suggested that a multiplicative model of gene action was more appropriate in this case than an additive model, and could account for the observed increases in variance. As was discussed in Chapter 14, scale effects can be especially important in threshold characters (also see LW Chapters 11 and 25).

Variances can also increase due to environmental effects. For example, the environmental variance can increase as genotypes become more homozygous, although this is not inevitable (see LW Table 6.1). Likewise, we showed in Chapter 17 that directional selection on a trait can result in an increase in σ_E^2 if the environmental variance has heritable variation. Finally, changes in the environment during the course of selection can sometimes increase the additive variance. A possible example of this effect derives from observations on long-term selection on milk yield in North American dairy cows, where the additive variance in yield has been increasing rather than decreasing (Kennedy 1984). One explanation for such behavior is environmental change, as improved management techniques likely allow for greater discrimination between genotypes, although scale effects may also play a role.

Linkage Effects

Recombinational breakdown of preexisting gametic-phase disequilibrium can also generate an accelerated response. Why might such disequilibrium be present? Mather (1941, 1942, 1943) suggested that QTLs are often in negative disequilibrium as a result of previous natural selection (he considered mainly stabilizing selection), referring to this genetic architecture as **polygenic balance**. More generally, selection tends to build up such negative associations based on fitness (as, by definition, fitness is always under directional selection, which generates negative values of d ; see Chapter 16). As a result, alleles influencing fitness tend to be in negative gametic-phase disequilibrium, with gametes containing two favorable alleles occurring at a lower frequency than expected under linkage equilibrium (Chapters 16 and 24). As a result, alleles favored by artificial selection on a character and alleles at linked loci that improve other components of fitness (Sved 1977) have a tendency to become negatively correlated. A character with extensive negative disequilibrium (either between QTLs controlling the character or between QTLs for the character and other fitness loci) can show accelerated selection response in the mean as this disequilibrium decays (Figure 25.13).

An accelerated response can also occur when recombination generates coupling

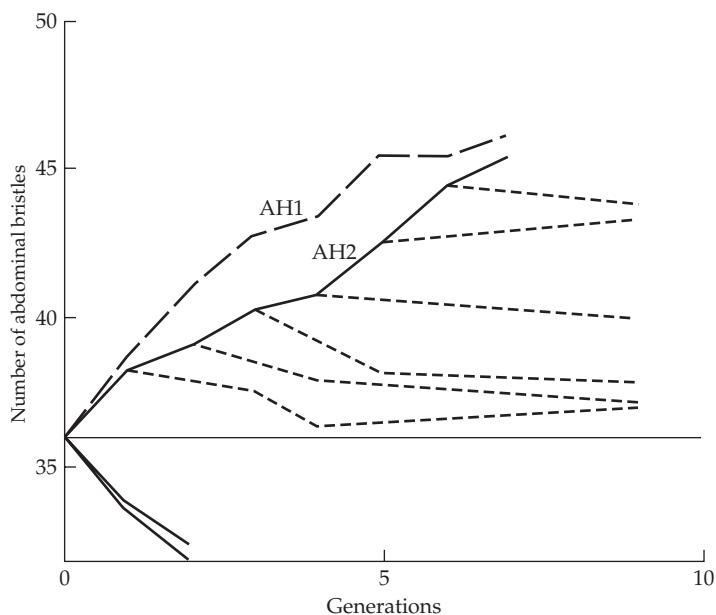

Figure 25.13 An apparent example of linkage between QTLs and deleterious fitness loci. Latter and Robertson (1962) selected for increased abdominal bristle number in *Drosophila melanogaster*, creating sublines (indicated by the dashed lines) from the selected lines at various generations and subjecting these sublines to relaxed selection. Sublines of line AH2 extracted in the first three generations of selection showed significant erosion of response upon relaxation of selection, while sublines extracted in later generations show little erosion. Note also that line AH2, which has a depressed response relative to line AH1 over generations 1–4, shows an accelerated response following generation 4. One explanation for this pattern is that alleles increasing the character were initially in gametic-phase disequilibrium with alleles having deleterious effects on fitness in line AH2. By generation 4, this disequilibrium had largely broken down, allowing the frequencies of alleles increasing the character value to remain stable following relaxation of selection and allowing a faster response to selection. (After Latter and Robertson 1962.)

gametes for alleles that increase character value. A classic example is Thoday's selection experiments for increased sternopleural bristle number in *Drosophila* (Thoday and Boam 1961; Thoday et al. 1964). As shown in Figure 25.14, a burst of response was seen after about 20 generations of selection. Using polygenic mapping, Thoday et al. (1964) were able to show that the initial population consisted mainly of $--$ chromosomes with only a few $+-$ and $-+$ chromosomes (each $+$ indicates a major allele increasing bristle number). Selection reduced the frequency of $--$ chromosomes, increasing the frequency of $+- / -+$ heterozygotes, which in turn increased the frequency at which $++$ chromosomes were generated by recombination. The selection response accelerated as these newly created gametes became sufficiently common to increase additive variance.

While recombination removes gametic-phase disequilibrium, selection generates it (Chapters 5, 16, and 24). It follows that if linkage effects are important, a relaxation of selection should facilitate long-term response by allowing negative gametic-phase disequilibrium to decay, which increases the additive variance (Chapter 16). Thoday and Boam (1961) observed a large increase in *Drosophila* sternopleural bristle number after reselecting a line in which selection was relaxed for several generations following an apparent selective plateau. Similar patterns were seen by Mather and Harrison (1949) in some of their lines that were selected for increased abdominal bristle number. On the other hand, Rathie and Barker (1968) compared the effects of cycles of selection followed by no selection versus continuous selection on abdominal bristles and found no differences in response. However, the continuously

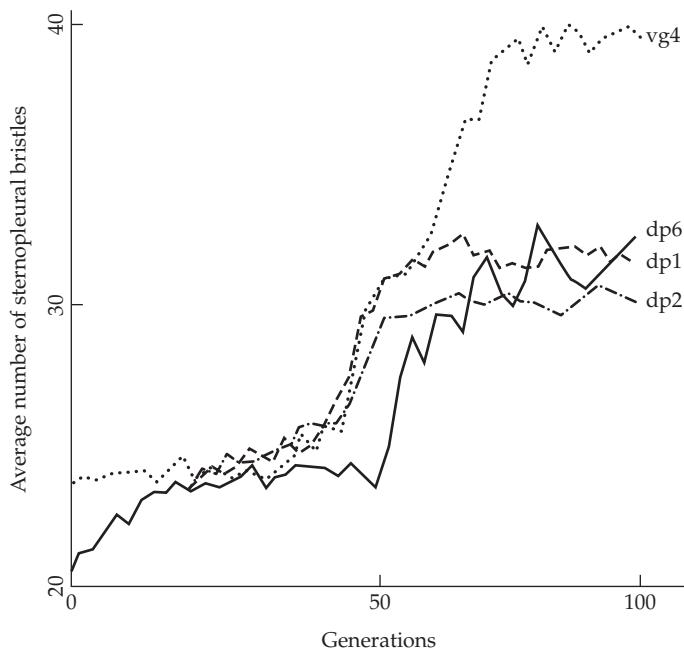

Figure 25.14 Accelerated response in sternopleural bristle number in *Drosophila melanogaster* lines selected by Thoday and Boam (1961). All lines showed acceleration in response, but the acceleration in line *vg* 4 was especially dramatic.

selected lines showed larger erosions of response upon relaxation of selection and had greater decreases in reproductive fitness, suggesting that disequilibrium between QTLs and fitness loci was greater in these lines.

Our discussion of the effects of linkage has been restricted to largely deterministic considerations. Here, in the absence of epistasis, linkage influences the rate, but not the ultimate limit, of response. When population size is finite, linkage can have an important impact on the ultimate selection limit as well. For example, in a small population, selection and drift could have fixed + – chromosomes in Thoday's experiment before + + chromosomes reached frequencies sufficiently high to overcome the effects of drift. We will defer further discussion of these complex interactions until Chapter 26.

Epistasis

While the permanent component of response in any particular generation is a function of the additive variance (Chapter 15), σ_A^2 itself changes as the frequencies of underlying genotypes change. While it is generally true that most genetic variance is additive, even when strong epistasis is present (Hill et al. 2008; Mäki-Tanila and Hill 2014), it is also true that changes in genotype frequencies can result in some of the epistatic variance being converted into additive variance (Goodnight 2004; also see Chapter 11). Eitan and Soller (2004) proposed the idea of **selection-induced genetic variation**, wherein the process of selection generates additional variation, as opposed to strictly removing it. An example of this is the study by Carlborg et al. (2006), who found a strongly epistatic locus in chicken lines that were divergently selected for growth. Alleles at three growth-specific loci (*Growth4*, *Growth6*, and *Growth12*) had much higher effects in a (high-growth) homozygous *Growth9* genotypic background. While Eitan and Soller were concerned with new variation being generated via epistasis, recall the very erratic pattern of response seen in Figure 25.11D for a *purely additive* model. If such a pattern were observed in an experiment, many researchers would declare that it could only be due to epistasis. This is based on the expectation that the additive variance is continually declining, which requires the assumption that the majority of loci

are at, or above, their frequencies for maximal additive variation. If this is not correct, such low-frequency additive alleles can (for at least part of the response) generate new additive variance as they increase toward the frequency that yields a maximal value of σ_A^2 , after which further allele-frequency change causes σ_A^2 to decline. As Figure 25.11 shows, bursts of response for rare additive alleles can occur > 50 generations after the start of selection.

There is a healthy debate on the impact of epistasis on the response to directional selection (Carlborg and Haley 2004; Malmberg and Mauricio 2005; Le Rouzic and Carlborg 2007; Crow 2008, 2010; Hansen 2013), with some researchers even claiming that models that do not incorporate epistasis are fundamentally flawed (Nelson et al. 2013). However, from the standpoint of predicting long-term response, epistasis is, in some sense, the least of our concerns. First, there is the important distinction between underlying epistasis being common versus epistatic *genetic variances* being large. By construction, even when the underlying gene action of a trait is highly nonadditive, the majority of the genetic variance tends to be additive, especially when contributing loci have alleles at extreme frequencies (LW Chapter 7; Hill et al. 2008). As the various mechanisms discussed previously illustrate, a number of different genetic conditions other than epistasis can result in bursts of selection response. Determining the underlying cause for a burst (or some other feature attributed to epistasis) is far from trivial, implying that epistasis should only be invoked when it is fully justified by the data.

CONFLICTS BETWEEN NATURAL AND ARTIFICIAL SELECTION

It is frequently seen that components of fitness (such as viability and fertility) decline rather dramatically during artificial selection experiments. Selected lines can even die out due to extreme declines in fitness. There are several (not mutually exclusive) reasons for these declines, which have rather different implications for long-term response.

1. *Selection increases the amount of inbreeding relative to control populations of the same size*, a point developed in Chapters 3 and 26. Drift effects associated with inbreeding can increase the frequency (and exposure) of deleterious recessives, as well as moving overdominant fitness loci away from their equilibrium frequencies. If inbreeding is sufficiently strong, deleterious alleles can be fixed.
2. *Loci favored by artificial selection can be in gametic-phase disequilibrium with loci having deleterious effects on fitness*. Fitness declines as these deleterious alleles increase in frequency due to hitchhiking with alleles favored under artificial selection. This disequilibrium need not be present initially—rather, it can be generated during artificial selection (Chapter 16). In infinite populations, the gametic-phase disequilibrium between QTL and fitness loci eventually decays, and deleterious alleles are not fixed. In small populations, deleterious alleles can be dragged along to fixation by linked major alleles.
3. *Alleles favored by artificial selection can have deleterious effects on fitness*. There are two different routes by which this can occur: the artificially selected character may itself be under natural selection, or loci controlling this character can have pleiotropic effects on other characters that are under natural selection (see Chapter 28). The impact on long-term response has been examined in some detail for two particular models: the **optimum model**, wherein the character under artificial selection is also subjected to natural stabilizing selection (Latter 1960; James 1962; Zeng and Hill 1986; Hill and Mbaga 1998); and the **homeostatic model**, wherein heterozygotes have the highest fitness under natural selection (Lerner 1954; Robertson 1956). While the genetic basis for these models is very different, Nicholas and Robertson (1980) noted that “despite the profound differences between the two models, the practical implications of each are essentially the same *in the context of artificial selection*. Consequently, there seems to be no aspect of observable response which would enable a distinction to be made between the two.”

What are the implications of these different fitness-decreasing mechanisms for long-term response? The inbreeding effect of selection is a consequence of finite population size being further exaggerated by selection: these effects should largely disappear if the effective population size is kept sufficiently large during selection.

If loci influencing the character also influence fitness (either directly or because of gametic-phase disequilibrium with other fitness loci), response is expected to decay upon relaxation of selection, provided alleles decreasing fitness are not fixed (e.g., Figure 25.8B). Erosion of response, however, does not automatically imply that fitness effects are important. For example, some erosion is expected when additive epistasis or maternal effects have contributed to the response (Chapter 15). If erosion is largely due to fitness effects, it should be correlated with increases in fitness.

Example 25.6. Frankham et al. (1988) selected *Drosophila melanogaster* for increased ethanol tolerance. Following the suggestion of Gowe (1983), they attempted to reduce the expected decline in reproductive fitness by further culling those artificially selected pairs showing reduced number of offspring. Their logic was that if deleterious fitness effects during selection were largely caused by rare recessives (the exposure of which increases by inbreeding during selection), then removing a very small fraction of the lowest-fitness individuals would cull individuals that are homozygous for deleterious recessives. Following the selection of parents based on increased tolerance, Frankham et al. placed single mated pairs in vials that were subsequently ranked according to the number of pupae produced. Vials with the lowest number of pupae were culled. The HS line, which was subjected to both selection for tolerance and subsequent culling on reproductive fitness, had the same tolerance response as the HO line (which was selected only for increased tolerance). The unselected control line and the HS line had the same fitness, as measured by Knight and Robertson's (1957) very general competitive index measure. Conversely, the HO line had significantly reduced fitness. If alleles increasing tolerance had either pleiotropic or linkage effects on fitness, the HS line should have reduced the tolerance response relative to the HO line. Given that the responses were identical, however, Frankham et al. suggested that the reduction in fitness in the HO line was mainly due to the effects of inbreeding, rather than linkage or pleiotropy.

A similar study was reported by Gowe et al. (1993), who examined 30 years of selection on laying hens. Again, a two-stage selection approach was used: following truncation selection for increased egg production, the lowest 10% of hens chosen as parents by truncation selection were then culled again on the basis of hatchability. Using this selection scheme, the increased production lines retained the same levels of hatchability as an unselected control. Typically, selection only on increased egg production alone reduces hatchability.

A final example of an experiment attempting to control for deleterious fitness effects was provided by Imasheva et al. (1991), who combined directional selection for increased *radius incompletus* expression in the wing venation of *Drosophila melanogaster* with stabilizing selection on a suite of wing morphological characters. After 16 generations of selection, the control and directional plus stabilized selected lines had similar population sizes, both of which were higher than the population that was subjected to strict directional selection. The three lines, however, did not differ when fitness was measured by looking at competitive ability.

Example 25.7. Enfield (1980) subjected the flour beetle (*Tribolium castaneum*) to selection for increased pupal weight. As mean pupal weight increased, components of reproductive fitness (percent sterility and mean number of progeny per fertile mating) declined. Upon the relaxation of selection, pupal weight decreased and fitness increased. When relaxed lines were again subjected to selection, fitness components again decreased as pupal weight increased. However, Enfield reported evidence that increased pupal weight, by itself, does not necessarily decrease fitness, having found that lines can be created with rather large mean pupal weight, that remain stable upon the relaxation of selection. Thus, it appears that reproductive fitness declines as a result of a correlated selection response with pupal weight, rather than natural selection acting directly on pupal weight itself. At least some of the alleles for increased pupal

weight thus appear to be associated with alleles that decrease reproductive fitness. If this is due to linkage disequilibrium, recombination will reduce this effect. If it is due to pleiotropy, however, one must select for modifiers of these deleterious effects.

Example 25.8. An interesting potential example of a decay in selection response upon relaxation of selection in a natural population was provided by Cruz and Wiley (1989), who examined egg-rejection behavior in the village weaver bird (*Ploceus cucullatus*) in Hispaniola. This species was introduced onto the island from western Africa around 200 years ago. Studies in western Africa by Victoria (1972) showed that female weavers can recognize their own eggs and eject foreign eggs from their nest, with the rate of rejection proportional to the amount of difference between eggs. Victoria postulated that this rejection behavior evolved in response to selective pressure from the Didric cuckoo (*Chrysococcyx caprius*), which is a brood parasite that lays its eggs in the nests of other species. The rejection of eggs that appear sufficiently different could lead to increased fitness when brood parasites are present but decreased fitness when they are absent (as any discarded eggs would be from the mother).

Victoria found an average rejection rate in Africa of eggs with a different appearance from their mothers of around 40–55%, while Cruz and Wiley found a rejection rate on Hispaniola of 12%. Because Hispaniola was free of brood parasites until the mid-1970s, Cruz and Wiley suggested that this difference in rejection rates amounts to a slippage in the selection gain (in Africa) following the relaxation of selection (in Hispaniola). Such a slippage shows that the 40–55% value in Africa does not represent a selection limit due to lack of additive variance in this behavioral trait. If a selection limit did exist in Africa, it would likely represent a tradeoff between the fitness costs of rejecting all eggs that appear to be different. This natural experiment continues today, as in the mid-1970s the shiny cowbird (*Molothrus bonariensis minimus*), another brood parasite, was introduced into Hispaniola.

Accumulation of Lethals in Selected Lines

Lethal alleles are often detected in lines that are subjected to long-term selection. If these alleles also influence the character under selection, they can result in increases in the additive variance during a period of the selection response, the presence of significant additive variance in the trait at an apparent selection limit, and some erosion of both the response and the additive variance upon relaxation of selection. In *Drosophila* experiments, lethals have been observed in lines that were subjected to directional selection on sternopleural bristles (Madalena and Robertson 1975; García-Dorado and López-Fanjul 1983), abdominal bristles (Clayton and Robertson 1957; Frankham et al. 1968b; Hollingdale 1971; Yoo 1980b), dorsocentral bristles (Domínguez et al. 1987), and wing length (Reeve and Robertson 1953). Skibinski (1986) also found that lethals accumulated during stabilizing selection on sternopleural bristle number. Yoo (1980b) and Skibinski (1986) found that most lethals arose during the course of the selection experiment, rather than being initially present in the base population. A similar example in mice involves the homozygous sterile allele *pygmy*, which reduces body size when heterozygous (Warwick and Lewis 1954; King 1955). This mutant arose during MacArthur's (1949) long-term selection experiments for decreased body size.

Newly arising lethals could be due to new mutation (such as the insertion of a mobile element; see Mackay 1988) or could be generated by recombination between strongly epistatic genes creating **synthetic lethals** (LW Chapter 10; Phillips and Johnson 1998). Once a lethal with a strong effect on the character appears, it partly shelters closely linked sites from further selection, creating linked clusters of lethals (Madalena and Robertson 1975; García-Dorado and López-Fanjul 1983).

Example 25.9. Consider the following estimated variance components from a selection ex-

periment by Reeve and Robertson (1953) for increased wing length in *Drosophila melanogaster*:

Population	σ_z^2	σ_A^2	σ_E^2	h^2
Selected	4.65	2.50	1.72	0.54
Relaxed	4.50	1.80	1.72	0.40
Base	3.20	1.02	1.72	0.32

The selected line shows large increases in additive variance and heritability relative to the base population, while upon the relaxation of selection, both the additive variance and the heritability decline to values that are intermediate between those in the base and the selected lines. Reeve and Robertson attributed this behavior to the presence of at least two major alleles that are lethal as homozygotes. As these alleles increase in frequency, they increase additive variance. Because they are never fixed (as is discussed below, their maximum frequency is 1/3), the genetic variance attributable to these alleles does not subsequently decline as selection proceeds. However, upon relaxation of selection, the component of response due to these alleles decays as their frequency is reduced by natural selection. The additive variance is also expected to decline as these alleles are eventually lost due to natural selection following the relaxation of artificial selection.

Why do lethal alleles persist in some selected populations? In many cases, this seems to be a result of fitness overdominance resulting from a balance between natural and artificial selection—the allele increases character value as a heterozygote, but it is lethal (or sterile) as a homozygote. Such alleles can be maintained at rather high frequencies if artificial selection acting on the locus is strong (i.e., the allele has a major effect on the character that is under strong directional selection). We can show this informally as follows: let the *BB* homozygote be lethal, while the *Bb* heterozygote increases the genotypic value of the trait under selection (relative to *bb*). Under directional selection, the fitness of *Bb* relative to *bb* can be written as $1 + s$, where s increases as the effect of *B* on the character under artificial selection increases, yielding total fitnesses of $1 : 1 + s : 0$ for the genotypes *bb* : *Bb* : *BB*. The resulting mean population fitness becomes $\bar{W} = 1 + 2sp(1-p) - p^2$, where p is the frequency of *B*. Applying Wright's formula (Equation 5.5b) and solving $\Delta\hat{p} = 0$ yields an equilibrium frequency of *B* in newly formed zygotes (before natural selection) of

$$\hat{p} = \frac{s}{1 + 2s} \quad (25.12a)$$

Following the loss of lethal homozygotes in the surviving offspring, \hat{p} decreases to

$$\tilde{p} = \frac{(1/2)\text{freq}(Bb)}{\text{freq}(Bb) + \text{freq}(bb)} = \frac{\hat{p}(1 - \hat{p})}{2\hat{p}(1 - \hat{p}) + (1 - \hat{p})^2} = \frac{\hat{p}}{1 + \hat{p}} \quad (25.12b)$$

Substitution of Equation 25.12a into Equation 25.12b yields $\tilde{p} = s/(1 + 3s)$. Thus, for large values of s , the equilibrium frequency of the allele approaches 1/3 at the start of each generation before artificial selection and increases to 1/2 after artificial selection. A more formal treatment of this problem is given in Example 25.10 (also see Figure 25.15).

While many lethal alleles have a demonstrated major effect on the character under selection, in some cases their frequencies are not consistent with this theory. Skibinski (1986) found no evidence that artificial selection accounts for the maintenance of lethals observed in his *Drosophila* lines. Instead, one lethal showed evidence of segregation distortion (Lyttle 1991, 1993; Taylor and Ingvarsson 2003), which could account for its observed frequency. Likewise, none of the *Drosophila* lethals isolated by Domínguez et al. (1987) had a significant effect on the character under selection. They also found evidence of segregation distortion, with at least one lethal allele being preferentially transmitted by males. Thus, in some experiments, lethal alleles may persist for reasons other than artificial selection and therefore should persist upon the relaxation of selection, whereas lethals maintained by artificial

selection will not. The increased drift generated by artificial selection can increase the frequency of even strongly deleterious alleles, and this, especially when interacting with other factors such as segregation distortion, might account for the increase in lethals that do not affect the character under artificial selection.

Example 25.10. For a more formal treatment of the expected equilibrium value, consider a major gene that is lethal as a recessive (BB), but increases character value as a heterozygote (Bb). What are the dynamics of this locus when truncation selection is used to increase character value? Suppose that the distribution of phenotypes for the two viable genotypes is normal, with $z_{Bb} \sim N(\mu + a, \sigma^2)$ and $z_{bb} \sim N(\mu, \sigma^2)$, and let p be the frequency of B . Following random mating, the expected zygotic frequencies will be in Hardy-Weinberg frequencies, with $\text{freq}(Bb) = 2p(1 - p)$, $\text{freq}(bb) = (1 - p)^2$, and $\text{freq}(BB) = p^2$. After natural selection, only the genotypes Bb and bb remain, and these now have frequencies of

$$\text{freq}'(Bb) = \frac{2p(1 - p)}{1 - p^2} = \frac{2p}{1 + p} \quad \text{and} \quad \text{freq}'(bb) = \frac{(1 - p)^2}{1 - p^2} = \frac{1 - p}{1 + p}$$

Truncation selection occurs on the survivors of natural selection, generating a mixture distribution for the trait value (LW Chapter 13), with

$$\begin{aligned} z &= \text{freq}'(Bb) p_{Bb}(z) + \text{freq}'(bb) p_{bb}(z) \\ &= \left(\frac{2p}{1 + p} \right) p_{Bb}(z) + \left(\frac{1 - p}{1 + p} \right) p_{bb}(z) \end{aligned}$$

Here $p_{Bb}(z)$ and $p_{bb}(z)$ denote the density functions for the normal distributions associated with these two genotypes.

Recall from Chapter 14 that truncation selection is usually framed in terms of the fraction, q , of individuals that are allowed to reproduce. However, it will prove easier to initially formulate this problem in reverse, assuming some trait threshold value, T , above which individuals are allowed to reproduce. Given the current mean and variance, we can obtain the value of T for a given value of q . For a fixed value of q , we expect T to increase in each generation as the trait mean increases. Hence, we first solve this problem for T , and then express the final result in terms of the fraction saved, q .

If the trait threshold value above which individuals are allowed to reproduce is T , then the fraction of individuals allowed to reproduce is given by

$$q = \left(\frac{2p}{1 + p} \right) \Pr(z_{Bb} > T) + \left(\frac{1 - p}{1 + p} \right) \Pr(z_{bb} > T)$$

Because $(z_{Bb} - \mu - a)/\sigma \sim U$ and $(z_{bb} - \mu)/\sigma \sim U$, where U denotes a unit normal, this rearranges to yield

$$q(1 + p) = 2p \Pr\left(U > T^* - \frac{a}{\sigma}\right) + (1 - p) \Pr(U > T^*) \quad (25.13)$$

where $T^* = (T - \mu)/\sigma$. The frequency of Bb following artificial selection becomes

$$\text{freq}''(Bb) = \left(\frac{2p}{1 + p} \right) \frac{\Pr(U > T^* - a/\sigma)}{q}$$

yielding the frequency p'' of B after a single round of both natural and artificial selection as

$$p'' = \frac{1}{2} \text{freq}''(Bb) = \left(\frac{p}{1 + p} \right) \frac{\Pr(U > T^* - a/\sigma)}{q} \quad (25.14)$$

If we let \hat{p} denote the equilibrium frequency of B in the zygotes at the start of the next generation (before natural selection), by rearranging Equation 25.14, it follows that

$$q(1 + p)p'' = p \Pr(U > T^* - a/\sigma)$$

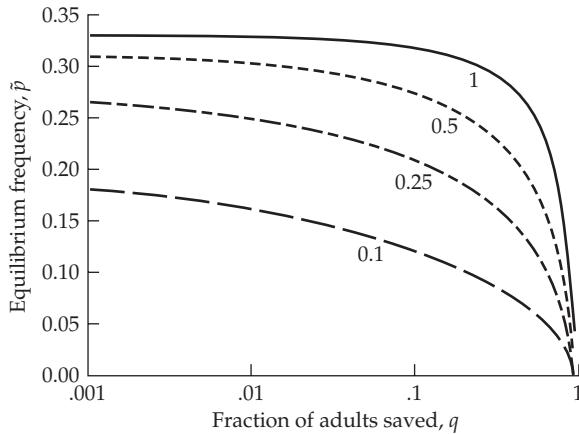

Figure 25.15 The equilibrium frequency, \tilde{p} , of a lethal allele that also increases the value of a trait under artificial selection. Selection is assumed to act in the zygote, so that \tilde{p} is the frequency of the allele in surviving individuals before artificial selection is performed. The equilibrium frequency is a function of the strength of artificial selection (measured by the fraction, q , of adults saved under truncation selection) and the contribution, a/σ , of the allele to the trait under artificial selection. The four curves are for values of $a/\sigma = 1, 0.50, 0.25$, and 0.10 , respectively. See Example 25.10 for further details.

Because $p'' = p = \hat{p}$ at equilibrium, this reduces to

$$q(1 + \hat{p}) = \Pr(U > T^* - a/\sigma)$$

Combining this result with Equation 25.13 yields

$$2\hat{p}\Pr(U > T^* - a/\sigma) + (1 - \hat{p})\Pr(U > T^*) = \Pr(U > T^* - a/\sigma)$$

Solving for \hat{p} returns

$$\hat{p} = \frac{\Pr(U > T^*) - \Pr(U > T^* - a/\sigma)}{\Pr(U > T^*) - 2\Pr(U > T^* - a/\sigma)} \quad (25.15a)$$

Likewise, the equilibrium frequency, \tilde{p} , following the removal of lethals (BB homozygotes) is

$$\tilde{p} = \frac{(1/2)\text{freq}(Bb)}{1 - \text{freq}(BB)} = \frac{\hat{p}(1 - \hat{p})}{1 - \hat{p}^2} = \frac{\hat{p}}{1 + \hat{p}} \quad (25.15b)$$

Figure 25.15 plots \tilde{p} as a function of q and a/σ . The figure was generated by applying Equations 25.15a and 25.15b for a given value of T^* , and then using Equation 25.13 to obtain the value of q , given the T^* , a/σ , and \hat{p} values.

Lerner's Model of Genetic Homeostasis

A second class of models assuming pleiotropic fitness effects is based on Lerner's (1954) theory of **genetic homeostasis**, which was motivated by the notion that natural selection tends to favor heterozygotes, a view that is still controversial and has weak support at best. Under Lerner's model, alleles segregating at a QTL are favored as heterozygotes by natural selection. The simplest case is that in which the QTL is additive for the character under selection. Let the genotypes $bb : Bb : BB$ have fitnesses (under natural selection) of $1 - s_2 : 1 : 1 - s_1$. Further, suppose the expected trait values for these offspring are $\mu - a : \mu : \mu + a$, where the trait is normally distributed and a is small. Then, from Equation 5.21,

the fitnesses under directional selection are approximately $1 - \bar{t}a/\sigma_z : 1 : 1 + \bar{t}a/\sigma_z$, resulting in (assuming weak selection; e.g. $s_1, s_2, \bar{t}a/\sigma \ll 1$) approximate total fitnesses of

$$(1 - s_2)(1 - \bar{t}a/\sigma_z) : 1 : (1 - s_1)(1 + \bar{t}a/\sigma_z)$$

If artificial selection is sufficiently strong relative to natural selection ($\bar{t}a/\sigma_z > s_1$), B is fixed. However, if $s_1 > \bar{t}a/\sigma_z$, the total fitness shows overdominance, and there is an internally stable equilibrium of

$$\hat{p} = \frac{s_2 + \bar{t}(a/\sigma_z)(1 - s_2)}{s_1 + s_2 + \bar{t}(a/\sigma_z)(s_1 - s_2)} \approx \frac{s_2 + \bar{t}(a/\sigma_z)}{s_1 + s_2} \quad \text{for } s_1, s_2 \ll 0 \quad (25.16)$$

This weak-selection result is due to Verghese (1974) and Nicholas and Robertson (1980), while Minvielle (1980) gave a more general equilibrium condition for alleles of major effect. The additive genetic variance for the trait contributed by this locus at equilibrium is $2a^2 \hat{p} (1 - \hat{p})$, which can be considerable.

Changes in reproductive fitness in divergent selection lines (Chapter 18) are often asymmetric, with lines selected in one direction showing a much larger decrease in fitness than lines selected in the opposite direction. Such asymmetries are not necessarily inconsistent with genetic homeostasis, as they can be accounted for by directional dominance in fitness (e.g., if $s_1 < s_2$, namely, that alleles increasing the character under artificial selection also tend to be more fit as homozygotes, holds for most loci).

Artificial Selection Countered by Natural Stabilizing Selection

Lerner's model is an example in which the QTL influencing a character under artificial selection also influences fitness under natural selection through paths that are independent of the phenotypic value of the focal trait. Under his model, extreme phenotypes are less fit because they are more homozygous than intermediate phenotypes. Alternatively, the phenotypic value, z , itself could be under natural selection. Here, extreme phenotypes are intrinsically less fit, independent of their genotypes. For example, z could be under natural selection for an intermediate optimum, with directional artificial selection being opposed by stabilizing natural selection. This can also lead initially to an apparent selection limit in the presence of additive variance in the artificially selected trait (Latter 1960; James 1962; Zeng and Hill 1986; Hill and Mbaga 1998).

Suppose we assume that stabilizing selection is occurring according to Equation 16.17, with the width of the selection function given by ω^2 (with smaller values implying stronger stabilizing selection) and the optimum set at zero. From Equation 16.18b, the selection differential imparted on a population whose mean is at a distance of μ from the optimum is

$$S_{st} = -\mu \frac{\sigma_z^2}{\sigma_z^2 + \omega^2} \quad (25.17a)$$

and, from Equation 16.18a, the new phenotypic variance after stabilizing selection becomes

$$\sigma_{z^*}^2 = \frac{\sigma_z^4 + \sigma_z^2 \omega^2 - \sigma_z^4}{\sigma_z^2 + \omega^2} = \frac{\sigma_z^2 \omega^2}{\sigma_z^2 + \omega^2} \quad (25.17b)$$

Now suppose directional selection operates with a selection intensity of \bar{t} , yielding a selection differential from artificial selection of

$$S_a = \bar{t}\sigma_{z^*} = \frac{\bar{t}\sigma_z \omega}{\sqrt{\sigma_z^2 + \omega^2}} \quad (25.17c)$$

for a total selection differential of

$$S = S_a + S_{st} = \frac{\bar{t}\sigma_z \omega}{\sqrt{\sigma_z^2 + \omega^2}} - \mu \frac{\sigma_z^2}{\sigma_z^2 + \omega^2} \quad (25.17d)$$

Response stops (a limit is reached) when $h^2 S = 0$, which can occur for $h^2 \neq 0$ when $S = 0$. Setting Equation 25.17d equal to zero and solving for the limiting mean yields

$$\mu_\infty = \bar{\tau} \omega \frac{\sqrt{\sigma_z^2 + \omega^2}}{\sigma_z} \quad (25.18a)$$

or a total response of $\mu_\infty - \mu_0$, a result first obtained by James (1962). Note that this limit does not appear to depend on h^2 (provided it is nonzero at the limit). However, this expected response is an approximation, as disequilibrium and allele-frequency change alter h^2 , changing the value of σ_z^2 and altering the ultimate limit.

Hill and Mbaga (1998) noted that for standard $\bar{\tau}$ values of 1 to 2 (corresponding to saving between 5% to 35% of the population; Equation 14.3a) and the typically assumed value of ω^2/σ_z^2 of 5 to 20 (Chapter 28), that a total response of 5 to 40 phenotypic standard deviations can occur (assuming the limit is caused by opposing selection, not lack of variation). If the initial mean is zero ($\mu_0 = 0$, i.e., the population mean starts at the optimum), then recalling Equation 25.17d yields a response after an initial generation of selection of

$$R_1 = h^2 S = h^2 \left(\frac{\bar{\tau} \sigma_z \omega}{\sqrt{\sigma_z^2 + \omega^2}} \right) \quad (25.18b)$$

returning the ratio of the total to initial response as

$$\frac{R_c(\infty)}{R_1} = \frac{\sigma_z^2 + \omega^2}{\sigma_z^2 h^2} = \frac{\sigma_z^2 + \omega^2}{\sigma_A^2} \quad (25.18c)$$

The half-life of response (in generations) is

$$t_{0.5} = \ln(2) \frac{\sigma_z^2 + \omega^2}{\sigma_z^2 h^2} \quad (25.18d)$$

as found by James (1962) and Zeng and Hill (1986).

While the population will display additive variation in the selected trait when these forces of directional and stabilizing selection balance, this situation is similar to strict stabilizing selection. As introduced in Example 5.6 (and discussed at length in Chapter 28), in the absence of mutation, strict stabilizing selection eventually results in the loss of essentially all genetic variation (Robertson 1956). Hence, the balance between artificial directional and natural stabilizing selection is not, by itself, sufficient to maintain variation. However, the loss of additive variation may be rather slow once the limit is reached (Chapter 28), leading to the appearance of the maintenance of variation over moderate time scales.

26

Long-term Response:

2. Finite Population Size and Mutation

It is almost impossible with any brevity to exemplify the notion of adaptation. Fisher (1934)

Adaptation depends on how the various evolutionary processes shape variation in populations.
Barton and Partridge (2000)

As we saw in Chapter 18, drift has significant short-term consequences for a population under selection, generating variation around the expected response. Through its role in changing allele frequencies, drift has even more impact over longer time scales. Given that most artificial selection experiments tend to have small effective population sizes, drift is a major factor in the limit of selection response and usually causes a population to plateau at levels below its genetic potential. Another evolutionary force entering into long-term response is mutation. After a sufficient amount of time, new response will be entirely driven by variation that was not present at the start of selection.

This chapter examines the roles of both finite population size and mutation in long-term response, considering how drift interacts with selection to change allele frequencies and how new mutations contribute to selection response. Throughout, we restrict attention to directional selection, deferring the consideration of stabilizing selection until Chapter 28. To distinguish between the contributions of initial variation and new mutation to selection responses, we use **long-term response** to refer to the gain due to variation in the population at the start of selection. As this initial variation is progressively exhausted, response from this component reaches a selection limit. The actual response, however, can continue well past this limit due to the input from new mutation, eventually (under constant selection) approaching an **asymptotic rate of response**, wherein the contribution to σ_A^2 from new mutation is balanced by its removal by drift and selection.

Much of the material here builds on results from Chapter 7 on the interaction between selection and drift, and it may prove useful to review that material before proceeding. This chapter is organized as follows. First, we review a few key results from Chapter 7, and then we expand on our brief discussion from Chapter 3 on the subtle (but important) effects of selection in decreasing the effective population size. We then turn to drift and mutation. Historically, long-term response theory focused solely on the effects of drift, and was only augmented later to include the role of mutation. Our discussion follows this same historical development by first considering Robertson's theory for the expected response in the presence of drift using only the initial variation.

Two important results emerge from Robertson's work. First, he obtained a *simple upper bound* of $2N_e R(1)$, twice the effective population size times the response in the first generation, for the selection limit. This simple, and rather general, result is in sharp contrast to the lack of such an analytical bound (based on easily quantified measures) under completely deterministic theory (Chapter 25). Second, there is an *optimal selection intensity*. If there is a fixed number of measured individuals, as we increase the selection intensity (and hence the short-term response), we do so at the expense of reducing the effective population size, thus reducing long-term response. We conclude our discussion of Robertson's theory by considering extensions allowing for linkage and various aspects of population structure (such as family selection, drift in the base population, and selection in a subdivided population).

Finally, we consider the effects of new mutations, both in terms of their (generally) minor role at the start of selection (except for rare mutations of large effect), and their

growing role as drift and selection erode the initial variance, which eventually leads to an asymptotic rate of response biased entirely on mutational input. Over sufficiently long time scales, response to continual directional selection is due to the fixation of a series of new mutations, an **adaptive walk**, which is examined in Chapter 27.

THE POPULATION GENETICS OF SELECTION AND DRIFT

In Chapter 7 we examined the interaction of selection and drift at a single locus, and we briefly review a few of the key results here. If the population size is finite, a favorable allele may become lost, and hence our interest is in u , the probability that an allele is fixed. In an infinite population, $u = 1$ for an allele favored by selection (provided it is not overdominant). In a finite population, $u < 1$, and its particular value depends on (among other things) its initial frequency, p_0 , and the effective population size, N_e . Let $u(p_0)$ denote the probability that an allele starting at an initial frequency of p_0 becomes fixed. Recall from Chapter 2 that the fixation probability of a neutral allele depends only on its initial frequency, with

$$u(p_0) = p_0 \quad (26.1)$$

This independence from population size is not the case for an allele under selection. For additive selection (with fitnesses of $0 : s : 2s$)

$$u(p_0) \simeq \frac{1 - e^{-4N_e sp_0}}{1 - e^{-4N_e s}} \quad (26.2a)$$

$$\simeq p_0 + 2N_e s p_0 (1 - p_0) \quad \text{when} \quad 2N_e |s| \leq 1 \quad (26.2b)$$

Equation 26.2a, from Kimura (1957), is derived using diffusion theory in Appendix 1, and values of $u(p_0)$ are plotted in Figure 26.1. Equation 26.2b, which is from Robertson (1960a), uses the approximations $e^{-x} \simeq 1 - x + x^2/2$ and $(1 - x)^{-1} \simeq 1 + x$ (both for $|x| \ll 1$) to simplify Kimura's result under weak selection. Equation 26.2b shows that

$$u(p_0) \simeq p_0 \quad \text{if} \quad 2N_e |s| \ll 1 \quad (26.2c)$$

Comparing this result to Equation 26.1 shows that an allele whose selection coefficient satisfies $2N_e |s| \ll 1$ behaves as if it were neutral over all allele frequencies, and it is called **effectively neutral** to reflect this fact. Equations 7.18–7.20 present corresponding expressions for the probability of fixation when dominance is present.

Even when an allele is strongly selected ($4N_e s \gg 1$), drift is important when its frequency is near zero or one. Taylor-expanding the numerator of Equation 26.2a yields

$$1 - e^{-4N_e sp_0} \simeq 1 - (1 - 4N_e sp_0) = 4N_e sp_0, \quad \text{or} \quad 2s \frac{N_e}{N} \quad \text{for} \quad p_0 = \frac{1}{2N}$$

Hence, the probability of fixation starting with a single copy, $p_0 = 1/(2N)$, of an advantageous allele is approximately $2s(N_e/N)$ when $4N_e s \gg 1$, implying that a favorable allele introduced as a single copy is usually lost by drift. Conversely, the fixation of a favored allele becomes almost certain as its frequency becomes sufficiently large. Equation 26.2a shows that if $p_0 \geq 1/(2N_e s)$, the probability of fixation exceeds 0.86, while if $p_0 \geq 1/(N_e s)$, the probability of fixation exceeds 0.98. Thus, if a favorable allele initially increases by drift, it can reach a threshold frequency above which deterministic selection dominates, which rapidly increases its frequency toward 1.0. As it approaches a frequency of 1.0, drift will again dominate, fixing the allele much more rapidly than expected under deterministic selection (Example 8.1).

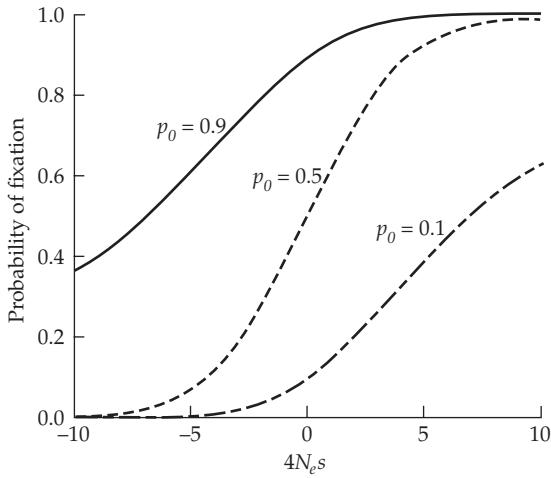

Figure 26.1 The probability of fixation of an additive allele as a function of $N_e s$ and its initial allele frequency, p_0 (from Equation 26.2a).

Finally, recall the Cohan effect (Example 7.4), which states that uniform selection can result in greater between-replicate divergence than drift. This occurs because the between-line divergence is maximized when the fixation probability of an allele is 0.5. Given that the fixation probability under neutrality is p_0 , selection results in greater divergence than it does under neutrality when $u(p_0)[1 - u(p_0)] > p_0[1 - p_0]$. Figure 7.3 shows that the conditions for this to occur are not very restrictive under additive selection. As is discussed below, the Cohan effect has implications when crossing and then reselecting replicate lines.

Fixation Probabilities for Alleles at a QTL

We can translate the above results (and those from Chapter 7) for the fixation probability of an allele given its additive (s) and dominance (h) effects on *fitness* into the fixation probability for a favorable QTL allele as a function of its additive (a) and dominance (k) effects on the *trait* under selection. When the locus has only a small effect on the character, selection coefficients of $s = \bar{t}a/\sigma_z$ and $h = k$ (Equation 25.4) can be used in conjunction with Equation 7.18a to obtain fixation probabilities. If the allele displays no dominance in the character ($k = 0$), previous results imply that the probability of fixation exceeds 0.86 when $N_e s p_0 \geq 1/2$, or

$$N_e \left(\bar{t} \frac{a}{\sigma_z} \right) p_0 \geq 1/2 \quad (26.3a)$$

For the fixation probability to exceed 0.86, the starting allele frequency must exceed

$$p_0 > \frac{\sigma_z}{a 2 N_e \bar{t}} \quad (26.3b)$$

The fixation probability exceeds 98% when $N_e s p_0 > 1$, which corresponds to a critical allele frequency of twice that given by Equation 26.3b, namely,

$$p_0 > \frac{\sigma_z}{a N_e \bar{t}} \quad (26.4)$$

Note that if the product of initial allele frequency and its standardized effect, $p_0|a|/\sigma_z$, is sufficiently small, drift will dominate even if selection (\bar{t}) on the character is strong. With small values of $N_e \bar{t}$, only alleles of large effect or at moderate to high frequency are likely to be fixed by selection. As $N_e \bar{t}$ increases, favored alleles with smaller effects, or at lower frequencies, are increasingly more likely to become fixed. As a technical aside, the

careful reader might recall from Chapter 14 that sampling causes fluctuations in \bar{t} in a finite population. This additional complication need not overly concern us, as Hill (1969a, 1985) and Kojima (1961) showed that the error introduced by assuming a constant \bar{t} is small.

Increased Recombination Rates Following Selection

We previously discussed the Hill-Robertson effect (Chapters 3, 7, and 8), wherein the effective population size is reduced in regions linked to a selected site, and in Chapter 4 we examined the evolution of the recombination rate. Otto and Barton (1997) showed that alleles at modifier loci that increase the recombination rate also increase the probability of fixation of favored alleles at selected loci linked to the modifier (also see Felsenstein 1974; Felsenstein and Yokoyama 1976). This can result in recombination modifiers hitchhiking along to fixation with the favored mutations. Such modifiers are favored because under low recombination, the effective selection coefficient on a particular mutation affecting a character depends on the selection coefficients at linked loci (e.g., Equation 7.42). Thus, the fate of a particular mutant is highly dependent upon the background in which it arose. As recombination increases, the fate of a mutation becomes increasingly uncoupled from the fate of its initial background. Rice and Chippindale (2001) experimentally demonstrated this by showing that the fixation probability of a mutation favored by artificial selection (white eye color in *Drosophila*) increased with the recombination rate. Otto and Barton's theory makes the prediction that recombination rates may increase in selected populations relative to unselected controls, which is indeed observed in some experiments.

Example 26.1. Korol and Iliadi (1994) subjected a *Drosophila melanogaster* population to divergent selection for positive and negative geotaxis (an increased tendency to fly up and down, respectively). Recombination frequencies were scored on the unselected controls and the positively (geo^+) and negatively (geo^-) selected lines, with chromosomes II, III, and X scored after 36, 40, and 44 generations of selection. Over the scored regions (roughly 220 cM in the control), the map distance in the geo^+ line increased by a total of 78 cM (35%), while the geo^- line increased by 66 cM (30%). Presumably, these increases resulted from the increased probability of fixation of favorable mutations linked to modifiers increasing recombination frequencies. Other experiments in *Drosophila* also showed an increase in the recombination frequency following either directional or stabilizing selection (e.g., Thoday et al. 1964; Flexon and Rodell 1982; Zhuchenko et al. 1985; Rodell et al. 2004). A potentially related observation is that by Morran et al. (2009), who found that a collection of wild-type populations of the nematode *C. elegans* that were exposed to a bacterial pathogen had elevated rates of outcrossing compared with a set of controls that were not exposed. One concern with any such list of positive results is ascertainment bias, reporting a positive finding when it is present, but not when it is absent, thus inflating its apparent importance.

THE EFFECT OF SELECTION ON EFFECTIVE POPULATION SIZE

The simple act of selecting on a trait reduces the effective size, N_e , of a population below its actual size, N . Part of this is obvious, in that artificial selection proceeds by first choosing M (random) individuals to score and then selecting a fraction p of these to reproduce. Hence, $N_e \leq pM < N$, with stronger selection (smaller p) increasing the reduction in effective population size. As introduced in Chapter 3, there is a second, and much more subtle, effect that further reduces N_e for a selected population below that of an unselected control population with the same number of parents (i.e., $N_e < pM$). This additional reduction arises because selection inflates the variance in offspring number (more offspring are chosen from favorable families), reducing N_e . The initial realization of this phenomenon is often attributed to Morley (1954), who noted in sheep flocks exposed to selection that “the genetically superior

individuals will tend to be most inbred,” a result of a smaller (inbreeding) effective population size in the selected population relative to a control population of the same census size. However, Lush (1946) also very clearly understood this process, noting the “correlation between the fates of relatives” under selection and how this is expected to inflate the variance in offspring number.

While the effective size of a population under artificial selection can be retrospectively computed from either pedigree information or from the sampling variance in marker-allele frequencies (Chapter 4), predicting N_e in advance is more difficult. Its exact value depends on a variety of assumptions about both the family and population structure, and also on the underlying genetic model (the infinitesimal model is typically assumed). Theoretical investigations of the effects of selection on N_e were initiated by Robertson (1961), who presented simple approximations for both the single generation change and the asymptotic change following many generations of selection (Equations 3.29a and 3.29c).

Two different approaches have been used to examine the reduction in N_e from selection on unlinked loci. The first computes the expected variance in gene frequency for a neutral locus that is unlinked to any locus under selection (Robertson 1961; Nei and Murata 1966; Caballero 1994; Santiago and Caballero 1995), while the second computes the rate of inbreeding from the number of ancestors (Burrows 1984a, 1984b; Wooliams 1989; Verrier et al. 1990; Wray and Thompson 1990; Wray et al. 1990, 1994; Wooliams et al. 1993). The former corresponds to the variance effective population size, and the latter to the inbreeding effective population size. Strictly speaking, results based on diffusion theory require the usage of the variance effective size (as diffusion approximations use the sample variance in allele frequency). However, as discussed in Chapter 3, inbreeding and variance effective population sizes are usually equivalent unless the population size is changing over time. While all these treatments of the impact of selection on N_e consider the effective population size experienced by a neutral locus unlinked to loci influencing the traits under selection, the results should be very similar for selected loci under the infinitesimal model, as in this case drift (rather than selection) provides the major impetus for allele-frequency change.

The Expected Reduction in N_e from Directional Selection

Before proceeding, we will briefly review some results from Chapter 3. In the following discussion, N refers to the number of parents, pM . One of the assumptions of an ideal population (where the actual size, N , equals the effective size, N_e) is that all parents have an equal chance of contributing offspring. Equation 3.4 shows that variance, σ_k^2 , in the number of offspring contributed by an individual reduces N_e , as $N_e = (N - 1/2)/(\sigma_k^2/4 + 1/2)$. If the number of offspring per parent follows a Poisson distribution, then $\sigma_k^2 = 2$ and $N_e = N - 1/2 \approx N$. However, if some parents contribute a disproportionate number of offspring, then $\sigma_k^2 > 2$ and $N_e < N$. The more disproportionate the contribution, the larger is the offspring variance and the smaller is N_e .

As in Chapter 3, we use σ_k^2 to denote variation in offspring number for entirely nonheritable reasons. Here, the children of a parent contributing an excessive number of offspring are themselves no more likely to contribute an excessive number. But with selection on a heritable trait, this will no longer be true. A selected parent is likely to have offspring with favorable trait values that then *disproportionately* contribute to the next generation. Following Chapter 3, we separate these two sources of variance in offspring number, letting σ_k^2 refer to the variation in an unselected population and σ_w^2 to the additional among-family genetic variance in relative fitness (due to differential contribution from families with more favorable trait values). Because each family is assumed (on average) to contribute two offspring (in a population maintained at a stable size), the additional variance from selection is $2^2\sigma_w^2$, yielding an effective population size after a generation of selection of

$$N_e = \frac{4N}{\sigma_k^2 + 2 + 4\sigma_w^2} \quad (26.5)$$

Assuming $\sigma_k^2 = 2$ gives

$$N_e = \frac{N}{1 + \sigma_w^2} \quad (26.6a)$$

a result from Robertson (1961). For truncation selection, Robertson (1961) and Milkman (1978) showed that $\sigma_w^2 \simeq \bar{t}^2 t_{FS}$, where $t_{FS} = \text{Cov}(FS)/\sigma_z^2$ is the intraclass correlation of full sibs (LW Equation 17.3). Thus, the reduction in effective population size after a single generation of selection on unlinked loci becomes

$$N_e = \frac{N}{1 + \bar{t}^2 t_{FS}} \quad (26.6b)$$

There are two complications to consider when moving from this simple result for a single generation to the reduction in N_e over multiple generations of selection. First, as selection proceeds, genetic variances change, which in turn changes t_{FS} . The second complication, which was briefly noted in Chapter 3, is that continued selection has a *cumulative* effect. Robertson (1961) approximated this effect by noting that only half of the association between a neutral locus and unlinked loci under selection persists in each generation, yielding the among-family variance after τ generations of selection as

$$(1 + 1/2 + 1/4 + \cdots + 1/2^\tau)^2 \sigma_w^2 = Q_\tau^2 \sigma_w^2$$

where Q_τ is the cumulative effect of τ generations of selection. Equation 26.6a thus becomes

$$N_{e,\tau} = \frac{N}{1 + Q_\tau^2 \sigma_w^2} = \frac{N}{1 + Q_\tau^2 \bar{t}^2 t_{FS}} \quad (26.6c)$$

Q_τ approaches a limiting value of $Q = 2$, which yields Equation 3.29c, Robertson's long-term effective population size of $N/(1+4\sigma_w^2)$. As noted in Chapter 3, this result is approximate for several reasons, most importantly because selection also reduces genetic variation, resulting in less than half of the value from the previous generation being passed along.

A more complete treatment was given by Santiago and Caballero (1995), who obtained a general expression for N_e under selection that allows for nonrandom mating. Assuming random mating, their expression for N_e after τ generations of selection is

$$\frac{N_{e,\tau}}{N} = \left[\frac{1 - \gamma}{2} + \left(\frac{\sigma_k^2}{4} + Q_{*\tau}^2 \sigma_w^2 \right) (1 + \gamma) \right]^{-1} \quad (26.6d)$$

where $\gamma = -1/(N - 1)$ is a measure of the departure from Hardy-Weinberg due to finite population size (we generally assume that $\gamma \simeq 0$), and $Q_{*\tau}$ (given below; see Equation 26.9a) is a generalization of Robertson's Q_τ . For a single generation of selection, $Q_{*1} = 1$, implying that σ_w^2 is the effect of selection in the current generation, while $(Q_{*\tau}^2 - 1)\sigma_w^2$ is the cumulative effect of selection in previous generations. As will be shown, $Q_{*\tau}$ is a function of the selection intensity and heritability. Assuming that N is large (so $\alpha \simeq 0$) and a Poisson distribution of offspring in the absence of selection ($\sigma_k^2 = 2$), Equation 26.6d reduces to Equation 26.6c, but with $Q_{*\tau}$ replacing Q_τ . We are still, however, left with two complications—obtaining the value of t_{FS} , and finding $Q_{*\tau}$ —which we address in turn.

Under the infinitesimal model, all of the selection-induced change in genetic variance is due to gametic-phase disequilibrium (Chapters 16 and 24). In Chapter 16 we showed that $\sigma_A^2 = \sigma_a^2 + d$, where σ_a^2 (the additive genic variance) is the additive genetic variance in the absence of disequilibrium and d is the disequilibrium contribution. Under the infinitesimal model, the within- and among-family contributions to the additive genetic variance differ, as (for unlinked loci) the within-family contribution ($\sigma_a^2/2$) is not influenced by disequilibrium, while the among-family variance ($\sigma_a^2/2 + d$) is (Chapter 16). Assuming the absence of both dominance and shared sib environmental effects, the intraclass correlation becomes

$$t_{FS} = \frac{\sigma_a^2/2 + d}{\sigma_A^2 + \sigma_E^2} = \frac{\sigma_a^2/2 + d}{\sigma_a^2 + d + \sigma_E^2} = \frac{h_0^2/2 + d/\sigma_{z(0)}^2}{1 + d/\sigma_{z(0)}^2} \quad (26.7a)$$

where h_0^2 and $\sigma_{z(0)}^2 = \sigma_a^2 + \sigma_E^2$ are, respectively, the heritability and phenotypic variance in the unselected base population ($d = 0$). Increasing either \bar{t}^2 or h^2 increases $\sigma_w^2 = \bar{t}^2 t_{FS}$, which in turn decreases N_e . Dominance variance does not change under the infinitesimal model (Chapter 16), so when it, or a common-family effect, occur, both appear as constants in the numerator and denominator of Equation 26.7a.

We now have all of the results needed to compute an improved expression for the single-generation reduction in N_e . Expressing the fraction of phenotypic variance in the selected parents as $\sigma_{z^*}^2/\sigma_z^2 = (1 - \kappa)$, Equation 16.7a yields $d(1)/\sigma_{z(0)}^2 = -\kappa h_0^4/2$ (Equation 16.11a gives κ as a function of \bar{t}). Substituting this value for $d(1)/\sigma_{z(0)}^2$ into Equation 26.7a,

$$t_{FS}(1) = \frac{h_0^2(1 - \kappa h_0^2)/2}{1 - \kappa h_0^4/2} \quad (26.7b)$$

Recalling that $Q_{*1} = 1$, Equation 26.6d (assuming $\gamma = 0, \sigma_k^2 = 2$) yields a reduction in N_e from a single generation of selection of

$$N_{e,1} \simeq N \left(1 + \bar{t}^2 \frac{(h_0^2/2)(1 - \kappa h_0^2)}{1 - \kappa h_0^4/2} \right)^{-1} \quad (26.8)$$

This result was first obtained by Robertson (1961), who did not include the $(1 - \kappa h_0^4/2)$ term, which was subsequently added by Wray and Thompson (1990).

Turning to $Q_{*\tau}$, the cumulative effect of past selection, Santiago and Caballero (1995) showed that

$$Q_{*\tau} = 1 + \frac{G}{2}(1 + \rho) + \cdots + \left[\frac{G}{2}(1 + \rho) \right]^\tau = \sum_{i=0}^{\tau} \left[\frac{G}{2}(1 + \rho) \right]^i \quad (26.9a)$$

where G is the fraction of genetic variance remaining after selection and ρ is the correlation between the selective values of mates ($\rho = -1/[N - 1]$ under random mating). If $(1 - \kappa)$ is the fraction of phenotypic variance after selection, then $G = 1 - \kappa h^2$ is the fraction of additive variance (Chapter 16). As with t_{FS} , G (and hence $Q_{*\tau}$) depends on a parameter (h^2) that changes under selection. However, recall from Chapter 16 that, under the infinitesimal model, h^2 quickly reaches its equilibrium value under directional selection (in roughly two or three generations). Thus, we typically use $G = 1 - \kappa \hat{h}^2$, a function of the equilibrium heritability under the effects of selection and disequilibrium alone. In the limit ($\tau \rightarrow \infty$), the sum in Equation 26.9a converges to

$$\tilde{Q}_* = \frac{2}{2 - G(1 + \rho)} \simeq \frac{2}{1 + \kappa \hat{h}^2} \quad \text{when } \rho \simeq 0 \quad (26.9b)$$

Robertson assumed a limiting value of $Q = 2$, but Equation 26.9b shows that this is an overestimate, which results in an underestimation of N_e . Substitution of Equation 26.9b into Equation 26.6c recovers Equation 3.29b (with the latter expressed in terms of $L = 1 - G$, where $L = \kappa h^2$ is the fractional loss of additive variance).

The general prediction that effective population size decreases in selected populations has been examined in a number of *Drosophila* experiments, where inbreeding is estimated directly from parental pedigrees. This prediction has generally been confirmed, with a reasonable fit to Robertson's theory (McBride and Robertson 1963; Jones 1969a, 1969b; López-Fanjul 1989). As expected from Equation 26.8, N_e is lowest in lines showing the greatest response to selection, as these lines have the highest realized heritabilities. Gallego and López-Fanjul (1983) tested a second prediction using selection on sternopleural bristles: because the reduction in N_e occurs from among-family selection (inflating the among-family variance, σ_k^2), no reduction in N_e is expected under within-family (full-sib) selection (Chapter 21). In accordance with theory, no reduction was observed.

As reviewed in Chapter 25, reproductive fitness often declines during long-term selection experiments. This can result in a further increase in the variance in fitness among individuals, which in turn further increases the variance in offspring number (as the latter is a measure of fitness). This increased variance can significantly decrease the effective population size below that predicted by Equation 26.8, which incorporates only the variance effects associated with artificial selection. Yoo (1980c) found that differences in fertility were more important in reducing effective population size than the effects of artificial selection during a long-term selection experiment for increased *Drosophila* bristle number.

Example 26.2. Consider directional truncation selection on a normally distributed character in which the uppermost 20% of the population ($p = 0.2$) is saved. From Example 16.3, this yields a selection intensity of $\bar{t} = 1.40$ and a reduction in variance of $\kappa = 0.781$. If we assume initial (before selection) values of $h_0^2 = 0.5$ and $\sigma_{z(0)}^2 = 100$, Example 16.2 yields (under the infinitesimal model) equilibrium values of $\hat{d} = -12.54$ and $\hat{h}^2 = 0.428$. Hence

$$G = 1 - \kappa \hat{h}^2 = 1 - 0.781 \cdot 0.428 = 0.665$$

Because we are assuming no dominance or common-family effects, the initial value of t_{FS} in the base population is $h_0^2/2 = 0.25$, while its equilibrium value becomes

$$\hat{t}_{FS} = \frac{h_0^2/2 + \hat{d}/\sigma_{z(0)}^2}{1 + \hat{d}/\sigma_{z(0)}^2} = \frac{(0.5/2) - (12.54/100)}{1 - (12.54/100)} = 0.142$$

Hence, $\sigma_w^2 = \bar{t}^2 \cdot \hat{t}_{FS} = 1.4^2 \cdot 0.142 = 0.279$. Assuming $\rho = -1/(N-1) \simeq 0$, Equation 26.9b yields

$$\tilde{Q}_* = \frac{2}{2-G} = \frac{2}{2-0.665} = 1.498$$

Equation 26.6c yields an equilibrium effective population size of

$$N_e = \frac{N}{1 + \tilde{Q}_*^2 \sigma_w^2} = \frac{N}{1 + 1.498^2 \cdot 0.279} = 0.615 N$$

In contrast, using Robertson's approximation ($Q = 2$) in place of \tilde{Q}_* in the previous expression returns a smaller value, $N_e = 0.473 N$. Similar calculations using other p values (a smaller p equals stronger selection) yields

p	κ	\hat{d}	\hat{t}_{FS}	G	σ_w^2	\tilde{Q}_*	N_e/N
0.50	0.64	-10.92	0.16	0.72	0.10	1.56	0.80
0.10	0.83	-13.05	0.14	0.65	0.42	1.48	0.52
0.05	0.86	-13.36	0.13	0.64	0.57	1.47	0.45
0.01	0.90	-13.76	0.13	0.62	0.93	1.45	0.34

Example 26.3. Cohan and Hoffmann (1986) examined the divergence between replicate lines of *Drosophila melanogaster* selected for increased resistance to ethanol. The selected lines had a higher among-line variance for characters associated with increased resistance than did the unselected control replicates. This could be explained by a reduction in effective population size due to selection or by the Cohan effect (Example 7.4). The reduction in effective population size, by increasing drift, is expected to increase the among-line variance in *any* character, selected or unselected. Conversely, the Cohan effect predicts that only characters under selection, or characters controlled by loci tightly linked to QTLs for these selected characters, should show increased divergence. Cohan and Hoffmann found no differences between the selected and control lines for three unselected characters, which suggested that the main cause of increased divergence was the Cohan effect.

DRIFT AND LONG-TERM SELECTION RESPONSE

Recall that in our distinction between long-term and asymptotic response, the former is attributable to the existing variation at the start of selection, while the latter is the expected eventual rate of response due to the input of new mutation. When the effective population size is small, essentially all of the observed response is due to the initial variation, with the population reaching an apparent limit until the appearance of new mutations allows for further response. In larger populations, these two components of response become more difficult to separate, and no limit may be observed when in fact all of the initial variation has been exhausted. Much of the initial theory of long-term response ignored mutation, and we examine this drift-only version first, as it provides a good description of how a population exhausts its initial variation.

Basic Theory

We expect the response to selection in very small populations to be significantly influenced by drift, showing less total response than in larger populations starting with the same initial genetic variance. A fairly extensive theory examining the effects of drift on long-term response (the utilization of the initial genetic variation) has been developed, starting with the extremely influential paper of Robertson (1960a). Most of this theory is based on summing over single-locus results, which we adhere to unless stated otherwise (this assumes that epistasis and linkage effects can be ignored).

As before, we first consider a single diallelic locus (indexed by i) where the genotypes $aa : Aa : AA$ have genotypic values (for the character under selection) of $0 : a(1 + k) : 2a$. Let p_t denote the frequency of A at this locus in generation t , $\Delta_i(t)$ be the contribution to total response from this locus in generation t , and $u_i(p_0)$ be the probability that A is ultimately fixed at this locus, provided it starts at a frequency of p_0 . The total response is obtained by summing over all loci, $R(t) = \sum_i \Delta_i(t)$. Under drift, both p_t and $\Delta_i(t)$ are random variables and (assuming that the genotypes are in Hardy-Weinberg proportions) are related by

$$\begin{aligned}\Delta_i(t) &= m_i(p_t) - m_i(p_0) \\ &= 2a \left[p_t - p_0 + k \left(p_t(1 - p_t) - p_0(1 - p_0) \right) \right]\end{aligned}\quad (26.10a)$$

where $m_i(p)$, the expected contribution to the trait from locus i when the frequency of A is p , is given by Equation 25.1a. The expected contribution (at generation t) from this locus is

$$E[\Delta_i(t)] = 2a \left[E(p_t) - p_0 + k \left(E[p_t(1 - p_t)] - p_0(1 - p_0) \right) \right] \quad (26.10b)$$

Because A is ultimately either fixed ($p_\infty = 1$) or lost ($p_\infty = 0$), $E(p_t)$ converges to

$$1 \cdot u_i(p_0) + 0 \cdot [1 - u_i(p_0)] = u_i(p_0)$$

while $E[p_t(1 - p_t)]$ converges to zero. The limiting expected contribution from locus i becomes

$$E[\Delta_i(\infty)] = 2a \left[u_i(p_0) - p_0 - k \left(p_0(1 - p_0) \right) \right] \quad (26.11a)$$

Two cases of special interest are when A is additive ($k = 0$), yielding

$$E[\Delta_i(\infty)] = 2a [u_i(p_0) - p_0] \quad (26.11b)$$

and when A is recessive ($k = -1$), in which case

$$E[\Delta_i(\infty)] = 2a [u_i(p_0) - p_0^2] \quad (26.11c)$$

The variance (and indeed all higher moments) of the total response at the selection limit are easily computed, as, regardless of the value of k , $\Delta_i(\infty)$ takes on only two values,

$$\begin{aligned}\Delta_i(\infty) &= 2a - m_i(p_0) \quad \text{with probability } u_i(p_0) \\ &= 0 - m_i(p_0) \quad \text{with probability } 1 - u_i(p_0)\end{aligned}\quad (26.12)$$

In particular, the variance in the contribution from this locus over replicate selected lines is

$$\begin{aligned}\sigma^2 [\Delta_i(\infty)] &= E [\Delta_i^2(\infty)] - \left(E [\Delta_i(\infty)] \right)^2 \\ &= 4a^2 u_i(p_0) [1 - u_i(p_0)]\end{aligned}\quad (26.13a)$$

With weak selection, $u_i(p_0) \simeq p_0$ (i.e., the allelic dynamics are largely governed by drift), implying

$$\sigma^2 [R(\infty)] \simeq 4 \sum a^2 p_0 (1 - p_0) \quad (26.13b)$$

which is twice the initial additive-genetic variation (assuming that all loci are additive), and also is the expected among-line divergence under pure drift (Chapter 11). Under sufficiently strong selection, almost all favorable alleles will be fixed and the variance will be close to zero, as $u_i(p_0) \simeq 1$. When selection is moderate to weak, loci for which $u_i(p_0)[1 - u_i(p_0)] > p_0(1 - p_0)$ show a Cohan effect. If such loci are sufficiently frequent, selection increases the among-line variance relative to drift. This requires both weak selection and that most favored alleles be rare. The variance in response at the selection limit was considered in more detail by Hill and Rasbash (1986), Zeng and Cockerham (1990), and Zhang and Hill (2005a).

The variance in the selection limit across replicate lines has a direct bearing on whether further response can occur by crossing plateaued lines and then reselecting. If drift has played a significant role in the selection response, a line formed by crossing replicate plateaued lines should show further response to selection, as each line should be fixed for a considerable number of unfavorable alleles. In particular, with weakly selected loci, the Cohan effect can inflate the among-replicate variance over that expected under drift, increasing the potential for additional response when crossing weakly selected lines over that expected from crossing lines generated by drift alone.

Replicate lines at their selection limits usually show considerable genetic differences (reviewed by Cohan 1984a, 1984b). For example, Scowcroft (1965) used chromosomal analysis to show that three replicate *Drosophila* lines selected for increased scutellar bristles differed considerably in the amount of response attributable to each chromosome and the nature of interactions between chromosomes. Synthetic lines formed by crossing either replicate plateaued lines (Frankham et al. 1968b; Eisen 1975; Frankham 1980) or unrelated plateaued lines (Falconer and King 1953; Roberts 1967) generally respond to selection.

An interesting exception was revealed by Gallego and López-Fanjul (1983), who selected on sternopleural bristle number in *Drosophila*. Replicate lines showed a very rapid exhaustion of response, and crosses between lines did not result in further response. The authors interpreted these results as being consistent with a few alleles of large effect, which were initially at an intermediate frequency. These alleles rapidly go to fixation, with all lines being fixed for the same major alleles. Similarly, Skibinski and Shereif (1989) found that the among-line variance of lines selected for sternopleural bristle number decreased over time. The among-line variance is expected to increase over time if drift dominates (e.g., Equation 12.1b) or if there is weak selection on the underlying loci, but it is expected to decrease if the lines are fixed for the same few major genes.

Robertson's Theory of Selection Limits

Equations 26.10–26.13 are fairly general, assuming only Hardy-Weinberg, no epistasis, and that single-locus results can be added across loci. To proceed further, we need explicit

expressions for $u_i(p_0)$ to describe the limit, and for both $E(p_t)$ and $E[p_t(1 - p_t)]$ to describe the dynamics. The most complete description, by Robertson (1960a), is for additive alleles, where $E[\Delta_i(t)] = 2a[E(p_t) - p_0]$. Recalling Equation 7.28a yields

$$E(p_t) \simeq p_0 + 2N_e \left(1 - e^{-t/2N_e}\right) s p_0(1 - p_0)$$

as an approximate expression for the expected allele frequency, under the assumption that the allele has a small effect (i.e., is nearly neutral). For notational ease, we will drop the expectation notation, but the reader should keep in mind that we are examining the expected response. Recalling from Equation 25.4 that $s = a\bar{i}/\sigma_z = aS/\sigma_z^2$ (as $\bar{i} = S/\sigma_z$), substitution into Equation 7.28a yields an expected response from locus i after t generations of selection of

$$\Delta_i(t) = 2a[E(p_t) - p_0] \simeq 2N_e \left(1 - e^{-t/2N_e}\right) \left(\frac{aS}{\sigma_z^2}\right) 2a p_0(1 - p_0) \quad (26.14a)$$

This can be simplified further by noting that $2a^2 p_0(1 - p_0)$ is the initial additive variance contributed by the locus. Because we assumed no epistasis and no linkage disequilibrium, summing over all loci gives the cumulative response at generation t as

$$R(t) \simeq 2N_e \left(1 - e^{-t/2N_e}\right) \frac{S\sigma_A^2(0)}{\sigma_z^2} \quad (26.14b)$$

Note that $S\sigma_A^2(0)/\sigma_z^2 = Sh^2(0) = R(1)$ is the expected response in the first generation, provided that the conditions for the breeder's equation hold. Equation 26.14b implies that

$$R(t) \simeq 2N_e \left(1 - e^{-t/2N_e}\right) R(1) \quad (26.15a)$$

returning an expected limiting total response of

$$R(\infty) \simeq 2N_e R(1) \quad (26.15b)$$

Because $R(1)/\sigma_z = h^2 S/\sigma_z = h^2 \bar{i}$, the expected limiting response in terms of phenotypic standard deviations is

$$R(\infty)/\sigma_z \simeq h^2(2N_e \bar{i}) \quad (26.15c)$$

Note that Equation 26.15a motivates the use of exponential regressions in Chapter 25 to estimate selection limits (Equation 25.10). The careful reader will note that we assumed that the phenotypic variance remains relatively constant over time, as would occur if h^2 were small (and hence a decrease in the heritability will have little impact on σ_z^2). Provided this assumption holds, the total expected response is simply $2N_e$ times the initial response, as first suggested by Dempster (1955b) and formally derived by Robertson (1960a). An alternative derivation of Equation 26.15a is as follows. Assuming the main force for allele-frequency change is drift, Equation 11.2 yields

$$\sigma_A^2(t) \simeq \sigma_A^2(0)[1 - 1/(2N_e)]^t \simeq \sigma_A^2(0) \exp[-t/(2N_e)] \quad (26.15d)$$

Writing the response in generation t as $h^2(t)S = \sigma_A^2(t)\bar{i}/\sigma_z$, summing over generations and applying Equation 7.28b recovers Equation 26.15a.

Equation 26.15b is an *upper limit* for the total response, which may seem somewhat counterintuitive because it was derived by assuming weak selection. The key to understanding this upper bound is that (everything else being equal) the initial response $R(1)$ when selection dominates is much larger than when drift dominates, so $2N_e$ (the time for drift to remove a significant amount of genetic variation) times the initial response overestimates the total response when selection dominates. To see this point, consider the maximal contribution, $\Delta_i^{max} = 2a(1 - p_0)$, from a locus (which occurs when the favored allele is fixed) relative to the predicted contribution, $\Delta_i(\infty)$. From Equation 26.14a, it follows that

$\Delta_i(\infty) = 2N_e 2a^2 p_0(1 - p_0)S/\sigma_z^2$. Substituting $S/\sigma_z^2 = \bar{t}/\sigma_z$ yields the ratio of maximum to expected contribution as

$$\frac{\Delta_i^{max}}{\Delta_i(\infty)} = \frac{1}{2N_e} \frac{2a(1 - p_0)}{2a^2 p_0(1 - p_0) \bar{t}/\sigma_z} = \frac{\sigma_z}{2N_e \bar{t} a p_0} \quad (26.16a)$$

Thus, $2N_e R(1)$ overestimates the ultimate limit ($\Delta_i(\infty) > \Delta_i^{max}$) when

$$2N_e \bar{t} a p_0 > \sigma_z \quad (26.16b)$$

implying that $2N_e R(1)$ overestimates the ultimate limit when this inequality is satisfied.

Recalling Equation 26.3b, the probability of fixation is greater than 86% when Equation 26.16b is satisfied. Increasing the effective population size above this threshold has little effect on increasing the selection limit, as $u_i(p_0) \simeq 1$ and, hence, the contribution from the i th locus is Δ_i^{max} . In contrast, when the inequality provided by Equation 26.16b fails, $\Delta_i^{max} > \Delta_i(\infty)$. However, in this case drift is expected to dominate (see Equation 26.3a), so we do not expect to obtain the maximal possible response from each locus, as many favored loci will be lost, rather than fixed.

Another quantity of interest is the expected half-life of response, $t_{0.5}$, the time required to obtain half the final response. Recalling Equation 26.14a, and solving $1 - e^{-t_{0.5}/2N_e} = 1/2$, yields an expected half-life of

$$t_{0.5} = N_e \ln 2 \simeq 1.4N_e \quad (26.17)$$

Again, this is an *upper limit*, with the half-life decreasing as the product $N_e \bar{t}$ increases. An observed half-life considerably below that predicted by Equation 26.17 suggests that a large portion of the response is due to the fixation of favorable alleles by selection, as selection (when it dominates) changes allele frequencies much faster than drift.

Equations 26.14–26.17 rely on a number of assumptions besides additivity: no opposing natural selection, no linkage effects, two alleles per locus, and weak selection (on loci). Several authors have examined the robustness of these results. Hill and Rasbash (1986) found, for diallelic loci, that the distribution of allelic effects is relatively unimportant, but differences in allele frequencies can be critical. In particular, increasing the effective population size has much more of an effect on the selection limit when favored alleles are rare. This is expected, as the dynamics of common alleles at selected loci are largely governed by selection rather than drift (Equation 26.3b). Increasing population size lowers the critical allele-frequency threshold for selection to dominate, eventually capturing even rare alleles (Zhang and Hill 2005a). Latter and Novitski (1969) and Zeng and Cockerham (1990) examined the effects of multiple alleles, and found that the results for the expected limit (Equation 26.15b) and the half-life (Equation 26.17) are reasonable when selection is weak. As $N_e \bar{t}$ increases, $R(\infty)/R(1)$ becomes highly dependent on the number and frequencies of alleles at each locus (Chapter 25). In general, this ratio increases with the number of alleles, and decreases with increasing $N_e \bar{t}$, all the while remaining bounded by a factor of $2N_e$. Likewise, $t_{0.5}$ decreases as $N_e \bar{t}$ increases, but it is rather insensitive to the number of alleles.

With dominance, analytic results for the limit and half-life ($R[\infty]$ and $t_{0.5}$) are more complicated. Strictly recessive alleles have received the most study. In this case, the selection limit can considerably exceed $2N_e$ times the initial response when the character is controlled by a large number of rare recessives (Robertson 1960a). Additive genetic variance increases, often considerably, as these recessives increase in frequency, so this result should not be surprising (Chapter 25). With weak selection, the half-life from recessives varies from approximately N_e when $p \simeq 1$ to approximately $2N_e$ when $p \simeq 0$ (Robertson 1960a). Again, as $N_e \bar{t}$ increases, half-life decreases. Even with strictly additive loci, a temporary increase in the genetic variance (even in the face of genetic drift) can occur if there are a number of rare, but favored, alleles (Chapter 25). As these alleles increase in frequency, the additive variance also increases. If genetic drift strictly governs the dynamics of the additive variance, these rare alleles have only a small chance of increasing and do not significantly (on average) inflate the variance. However, if selection is of even modest importance to the dynamics

Table 26.1 Observed and predicted selection limits ($2N_e h^2 \bar{t}$, scaled in terms of σ_z ; Equation 26.15c) and half-lives (scaled in terms of N_e) for a variety of characters in laboratory populations of mice. The Ratio column under Half-life is the fraction of the predicted upper limit for the half-life ($1.4N_e$; Equation 26.17), observed. (From Hanrahan et al. 1973; Eisen 1975; and Falconer 1977.)

at any particular locus, as Chapter 25 highlights, the single-generation response is a very poor predictor of the long-term response.

James (1962), Verghese (1974), Nicholas and Robertson (1980), and Zeng and Hill (1986) extended Robertson's theory for various models of natural selection opposing artificial selection. Not surprisingly, the selection limit is reduced by the presence of opposing natural selection. In the absence of mutation, none of these models retain genetic variability, as drift eventually fixes all loci, even those displaying overdominance in fitness.

TESTS OF ROBERTSON'S THEORY OF SELECTION LIMITS

Robertson's theory applies to the expected response from the existing variation in the base population at the start of selection. Eventually, mutational input becomes important and will ultimately dominate the long-term response, a point we will develop in detail shortly. In the very small population sizes common in many selection experiments, the distinction between exhaustion of the initial variation and the additional response due to new mutation can be fairly clear, as the latter takes many more generations to become apparent than it takes to remove existing variation. For larger population sizes, the two sources of response become increasingly blurred. Hence, most tests of Robertson's theory use very small populations.

Observed limits and half-lives are usually considerably below the values predicted from Robertson's theory (reviewed in Roberts 1966; Kress 1975; Eisen 1980; Falconer and Mackay 1996). Table 26.1 gives various results from experiments with mice. These discrepancies between observation and theory are not unexpected. Robertson's theory assumes that the limit is reached as genetic variance is exhausted by fixation at all loci. As noted in Chapter 25, selection limits can occur despite significant additive genetic variance, often because natural and artificial selection are in conflict. Further, the selection limit of $2N_e R(1)$, and the half-life of $1.4N_e$, are expected *upper* limits that assume that drift largely dominates. An additional complication is that the effective population size is overestimated by taking N_e as the number of parents (Chapter 3). For example, variation in male mating success in *Drosophila* can decrease the effective population size to less than half the actual number of male parents (Crow and Morton 1955). Further, most experiments have not corrected for the expected reduction in N_e from the effects of artificial selection (Equation 26.6c).

Table 26.2 The cumulative response after 50 generations of selection for increased abdominal bristle number in *Drosophila melanogaster* as a function of the effective population size and the selection intensity. N_e is estimated as half the number of parents. None of the lines showed an apparent plateau, but the experiment was stopped after 50 generations. For fixed N_e , the response increases with \bar{i} (compare entries within a column), while for fixed \bar{i} , response increases with N_e (compare entries across a row). (After Jones et al. 1968.)

N_e	\bar{i}	$R(50)$	N_e	\bar{i}	$R(50)$	N_e	\bar{i}	$R(50)$
10	1.6	16.3	20	1.7	20.3	40	1.7	31.7
10	1.3	11.2	20	1.4	14.7	40	1.4	18.8
10	0.9	8.1	20	1.0	12.2	40	1.0	16.4

A more direct test of Robertson's theory evaluates whether the selection limit increases, and the half-life decreases, as $N_e \bar{i}$ increases. In general, both of these predictions hold. For example, the estimated effective population sizes of lines M4, M8, and M16 in Table 26.1 were 7.7, 18.6, and 40.9, while each line experiences essentially the same value of \bar{i} (Eisen 1975). For this data set, half-life decreases as $N_e \bar{i}$ increases, as predicted by theory. In a more extensive experiment, Jones et al. (1968) examined the effects of changing N_e or \bar{i} on otherwise replicate lines of *Drosophila melanogaster*. Because all of their populations were still responding at the end of the experiment (50 generations), they did not estimate the limit or half-lives (although one could use their data with Equation 25.10a to do so). Nevertheless, their data (Table 26.2) are consistent with Robertson's qualitative predictions, as long-term response increases with $N_e \bar{i}$ (Figure 26.2).

Robertson's theory further predicts that when the effective population size is sufficiently large, further increases in N_e should not change the limit (provided mutational input can be ignored), as all favorable alleles that were initially present become fixed. This has yet to be observed, which is perhaps not surprising given that most experiments have values of N_e below 50. By designing ingenious devices to facilitate mass selection in *Drosophila melanogaster*, Weber (1990, 1996, 2004; Weber and Diggins 1990) were able to examine the consequences of larger population sizes. Selection experiments on wing-tip height (Weber 1990) and ethanol tolerance (Weber and Diggins 1990) had effective population sizes on the order of $N_e \simeq 200\text{--}400$. Both characters showed an increased response with increasing N_e . The data for wing-tip height are given in Figure 26.3A. Figure 26.3B summarizes the results of nine other experiments from previous studies, showing the ratio of response after 50 generations to the initial response. As predicted, this ratio generally increases with values of N_e . The implication is that there is additional "usable" genetic variation present in the base population that can be exploited by increasing the scaled strength of selection ($N_e \bar{i}$). In very small populations, only major alleles are influenced by selection (Equation 26.3). The observation that response continues to increase with N_e suggests a large pool of alleles of smaller effects, or at lower frequencies, or both. As $N_e \bar{i}$ increases, favorable alleles at these loci are more likely to become fixed, increasing response. Larger populations also provide a greater chance for recombination to remove deleterious linked combinations, which might be fixed in smaller populations, further increasing the potential for response.

One complication with Robertson's theory is that as population size increases, the contribution from mutational input becomes increasingly important over the time scales that it takes to remove the initial variation. We will address this point shortly. A second complication is that when the character value is influenced by inbreeding depression (as will occur if directional dominance is present), its effects are more dramatic in smaller populations. One test for whether inbreeding depression is reducing the selection response is to cross divergently selected lines and look for significant increases in the mean in the resulting F_1 population (e.g., Eisen 1975; Kownacki 1979).

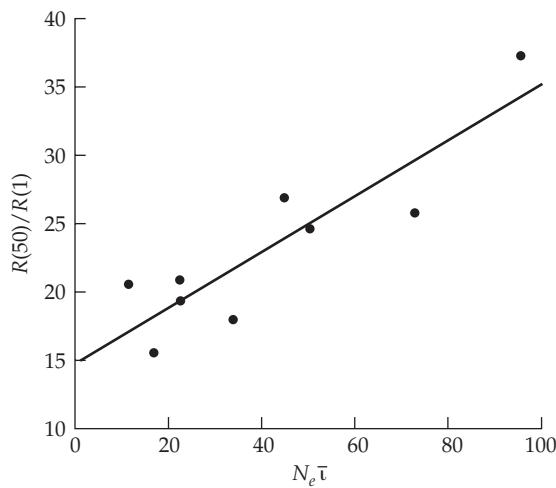

Figure 26.2 Cumulative response at generation 50 as a function of $N_e \bar{t}$ for selection on increased abdominal bristle number in *Drosophila melanogaster*. (After Jones et al. 1968.)

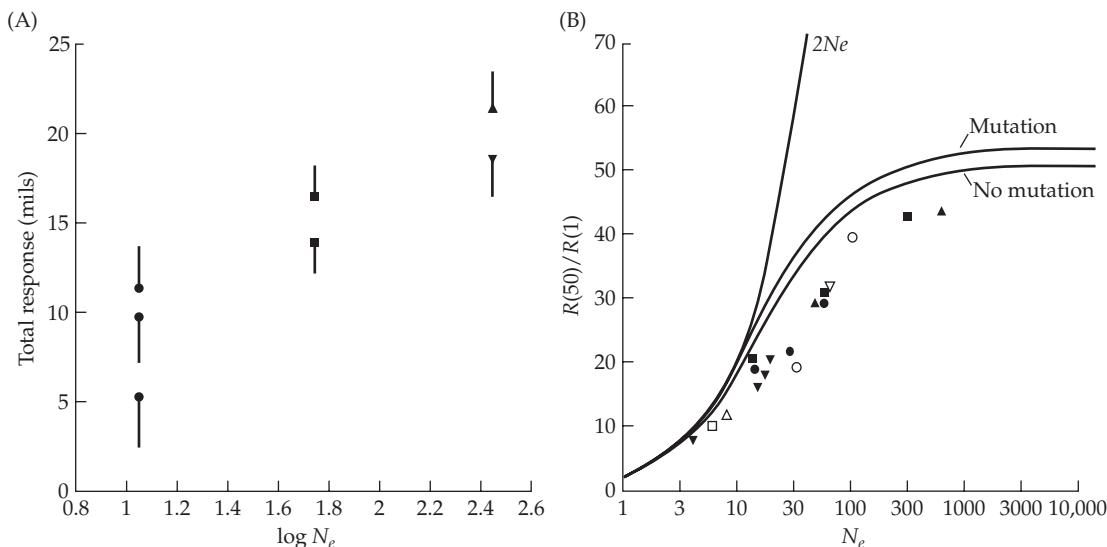

Figure 26.3 **A:** Selection for wing-tip height in *Drosophila melanogaster* (in mils = 0.001 inches). Three replicated selection lines (left to right) with estimated population sizes of 11 (3 replicates), 56 (2 replicates) and 280 (2 replicates) were used. Symbols represent the mean value, while the one-sided whisker shows its associated standard error (displayed in only one direction). Note that the response increases with N_e . (After Weber 1990.) **B:** The ratio of cumulative selection response at generation 50 to response in the first generation as a function of effective population size, for nine different experiments (represented by the different symbols). The lower sigmoidal curve is the prediction given by Equation 26.15a; the upper sigmoidal curve is the prediction given by Equation 26.30c, which allows for response from new mutations (assuming $\sigma_m^2/\sigma_E^2 = 0.001$). The curve marked $2N_e$ is the expected limit under Robertson's additive model (Equation 26.15b). (After Weber and Diggins 1990.)

Weber's Selection Experiment on *Drosophila* Flight Speed

Perhaps the largest long-term artificial selection experiment (outside of microbes) is the heroic effort of Weber, which was introduced in Chapter 25. Weber (1996) scored a total

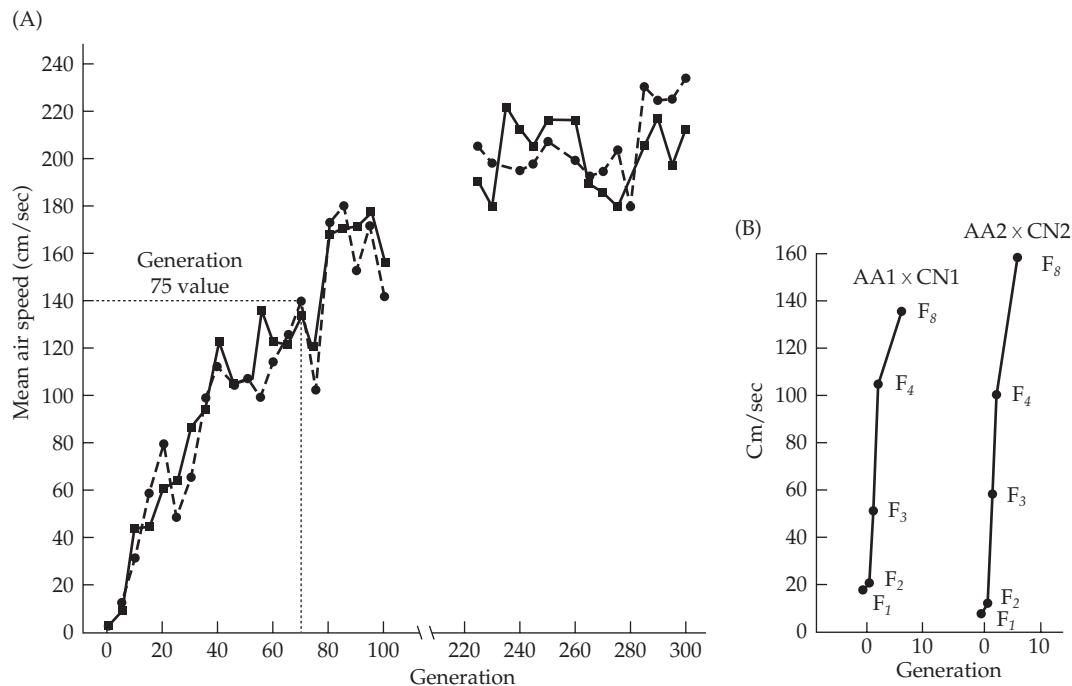

Figure 26.4 Weber's selection experiments for increased flight speed in *Drosophila*. **A:** Results of 300 generations of selection in two replicate lines (circles with dashed lines and squares with solid lines); also see Figure 25.9 for the first 100 generations. (After Weber 2004.) **B:** Response to selection in hybrid sublines formed by crossing two replicate generation 75 selection lines (AA1 and AA2) back to controls (CN1 and CN2). Selection started on the F₂ lines, with only six generations of selection (the F₈ lines) required to recover essentially all of the initial response of ~ 140 cm/sec. (After Weber 1996.)

of over 9,000,000 *Drosophila* for flight speed in two replicate lines subjected to 100 generations of selection (Figure 25.9). The resulting N_e was in the 500–1000 range, with a percent selected of $p = 0.045$ (for a selection intensity of $\bar{t} = 2.11$). The average speed before selection was around 2 cm/second, while the mean speed at generation 100 was 170 cm/sec. As shown in Figure 25.9, response continued in both lines for 100 generations but was diminishing with time, as indicated by a significant quadratic component in the response curve. Figure 26.3A shows the results for over 300 generations of selection from Weber (2004). As of this writing, the experiment is over 650 generations, with response, albeit diminishing, still occurring (Weber, pers. comm.).

Unlike in many artificial selection experiments, there was little slippage upon relaxation of selection and only a minimal loss in fitness relative to the control populations (fitness decreases of 6% and 7% at generations 50 and 85, respectively). Weber attributes this to the larger effective population size, which both reduces the level of inbreeding and allows for more efficient selection on modifiers. The latter can reduce deleterious pleiotropic effects that might accompany major alleles improving flight speed, as the weak second-order effects on modifiers are much easier to select for in larger populations. Larger population sizes also allow recombination to be more efficient, reducing the effects of deleterious alleles linked to alleles improving flight speed.

Weber gained some insight into the genetic nature of the response by examining the selection response in hybrid lines formed by crossing each replicate selection line at generation 75 (lines AA1 and AA2) back to control lines (CN1 and CN2). As Figure 26.4B shows, both the F₁ and F₂ were close to the control line values, indicating very strong dominance for reduced flight speed. Evidence for epistasis was more equivocal. From the theory of line-cross analysis (LW Chapter 9), an estimate of composite epistatic effects is provided by the linear

contrast of means of the parental and first two filial populations, $4\bar{z}_{F_2} - 2\bar{z}_{F_1} - \bar{z}_{P_1} - \bar{z}_{P_2}$, but the resulting value was not significantly different from zero (-38.5 ± 37.5). Selection on both resulting F_2 lines required only six generations to recover essentially all of the response seen in the parental (75-generation) lines (~ 140 cm/sec).

THE EFFECTS OF LINKAGE ON THE SELECTION LIMIT

When QTLs are linked, we expect some reduction in the limit because selection on linked loci reduces the fixation probabilities of beneficial alleles (Hill and Robertson 1966; Birky and Walsh 1988; Barton 1995a). Simulation studies (Fraser 1957; Gill 1965a, 1965b, 1965c; Latter 1965a, 1966a, 1966b; Qureshi and Kempthorne 1968; Qureshi 1968; Qureshi et al. 1968) show that linkage has only a small effect unless loci are very close ($c \leq 0.05$). As mentioned in Chapter 7, most of these studies inflated the importance of linkage by assuming that all loci have equal effects. Simulation studies by McClosky and Tanksley (2013) found only modest reductions ($\simeq 10\%$) in short-term (less than 20 generations) response for populations with normal versus fully unconstrained levels of recombination.

An approximate analytic treatment of linkage was offered by Robertson (1970a, 1977a), and later by Hospital and Chevalet (1993, 1996) and Zhang and Hill (2005a), who relied on certain normality assumptions. In the absence of recombination, selection acts on an entire chromosome, and Robertson framed his results in terms of the response contributed by a single chromosome. Robertson considered three different limiting expected responses, L , corresponding to different amounts of recombination: L_f , the chromosomal limit with free recombination between all loci; L_0 , the limit under complete linkage; and L_ℓ , the limit when the map length of the chromosome is ℓ (implying, for n loci, a recombination rate between the adjacent loci of approximately ℓ/n).

The completely additive model is assumed with loci starting in gametic-phase equilibrium. Let $\sigma_{A^*}^2$ be the initial additive genetic variance contributed by the focal chromosome and define $(h^*)^2 = \sigma_{A^*}^2/\sigma_z^2$ as the initial fraction of phenotypic variance attributable to this chromosome. The expected contribution from this chromosome following a single generation of selection is $S\sigma_{A^*}^2/\sigma_z^2 = \bar{h}^*\sigma_{A^*}$. When $N_e\bar{h}^*$ is small, the expected limit for a chromosome with freely recombining loci is $2N_e$ times the initial response, yielding $L_f \simeq 2N_e\bar{h}^*\sigma_{A^*}$ (Equation 26.15b, considering the response from a single chromosome). Assuming weak selection, Robertson (1970a) found that the ratio of the free-recombination limit to the complete-linkage limit (i.e., the best initial chromosome) is approximately

$$\frac{L_f}{L_0} \simeq 1 + \frac{2}{3}(N_e\bar{h}^*)^2 \quad \text{when } 2N_e\bar{h}^* < 1 \quad (26.18)$$

Hence, for weak selection, complete linkage has only a trivial effect when the chromosome contains a large number of QTLs.

When selection is strong ($N_e\bar{h}^* \gg 1$), the results are more complicated. Robertson assumed that there are n underlying loci, each with a frequency of p of the favored allele, which increases the character by $2a$ (the difference between the homozygotes). Under these assumptions, the additive variance contributed by this chromosome is $\sigma_{A^*}^2 = 2na^2p(1-p)$. If selection is sufficiently strong, under free recombination all favored alleles will be fixed, and the total response becomes $L_f = 2na(1-p)$. Noting that $a = \sigma_{A^*}/\sqrt{2np(1-p)}$, this can also be restated as

$$L_f = 2na(1-p) = \sigma_{A^*} \sqrt{\frac{2n(1-p)}{p}} \quad (26.19)$$

On the other hand, with complete linkage the limit approaches twice the value of the best of the initial $2N$ chromosomes sampled (as this chromosome is ultimately fixed). The expected value for the best chromosome is given by the expected value of the largest order statistic (see Example 6 in LW Chapter 9). For a unit normal, this is expressed in terms of

standard deviations (here σ_{A^*}) above the mean, so that if x_{2N} is the standardized largest order statistic in a sample of $2N$ chromosomes, the limit is given by

$$L_0 = (x_{2N} \sqrt{2}) \sigma_{A^*} \quad (26.20a)$$

Robertson (1970a) showed, for $10 < N < 40$, that $x_{2N} \sqrt{2} \simeq 3$, so that $L_0/\sigma_{A^*}^2 \simeq 3$. Hence, for these values of N ,

$$\frac{L_f}{L_0} \simeq \frac{1}{3} \sqrt{\frac{2n(1-p)}{p}} \quad (26.20b)$$

The factor of 3 increases to 3.8 when $N = 80$ and to 4.6 when $N = 500$. For larger values of N , if we use the asymptotic approximation for the largest order statistic given by Kendall and Stuart (1977), the factor of 3 is replaced by

$$x_{2N} \sqrt{2} \simeq \frac{0.577}{\sqrt{\ln(2N)}} + 2\sqrt{\ln(2N)} \quad (26.20c)$$

Note that the increase in the selection limit is only weakly dependent on N , as the largest order statistic scales as $\sqrt{\ln(2N)}$. For example, for $N = 10^9$, $x_{2N} \sqrt{2} \simeq 9.4$.

Robertson suggested that as the number of loci, n , increases, the limit under free recombination approaches a value independent of n and p , namely, the infinitesimal limit, $L_f = 2N_e \bar{h}^* \sigma_{A^*}$. Thus, with strong selection and a large number of loci, Equation 26.20a implies that

$$L_f/L_0 \simeq \frac{2N_e \bar{h}^* \sigma_{A^*}}{(x_{2N} \sqrt{2}) \sigma_{A^*}} = \left(\frac{\sqrt{2}}{x_{2N}} \right) N_e \bar{h}^* \quad \text{when } N_e \bar{h}^* > 5 \quad (26.20d)$$

Robertson also observed that for $N_e \bar{h}^* > 5$, the half-life with no recombination is

$$t_{0.5} \simeq \frac{2}{\bar{h}^*} \quad (26.20e)$$

generations, and that differences in response (relative to free recombination) only become apparent after this number of generations has passed.

Allowing for some recombination (at a rate of $\sim \ell/n$ between loci), Robertson found that the limit for a chromosome of length ℓ is

$$L_\ell/L_0 \simeq 1 + (N_e \ell / 3) \quad \text{when } N_e \ell \ll 1 \quad (26.21a)$$

To a poorer approximation, over the entire range of $N_e \ell$

$$L_\ell/L_0 \simeq 1 + \frac{K N_e \ell / 3}{N_e \ell / 3 + K} \quad (26.21b)$$

where $K = L_f/L_0$. Thus L_ℓ/L_0 approaches L_f/L_0 as $N_e \ell$ increases. Provided $L_f \gg L_0$, then L_ℓ is halfway between L_f and L_0 when $N_e \ell / 3 = K = L_f/L_0$. Assuming moderate to large values of N_e , this result (together with Equation 26.20d) implies that if the amount of recombination satisfies $\ell > 2\bar{h}^*$, then the selection response will be at least half that expected for free recombination. These expressions are approximate and assume that all loci have equal effects. Variation between loci in allelic effects reduces the effect of linkage (Hill and Robertson 1966; Robertson 1970a).

Experimental results generally confirm that the suppression of recombination has only a modest effect on the selection limit (Example 26.4). This is somewhat at odds with the increase in recombination rates seen during some artificial selection experiments (Example 26.1), although, as mentioned, this view may be tempered if there is significant ascertainment bias in the reporting of increased recombination following selection.

Robertson's result largely focused on the ultimate selection limit, while Hospital and Chevalet (1993, 1996) considered the dynamics of the approach to this limit. In particular, Hospital and Chevalet (1996) explicitly considered the effects of gametic-phase disequilibrium (also see Zhang and Hill 2005a). Initially, selection generates negative gametic-phase disequilibrium, which reduces the initial expressed additive-genetic variance and decreases the response. The tighter is the linkage, the more pronounced is this effect (Chapters 16 and 24). Surprisingly, Hospital and Chevalet (and also Zhang and Hill) showed that linkage can often result in an *increase* in the additive variation in later generations of selection. This seemingly counterintuitive result arises because selection increases the frequency of the gametes carrying the most favored alleles. Because any tightly linked alleles decreasing the trait are also dragged along, this reduces the ultimate selection limit (a phenomenon called **linkage drag**). On the other hand, rare recombination events among such gametes can result in the creation of new, even more favorable gametes, and generating a transient increase in the additive variance as these sweep through the population. Thus, the negative gametic-phase disequilibrium that suppresses the early response stores some genetic variation that can become released (via recombination) in later generations. This effect is most pronounced in larger populations, as in small populations, haplotypes can become fixed before such recombination events occur.

Example 26.4. By using the inversions *Curly* and *Moiré*, McPhee and Robertson (1970) were able to select for sternopleural bristles in *Drosophila* under conditions of suppressed recombination on chromosomes II and III. From previous work, $h^2 = 0.4$, with these chromosomes accounting for 1/3 and 1/2 (respectively) of the genetic variation in bristle number (and with the X chromosome accounting for the remaining 1/6). In lines that were suppressed for recombination on both chromosomes, the selection limit (on a transformed scale) was 0.166 ± 0.014 in up-selected lines and -0.134 ± 0.009 in down-selected lines, reductions of $28 \pm 8\%$ and $22 \pm 7\%$ relative to the limit obtained when normal recombination was allowed. For these studies, $N_e \simeq 10$ and $\bar{t} \simeq 1$, while $h_{II}^* = \sqrt{0.4/3} \simeq 0.37$ and $h_{III}^* = \sqrt{0.4/2} \simeq 0.45$. Thus, selection is strong on both chromosomes as $N_e \bar{t} h_{II}^* \simeq 3.7$ and $N_e \bar{t} h_{III}^* \simeq 4.5$.

Under these conditions, Robertson's theory predicts that the limiting contribution from each (recombination-suppressed) chromosome will be approximately $3\sigma_{A^*}$ (as $x_2 N \sqrt{2} \sim 3$; Equation 26.20a). Given $\sigma_z = 0.059$ and $\sigma_{A^*} = 0.059 \cdot h^*$, the expected contributions to the selection limit from chromosomes II and III become $3 \cdot 0.059 \cdot 0.37 \simeq 0.065$ and $3 \cdot 0.059 \cdot 0.45 \simeq 0.080$, respectively, for a total absolute contribution of 0.145, consistent with the observed limits. Robertson's theory (Equation 26.20e) further predicts that the half-life in recombinationaly suppressed lines is roughly $2/(\bar{t} h^*)$ generations, or $2/0.37 \simeq 5.4$ and $2/0.45 \simeq 4.4$ for chromosomes II and III, respectively, consistent with the observed half-life of 5 generations.

Other *Drosophila* experiments examined the consequences of suppressed recombination on selection response. Both Markow (1975) and Thompson (1977) used stocks with inversions while selecting for increased or decreased phototactic behavior. While Markow observed that recombination suppression reduced the selection limit, Thompson observed no differences. Markow did not use replicate lines, so the statistical significance of her results is unclear. However, she observed that the most recombinationaly suppressed lines had the most reduced response, consistent with theory. In Thompson's experiments, $N_e \simeq 50$, $\bar{t} \simeq 1$, and $h^* \simeq 0.1$ (for both autosomes), yielding an expected (linkage) half-life of $2/(\bar{t} h^*) = 20$ generations (López-Fanjul 1989), as opposed to the value of $1.4 \cdot 50 = 70$ in the absence of linkage (Equation 26.17). Thompson's experiments were stopped at generation 21, so it is not surprising that he found no difference in response, as the reduction in total response from linkage is not readily apparent until well after the expected linkage half-life (Equation 26.20e).

Bourguet et al. (2003) commented that a potential flaw in these *Drosophila* experiments is that balancer chromosomes were used to suppress recombination, which may have different levels of variation than their homologs in the base population. Using a more careful approach to suppress recombination, they observed no difference between normal and recombinationaly suppressed lines in the response after 38 generations of selection for geotaxis. However, they noted that their experiment, like most others, suffered from low power.

Table 26.3 Differences in short-term versus long-term response as a function of the number of adults saved, N , when $M = 50$. Initially, $h^2 = 0.5$ and $\sigma_z^2 = 100$. The infinitesimal model is assumed with $N_e = N$. The selection intensity, $\bar{\imath}$, is obtained by using Equation 14.3a (corrected for finite population size). From Equation 13.6b, $R(1) = 5 \bar{\imath}$, while from Equation 26.15b, $R(\infty) = 2N R(1)$.

N	p	$\bar{\imath}$	$R(1)$	$R(\infty)$
30	0.6	0.6	3.2	192
25	0.5	0.8	4.0	200
10	0.2	1.4	7.0	140
5	0.1	1.8	9.0	90

OPTIMAL SELECTION INTENSITIES FOR MAXIMIZING LONG-TERM RESPONSE

When a fixed number, M , of individuals is scored, there is a tradeoff between the intensity of selection ($\bar{\imath}$) and the amount of drift (N_e). If N individuals are allowed to reproduce (implying $p = N/M$ is the fraction saved), decreasing N (and hence p) increases $\bar{\imath}$ but also decreases N_e . Recalling Equation 26.15b, Robertson's selection limit can be expressed as

$$2N_e R(1) = N_e \bar{\imath} \left(\frac{2\sigma_A^2(0)}{\sigma_z} \right) \quad (26.22)$$

showing that the ultimate response (from the initial variation) depends on the product of N_e and $\bar{\imath}$. While decreasing p results in a larger short-term response due to increased $\bar{\imath}$, it also results in a decreased long-term response by decreasing N_e . Hence, the product $N_e \bar{\imath}$ decreases for sufficiently large or small values of p , suggesting that some intermediate value of p is optimal (see Equation 26.23). Table 26.3 and Figure 26.5B both illustrate this tradeoff. For example, while the single-generation response using $p = 0.50$ is less than half that for $p = 0.10$, it yields a selection limit over twice as large (200 vs. 90).

Supporting an earlier conjecture of Dempster (1955b), Robertson (1960a) found (for additive loci and normally distributed phenotypes) that the intensity of selection that yields the largest total response is $p = 0.5$, as $N_e \bar{\imath}$ is maximized for fixed M when half the population is saved. This can be seen directly for truncation selection on a normally distributed character. Recall from Equation 14.3a that $\bar{\imath} = \varphi(x_{[1-p]})/p$ (ignoring the correction for finite population size), where x_p satisfies $\Pr(U < x_{[p]}) = p$, and with U denoting a unit normal random variable and $\varphi(x)$ denotes the unit normal density function. Because the number saved is $N = Mp$, we have (following Hospital and Chevalet 1993)

$$\begin{aligned} R(t) &\simeq Mp \left(1 - e^{-t/2N_e} \right) \frac{\varphi(x_{[1-p]})\sigma_A^2(0)}{p\sigma_z} \\ &= \varphi(x_{[1-p]}) \left[\frac{M\sigma_A^2(0)}{\sigma_z} \left(1 - e^{-t/2N_e} \right) \right] \end{aligned} \quad (26.23)$$

Because the term in brackets is independent of p , response (as a function of p) is maximized at the maximum value of $\varphi(x_{[1-p]})$, which occurs at $x = 0$, or a p value of 0.5.

As Figure 26.5A illustrates, the selection limit as a function of p becomes extremely flat-topped as M increases, so even fairly large deviations from $p = 0.50$ yield essentially the same limit. If we relax the assumption of normality, Cockerham and Burrows (1980) found that the optimal proportion for truncation selection is still near 0.50, unless the phenotypic distribution is extremely skewed. Hill and Robertson (1966), Robertson (1970a), and Hospital and Chevalet (1993) found that the optimal proportion increases to above $p = 0.50$ when linkage is important (recall from Chapter 24 that linkage disequilibrium generates skew in the genotypic distribution, causing it to depart from a normal).

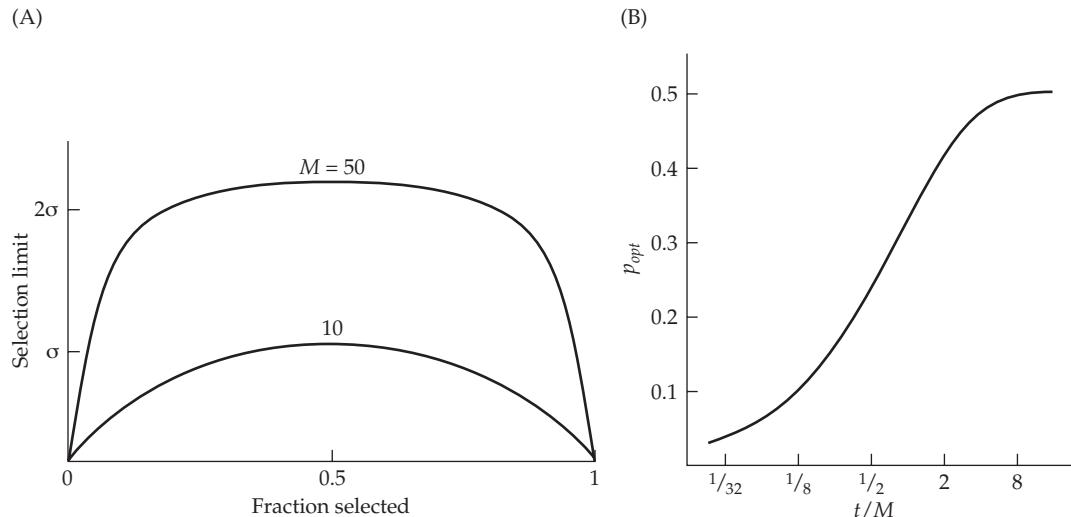

Figure 26.5 A: The selection limit as a function of the fraction selected (allowed to reproduce) for 10 and 50 individuals scored. (After Robertson 1960a.) B: The optimal proportion, p_{opt} , of individuals selected in each generation to maximize the selection advance over t generations, as a function of t/M , where M is the number of measured individuals. (After Robertson 1970b.) Both sets of curves can be generated using Equation 26.23, taking $M = N_e$.

Table 26.4 As selection intensity increases, the value of N_e becomes increasingly less than the actual number of parents ($N = pM$), further increasing drift. This additional reduction in effective population size due to selection is computed using the approach in Example 26.2. Parameters and assumptions are as in Table 26.3 ($M = 50$, $h^2 = 0.5$).

N	\bar{t}	N_e	N_e/N	$2N_e R(1)$
25	0.8	20.0	0.80	161
10	1.4	6.2	0.62	87
5	1.8	2.6	0.52	47

Robertson's prediction of the optimal selection intensity for long-term response is experimentally supported. Madalena and Robertson (1975) selected for decreased sternopleural bristle number in *Drosophila*. When the best 5 of 25 were chosen, the limit was 18.0 bristles, less extreme than the limit of 17.1 when the best 10 of 25 were chosen. Similar results were seen for increased abdominal bristle number in *Drosophila* (Jones et al. 1968), increased egg-laying in *Tribolium castaneum* (Ruano et al. 1975), and increased postweaning weight in mice (Hanrahan et al. 1973).

Using $N = pM$ as the effective population size is often a severe overestimate (Chapter 3), especially because, as Equations 26.6b–26.6d show, N_e/N decreases as selection intensity increases. Hence, increasing selection intensity increases drift by both reducing $N = pM$ and by further reducing the ratio of N_e to N . Table 26.4 illustrates this effect using the same parameters as Table 26.3. Without incorporating this further reduction in N_e , the ratio of expected limits when $p = 0.50$ versus $p = 0.10$ is $200/90 = 2.2$. When the reduction in N_e due to selection is accounted for, this ratio increases to $161/47 = 3.4$.

More generally, Robertson (1970b) obtained the optimal selection intensity when the goal is to maximize the total response (from the initial base population variation) at generation t . Robertson's derivation follows using Equation 26.15a. As Figure 26.5B shows, the optimal proportion is a function of t/M . Robertson assumed that the infinitesimal model held and that there were equal contributions from each sex. Jódar and López-Fanjul (1977) extended these results to unequal sex ratios, and found that the maximum response occurs

when the number of individuals scored and the proportions that are selected are the same in each sex. This follows because effective population size is reduced as the sex ratio deviates from 1:1 (Equation 3.12), which increases the effects of drift. Hospital and Chevalet (1993) examined the effects of linkage and found that the amount by which the optimal value of p exceeds the predicted value (Figure 26.5B) increases with population size. In small populations, the value predicted from drift (for any particular t/M value) is close to the optimal value, while Robertson's value seriously underestimates the optimal p value in larger populations when linkage is present.

Ruano et al. (1975) and Frankham (1977) tested Robertson's predictions for the optimal response at a particular generation with selection experiments for egg-laying in *Tribolium* and for abdominal bristle number in *Drosophila*, respectively. The theory holds up well for $t/M \leq 0.2$, but both authors found discrepancies between the observed and predicted rank order of lines subjected to different selection intensities when $t/M > 0.2$. One explanation of these discrepancies could be the presence of major alleles, resulting in additive variance declining more rapidly than expected under the infinitesimal model. This results in the optimal proportions being larger than those predicted from Figure 26.5B. Frankham (1977) also suggested that not correcting for the additional decrease in N_e with increased selection intensity (e.g., Table 26.4) results in incorrect values of N_e , and hence incorrect optimal proportions. García-Dorado and López-Fanjul (1985) examined the consequences of unequal sex ratios using sternopleural bristle number in *Drosophila*. Equal sex ratios gave the highest response, and good agreement with the optimal values predicted by Jódar and López-Fanjul was seen when there were unequal sex ratios.

EFFECTS OF POPULATION STRUCTURE ON LONG-TERM RESPONSE

Our development of Robertson's theory of selection limits has made two assumptions regarding population structure: selection occurs in a large panmictic population, and the initial base population is infinite in size. This section relaxes these assumptions. We first examine the consequences of founder effects in the initial base population and of passing the population through bottlenecks during selection. We conclude by examining the expected limits when the population is subdivided and when selection is entirely within families.

Founder Effects and Population Bottlenecks

So far, we have been considering only the effects of drift due to selecting N adults in each generation from an initial base population that is assumed to be infinite. However, drift can also occur prior to selection if the base population itself was founded by sampling individuals from some larger population. By altering the starting additive variance, this initial sampling modifies the expected response, and (provided the founding event is severe), can have a significant impact on the selection response. Robertson (1966b), reporting on the unpublished thesis of Da Silva (1961), found that lines formed from a single parental pair underwent a decrease in the selection response of roughly 30% relative to a nonbottlenecked line from the base population (Figure 26.6A). Lines formed from taking single parental pairs for three consecutive generations showed only a modest further reduction in response, suggesting that most of the founder effect occurred in the first generation. Robertson's interpretation was that response in this population was due largely to alleles that were at an intermediate frequency, as alleles that are at low frequency are expected to be lost during the initial sampling. Segregating alleles present after this initial bottleneck of two individuals have intermediate frequencies (1/4, 1/2, or 3/4), which somewhat decreases their sensitivity to further sampling events.

Using this reasoning, Robertson (1960a) predicted that the effect of restricting population size after several generations of selection is expected to be small, as favored alleles are expected to be at intermediate to high frequencies. However, Jones et al. (1968) found that, even after many generations of selection, such bottlenecks can have a large effect. Sublines formed by taking ten pairs of adults from a parental line selected for 16

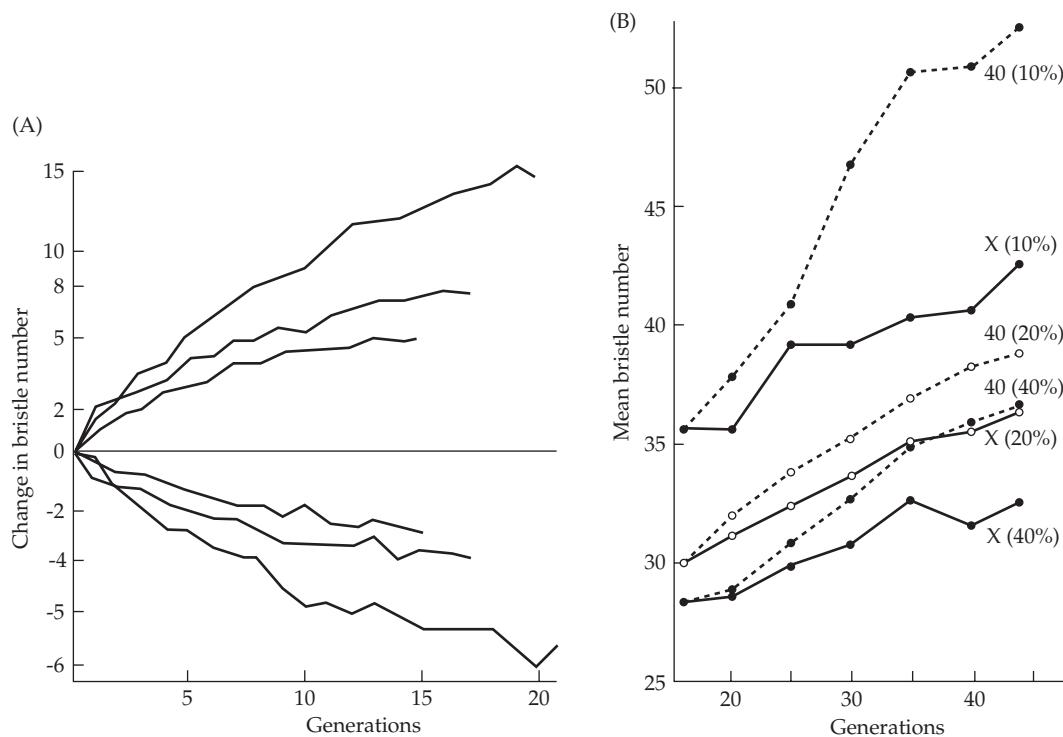

Figure 26.6 Effects of population bottlenecks on selection response. **A:** Selection for sterno-pleural bristle number in *Drosophila melanogaster*, with the most extreme 10 pairs out of 25 scored pairs selected in each generation. The outermost curves are responses using the base population. The middle curves are the responses for sublines formed from a single parental pair. The innermost curves correspond to sublines formed by single parental pairs for three consecutive generations prior to selection. (After Robertson 1966b.) **B:** Selection for abdominal bristle number in *Drosophila melanogaster*. The responses denoted by 40 (10%), 40 (20%), and 40 (40%) correspond to populations where the uppermost 40 pairs of adults are selected in each generation, with different selection intensities. For example, 200 pairs are scored and the uppermost 40 are chosen in the 40 (20%) population. Responses denoted by X (10%), X (20%), and X (40%) refer to lines split from the corresponding 40-pair lines after 16 generations of selection and selected thereafter at the same intensity with 10 pairs of parents per generation. Note that all X lines show reduced responses (being below their counterparts). (After Jones et al. 1968.)

generations showed reduced response relative to their parent lines (Figure 26.6B). One explanation for the results of Jones et al. is that there were still desirable alleles at low frequencies following 16 generations of selection. These alleles can be lost when the population passes through a bottleneck, reducing response. One source for these rare major alleles could be new mutations. Alternative explanations were considered by Frankham (1983b).

To present the theory for the impact of bottlenecks on selection response a bit more formally, results are developed for a single additive locus, and extended by assuming gametic-phase equilibrium and no epistasis. If N_0 is the number of founders, the initial expected additive-genetic variance in the founder population is $[1 - 1/(2N_0)] \sigma_A^2(0)$, with the expected response for the first generation of selection from a bottlenecked population being $[1 - 1/(2N_0)]$ times that for an initially infinite population (Jones 1970). The long-term effects of an initial bottleneck are more unpredictable, depending on initial allele frequencies and the relative strength of selection. When selection is weak at all loci (the infinitesimal model), the arguments leading to Equation 26.15a yield the expected response starting with a founder population of size N_0 as

$$R_{N_0}(t) = R(t) \left(1 - \frac{1}{2N_0}\right) \quad (26.24a)$$

where $R(t)$ is the response expected when the initial base population is infinite (Equation 26.15a). More generally, if two replicate populations of the same size are created using different numbers of founders (N_{01}, N_{02}) from a common, and large, base population, the ratio of the expected response at any generation is

$$\frac{R_{N_1}}{R_{N_2}} = \frac{1 - 1/(2N_{01})}{1 - 1/(2N_{02})} \quad (26.24b)$$

Thus, if selection at all loci is weak and all genetic variance is additive, the effect of a bottleneck depends only on the number of founders, N_0 .

Founder effects are most serious when rare favorable alleles of large effect are present, but predicting the magnitude of the effect in any given population is difficult. When selection on a locus is strong ($2N_e s \gg 1$), the probability that a selected line formed from a bottlenecked base population will eventually become fixed for the favored allele converges to

$$u_{N_0}(p_0) = 1 - (1 - p_0)^{2N_0} \quad (26.25a)$$

where p_0 is the major-allele frequency in the population being sampled. This follows because if selection is sufficiently strong, the favored allele will become fixed if it is found in the initial sample, which occurs with a probability of $1 - (1 - p_0)^{2N_0}$. Using this approximation, the ratio of the expected limiting contribution from such a locus to the expected contribution when the founding population is infinite is

$$\frac{u_{N_0}(p_0) - p_0}{u(p_0) - p_0} \simeq \frac{1 - (1 - p_0)^{2N_0} - p_0}{1 - p_0} = 1 - (1 - p_0)^{2N_0-1} \simeq 1 - e^{-p_0(2N_0-1)} \quad (26.25b)$$

A more accurate measure would be to weight the fixation probability, $u(p)$, by the sampling probability given a starting allele frequency, $\sum_{i=1}^{2N_0} \Pr(i | p_0, 2N_0) u(i/[2N_0])$, where $\Pr(i | p_0, 2N_0)$ is the i th term in a binomial with parameters of p_0 and $2N_0$.

Because the initial frequencies of major alleles are unknown, the long-term effect of a bottleneck, even when all genetic variance is additive, is unpredictable. To see this, suppose that a rare ($p_0 \simeq 0$), but favorable (a is large), allele is initially present. Its contribution to the initial additive variance is $V = 2a^2 p_0 (1 - p_0)$, while (if fixed), its contribution to the response is $R = 2a(1 - p_0)$. Hence, $R = V/(ap_0)$, so that if $ap_0 \ll 1$, but a is large, it makes a large contribution if it is fixed, but only a small contribution to the initial variance. If $p_0 \simeq 0$, an allele with a large effect can easily be lost by drift, with only a small effect on the additive variance, but leading to a large potential loss of response. Many artificial selection experiments examining the genetic architecture of a trait first start by breeding a wild-caught sample in the lab for many generations. This generates additional drift, and can result in rare (but important) alleles from the sampled population not being present at the start of artificial selection. Zhang and Hill (2005a) showed that a consequence of this sampling (coupled with selection-generated disequilibrium) is that a population with a significant number of rare alleles (and hence the potential for an accelerated response as rare alleles of large effect increase in frequency, increasing h^2 ; Chapter 25) often generates a response no different from that expected under an infinitesimal model.

Frankham (1980) examined founder effects in *Drosophila* populations that were selected for increased abdominal bristle number. As shown in Figure 26.7, the limit of bottlenecked populations formed from two founders was between 0.69 and 0.72 of that for nonbottlenecked populations, which is quite close to the value of $[1 - 1/(2N_0)] = 0.75$ that is predicted for additive loci under weak selection (Equation 26.24b). Frankham reported similar unpublished thesis results of Da Silva (1961) and Hammond (1973). However, while D. Robertson (1969, reported in James 1970) observed a decrease in response with decreasing number of

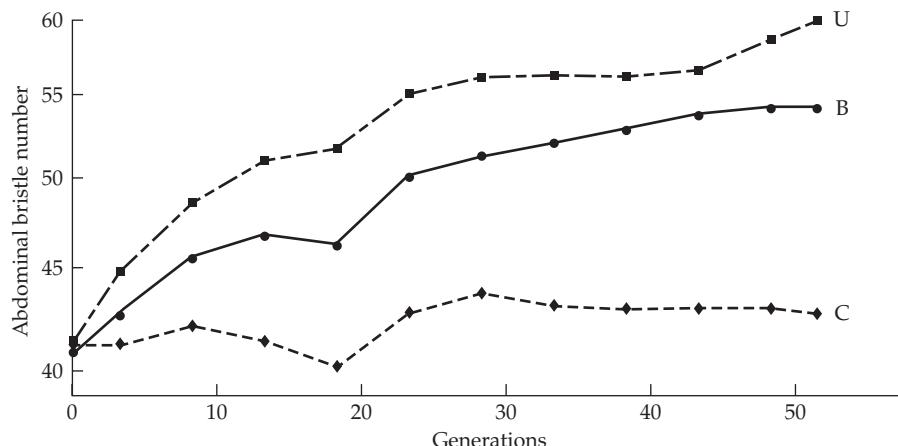

Figure 26.7 The effect of an initial bottleneck on selection for increased abdominal bristle number in *Drosophila*. Curve B corresponds to the response in bottlenecked populations formed from a single pair of parents ($N_0 = 2$), curve U to a nonbottlenecked population, and curve C corresponds to the response from the unselected control. All lines were maintained by using 20 pairs of parents in each generation. (After Frankham 1980.)

founders when the number of selected parents (N_e) was 10, there was no obvious effect when N_e was 40 (which is not unexpected because $1 - 1/80$ is negligible). We have been unable to find any reports of response increasing significantly when the population is passed through a bottleneck, as can occur if significant nonadditive variance is present (Chapter 11). Clearly, there is a need for further experiments.

An especially interesting experiment on founder effects was performed by Skibinski and Shereif (1989), who examined sternopleural bristle number in *Drosophila melanogaster*. Three initial lines were created from a large base population by taking parents from different parts of the distribution of bristle number to generate a high line, a low line, and a line from the central part of the distribution. The central line had the largest total response to divergent selection. Skibinski and Shereif suggested that these results were consistent with the assumption that a few major alleles underlay the trait, with the central line having higher heterozygosity at these loci (and hence more usable genetic variance) than the extreme lines. One caveat with this interpretation is that the central line had a larger initial population size than either extreme line.

Population Subdivision

Thus far, we have been considering the long-term response under mass selection in a single panmictic population. But how robust are these results if the total population is subdivided? Robertson (1960a) showed that when only additive variance is present, population structure has little effect on the selection limit. In particular, the expected limit for a population formed by crossing k (replicate) plateauxed lines of size N is the same as for a single line of size Nk . Maruyama (1970) generalized this result by showing (for additive loci and ignoring linkage effects) that any subdivision of the population has the same limit, independent of when and how lines are crossed, provided there is no selection *among* lines. One caveat with this result is that breeders typically try to maximize gain under a set level of inbreeding, and Smith and Quinton (1993) showed that selecting and crossing sublines produces less total selection response for a fixed level of inbreeding than does selection in a single line.

Madalena and Hill (1972) further showed that linkage has only a minor effect on this conclusion. They also found (again assuming only additive variance) that while among-line selection (i.e., culling some of the lines) may increase short-term response, removing lines decreases the total genetic variance of the entire population, which decreases the limit. This reduction in the limit is most severe with free recombination, and it is negligible with tight

linkage.

When significant nonadditive genetic variance is present, population subdivision may increase the selection limit. For example, when favorable rare recessives are present, subdividing the population and subsequently crossing these lines when they plateau and then reselecting yields a higher expected limit than using a single panmictic line of the same total size (Madalena and Hill 1972; Slatkin 1981b). The increased inbreeding in the sublines increases the frequency of homozygotes, which facilitates selection for favorable recessives.

Similarly, **Wright's shifting balance theory** (Wright 1931, 1951, 1978, 1982) asserts that local inbreeding due to population subdivision facilitates the accumulation of rare favorable epistatic combinations of loci. Crossing such fixed (or nearly fixed) lines increases the selection limit relative to a single panmictic population, much akin to what happens with rare recessives. Indeed, Enfield and Anklesaria (1986) found, in simulation studies, that when additive-by-additive epistatic variance is present, certain population subdivisions can result in greater short-term and long-term response than a single panmictic population.

There have been a number of contrasting views on the optimal population structure for evolution. Wright (1931, 1951, 1977, 1978, 1982) suggested that evolution is most rapid when the population is subdivided (henceforth, the **Wright structure**), while Fisher (1958) viewed a single large panmictic population (the **Fisher structure**) as the optimal structure. When mostly additive gene action is present, both the Wright and Fisher structures are expected to give comparable rates of evolution, although the Fisher structure may have a slight advantage when the effects of linkage are considered (in larger populations, the probability that a deleterious allele linked to a favorable allele will hitchhike to fixation is decreased, which increases the potential response). With nonadditive gene action, the optimal structure depends on the exact nature of gene action. With recessives, the Wright structure increases the response. With epistasis, this subdivision offers an advantage if epistatic combinations are such that their formation requires intermediate genotypes that are deleterious. Conversely, in other situations, the Fisher structure may offer an advantage in that it allows more gene combinations to be tested. There remains very significant debate over which structure is more relevant (Coyne et al. 1997, 2000; Peck et al. 1998, 2000; Wade and Goodnight 1998; Goodnight and Wade 2000).

Despite these concerns when nonadditive genetic variance is present, selection experiments with population subdivision (reviewed by Rathie and Nicholas 1980 and López-Fanjul 1989) generally have yielded results similar to those expected under the strictly additive model: subdivision usually has no effect on the selection limit. However, two experiments revealed exceptions to this trend. Madalena and Robertson (1975) selected for decreased sternopleural bristle number in *Drosophila melanogaster* under two different population structures: a single-cycle structure where sublines were crossed once, and a repeat-cycle structure where sublines were crossed multiple times. The limit under the single-cycle structure was essentially the same as for a panmictic population, regardless of whether among-line selection was practiced. The limit under the repeat-cycle structure was slightly more extreme than the panmictic population. These results are complicated by the presence in their lines of major alleles that are lethal as homozygotes but nevertheless suggest the presence of some favorable recessives initially at low frequency. The second exception was revealed an experiment by Katz and Young (1975), who selected for increased body weight in *Drosophila*. Populations that were subdivided with a small amount of migration among them gave a slightly larger response than the panmictic population.

One must keep in mind that the optimal population structure for maximizing response under one type of gene action may not be optimal for other types. In particular, many types of population structure that increase the probability of fixation of recessive or epistatic genes may retard the fixation of advantageous additive genes. Likewise, even structures that do not decrease the fixation probability may increase the fixation time, which reduces the rate of response.

Caballero et al. (1991) examined the types of mating schemes (following selection) that increase the fixation probability of recessive alleles while not significantly reducing the

fixation probabilities or increasing the fixation times for additive genes. They found that mating full sibs wherever possible following selection increased the fixation probabilities for recessives (relative to random mating following selection), without any significant effect on additive alleles. The tradeoff here is a reduction in N_e (due to the increased inbreeding by full-sib mating following selection) versus the increased selection on recessives by inbreeding (compare Equations 7.19b and 7.20c). Recall from Equation 7.20c that the measure, f , of departures from Hardy-Weinberg frequencies enters into the selection coefficients. Caballero et al. showed that

$$f = \frac{N_{FS} - 1}{4N_{TM} - 3N_{FS} + 3} + f_r \quad (26.26a)$$

where N_{FS} is the number of full-sib matings, N_{TM} is the total number of matings, and f_r is the departure from Hardy-Weinberg genotype frequencies under random mating in a finite population, which is given by

$$f_r = -\left(\frac{1}{8N_f} + \frac{1}{8N_m}\right) \quad (26.26b)$$

where N_m and N_f are the numbers of reproducing males and females. Note that the negative sign implies that under random mating, there is a slight expected excessive of heterozygotes relative to the frequency expected from the allele frequencies alone. Caballero et al. (1991) noted that, under their random-mating scheme, the expected number of full-sib matings is close to one, so $N_{FS} - 1$ represents the excessive number of such matings.

Within-family Selection

The variance in the number of offspring contributed by each selected parent is an important determinant of the effective population size—the larger this variance, the smaller N_e (Equation 3.4). Exploiting this relationship, Toro and Nieto (1984) noted that deliberately assigning selected parents different probabilities of contributing offspring (according to a specific formula) results in populations with the same selection intensity but different effective population sizes relative to the situation in which the selected parents are randomly mated.

Suppose 20 individuals are measured ($M = 20$), and we wish the expected selection intensity to be $\bar{\tau} = 1.2$. This occurs if the best 5 individuals are chosen (using Equation 14.4b to correct $\bar{\tau}$ for finite population size) and each parent has an equal probability of contributing offspring. This same selection intensity, $\bar{\tau} = 1.2$, can be achieved by instead choosing the best 10 individuals and assigning these individuals unequal probabilities for contributing offspring (using effective selection differentials, which were introduced in Example 13.2; see Toro and Nieto [1984] for details). This latter scheme (while holding both selection intensity and the number of measured individuals, $M = 20$, constant) increases effective population size from 5.0 to 5.9, which in turn increases the long-term response.

The most extreme example of using a mating scheme to control N_e in a selected population occurs when selection is entirely *within families*: the best male and female are chosen from each full-sib family and mated at random between families. This doubles the effective population size compared to the result from selecting the same number of individuals independent of family structure. We remind the reader at this point of the important, but subtle, distinction between parents having an equal *probability* of contributing offspring versus parents contributing exactly the same *number* of offspring. In the former case, some parents will contribute no offspring and others will contribute more than one, generating a nonzero variance. In the latter case, recall from Equation 3.4 that if all parents contribute the same number of offspring, there will be no variance in offspring number and N_e will equal $2N$.

Thus, using only within-family selection results in a population with twice the effective size as one undergoing mass selection with the same number of individuals selected. However, as Robertson (1960a) noted, the usable additive genetic variance within full-sib

families is only half that available under mass selection (see Chapter 21). This exactly cancels the advantage of a larger N_e , suggesting that both methods yield the same limit.

Dempfle (1975) pointed out that this conclusion relies critically on h^2 being low. Applying Equations 21.20 and 21.23, the response to a generation of within-family selection is (for full-sibs)

$$R_{wFS}(1) = \bar{t} h_{wFS}^2 \sigma_{wFS}$$

where (with only additive genetic variance), the within-family heritability, the fraction of within-family differences due to differences in breeding values, is

$$h_{wFS}^2 = \frac{\sigma_A^2/2}{\sigma_{wFS}^2}, \quad \text{where } \sigma_{wFS}^2 = \frac{\sigma_A^2}{2} + \sigma_{Es}^2$$

If the additive genetic variance is much larger than the within-family environmental variance (σ_{Es}^2), then $h_{wFS}^2 \approx 1$ and $\sigma_{wFS}^2 \approx \sigma_A^2/2$, which yields $R_{wFS}(1) \approx \bar{t} \sigma_A / \sqrt{2}$. If the total environmental variance is much smaller than the additive variance, the expected response to individual selection will become $R(1) \approx \bar{t} \sigma_A$. Thus, when additive genetic variance dominates, the ratio of expected limits is

$$\frac{4NR_{wFS}(1)}{2NR(1)} \approx \sqrt{2}$$

and within-family selection increases the limit.

Three other factors can favor within-family selection:

1. *Retardation of the cumulative reduction in N_e from selection.* Recall that individual selection reduces N_e below the actual number of parents by inflating the among-family variance in offspring number when h^2 or \bar{t} are large. This variance is zero under within-family selection ($Q = 0$ in Equation 26.6c), resulting in an effective population size greater than twice that for individual selection, so $N_e(\text{within-family}) > 2N_e(\text{individual})$.
2. *Significant among-family environmental variance.* If most of the environmental variance is due to among-family, rather than within-family, effects (i.e., if $\sigma_{Ec}^2 > \sigma_{Es}^2$), within-family selection results in a larger single-generation response than individual selection (Chapter 21). Within-family selection is thus superior when the among-family component of environmental variance is sufficiently large, especially because this factor is in addition to its advantage from within-family selection generating a larger effective population size.
3. *Gametic-phase disequilibrium.* The presence of gametic-phase (linkage) disequilibrium also increases the effectiveness of within-family selection relative to individual selection. Under the assumptions of the infinitesimal model, the negative gametic-phase disequilibrium generated by directional selection reduces the among-family component of additive variance, while (for unlinked loci) the within-family component remains unchanged (Chapters 16 and 24). Hence, the usable additive variance in the mass-selection lines is decreased, while the usable additive variance in the within-family lines is unchanged. This effect is largely negligible unless selection is strong and heritability is high.

On the experimental side, von Butler et al. (1984) compared individual and within-family selection on 8-week body weight in mice. In one set of replicates, within-family selection initially showed a reduced response, but after 18 generations they had essentially the same response as the mass-selected lines. In another set of replicates (using a different base population), mass selection did better than within-family selection, but both populations were still responding after the experiment was stopped (after 18 generations). Because within-family selection is expected to show a longer period of response (due to a larger effective population size), the results for the second set of replicates are inconclusive.

ASYMPTOTIC RESPONSE DUE TO MUTATIONAL INPUT

As reviewed in Chapter 25 (and by Frankham 1980, 1983a; Weber and Diggins 1990; Weber 2004), there is strong evidence that new mutations contribute to selection response even during the relatively short time scales of many so-called “long-term” laboratory experiments. The limit resulting from drift and selection removing all initial genetic variation is thus an artifact of time scale, as it ignores ongoing mutational input. Even if an observed limit is due to a balance between natural and artificial selection, new mutations with less deleterious pleiotropic effects on fitness can arise, resulting in further response.

Confounding the issue of new mutations is the appearance of homozygotes involving recessive alleles that were initially present at a low frequency. If a recessive allele is present as a single copy, the expected time (conditional on it not being lost by drift) until the first appearance of a homozygote in a diploid population with an effective size of N_e is approximately $2N_e^{1/3}$ generations, with the appearance time following a nearly geometric distribution (Robertson 1978; Karlin and Tavaré 1980, 1981a, 1981b; Santago 1989). Because $N_e \leq 500$ for most selection experiments, any rare recessives that are initially present (and not lost by drift) will be expressed as homozygotes by around generation 15.

Our discussions of the nature of long-term response with mutational input largely follow Hill’s pioneering treatment (1982a, 1982b). We start by assuming complete additivity. Recall from Chapter 11 (and LW Chapter 12) that one measure of mutational input is σ_m^2 , the amount of new additive variance produced by mutation in each generation. Consider the i th locus, where each allele mutates to a new one with a per-generation rate of μ_i . The **incremental-mutation model** is assumed: when an allele A mutates to a new allele A' , the genotypic values of AA' and $A'A'$ are $g_{AA} + \alpha$ and $g_{AA} + 2\alpha$, where g_{AA} is the genotypic value of AA . This model assumes that the genotypic value of the new mutant is the value of its parental allele plus an increment value, α . The distribution of α is assumed to be independent of the value of the parental allele, with $E[\alpha_i] = 0$ and $E[\alpha_i^2] = \sigma^2(\alpha_i)$. For n loci, the mutational variance for a diploid species becomes

$$\sigma_m^2 = 2 \sum_{i=1}^n \mu_i \sigma^2(\alpha_i)$$

We first consider the infinitesimal model before examining a more general model and the consequences of dominance. An extensive discussion of different mutational models is given in Chapter 28.

Results for the Infinitesimal Model

We start by assuming complete additivity and ignore any effects of gametic-phase disequilibrium. From Equation 11.20b, the expected additive genetic variance at generation t is

$$\sigma_A^2(t) \simeq 2N_e \sigma_m^2 + [\sigma_A^2(0) - 2N_e \sigma_m^2] \exp(-t/2N_e) \quad (26.27)$$

Setting $\sigma_A^2(0) = 0$ gives the additive variance contributed entirely from mutation as

$$\sigma_{A,m}^2(t) \simeq 2N_e \sigma_m^2 [1 - \exp(-t/2N_e)] \quad (26.28a)$$

Hence, the rate of response at generation t from mutational input is

$$r_m(t) = \bar{t} \frac{\sigma_{A,m}^2(t)}{\sigma_z} \simeq 2N_e \bar{t} \frac{\sigma_m^2}{\sigma_z} [1 - \exp(-t/2N_e)] \quad (26.28b)$$

where we have made the usual assumption that the phenotypic variance, σ_z^2 , does not significantly change over time and that any disequilibrium is ignored. For $t \gg 2N_e$, the per-generation response approaches an asymptotic limit of

$$r_m(\infty) = 2N_e \bar{t} \frac{\sigma_m^2}{\sigma_z} \quad (26.29)$$

Assuming $\sigma_A^2(0) = 0$, Equation 26.28b shows that half this rate is achieved by $t \simeq 1.4N_e$, independent of the value of σ_m^2 (Hill 1982a, 1982b). There are several ways to intuit the value of this asymptotic limit. From Robertson's theory, we expect the final response to be $2N_e$ times the initial response $R(1)$, which, for new mutants arising in any particular generation, is $R(1) = \bar{t} \sigma_m^2 / \sigma_z$. Alternatively, recall (Equation 11.20c) that the equilibrium additive variance (assuming pure drift) is $2N_e \sigma_m^2$, which (upon recalling Equation 13.6b) recovers Equation 26.29. The assumption of the infinitesimal model implies vanishingly small selection coefficients at each underlying locus, which makes them effectively neutral.

Summing Equation 26.28b over generations (using the approximation given by Equation 7.28b) yields a cumulative response due to new mutation of

$$R_m(t) = \sum_{\tau=1}^t r_m(\tau) \simeq 2N_e \bar{t} \frac{\sigma_m^2}{\sigma_z} \left(t - 2N_e [1 - \exp(-t/2N_e)] \right) \quad (26.30a)$$

as found by Hill (1982a, 1990) and Weber and Diggins (1990). An approximation for genes of sufficiently large effect ($|a| \gg \sigma_z/N\bar{t}$) is to consider them as being essentially fixed instantaneously, in which case only the first term in the large parentheses in Equation 26.30a need be included, and the response approaches

$$R_m(t) = 2tN_e \bar{t} \frac{\sigma_m^2}{\sigma_z} \quad (26.30b)$$

as suggested by Hill (1982a). Note by comparison with Equation 26.29 that the instantaneous fixation assumption is equivalent to assuming that the asymptotic rate of response applies from generation 1.

Combining the mutational response with the response due to genetic variation that was originally in the base population (Equation 26.15a) yields an expected cumulative response of

$$R(t) = 2N_e \frac{\bar{t}}{\sigma_z} \left[t \sigma_m^2 + \left(1 - \exp(-t/2N_e) \right) \left(\sigma_A^2(0) - 2N_e \sigma_m^2 \right) \right] \quad (26.30c)$$

The $t\sigma_m^2$ term, which represents the asymptotic response, eventually dominates for sufficiently large t . The product term in the braces represents the transient effect of the initial additive variance, and it is zero if the population starts at the mutation-drift equilibrium (i.e., $\sigma_A^2(0) = 2N_e \sigma_m^2$).

Of considerable interest is the expected number of generations until the selection response from mutational input exceeds that contributed by the initial variation. Let t^* be the generation when the per-generation response from both sources is equal. At this value, the initial additive variance remaining equals the new additive variance cumulatively generated, or

$$\sigma_A^2(0) \exp(-t^*/2N_e) = 2N_e \sigma_m^2 [1 - \exp(-t^*/2N_e)]$$

This equation has the solution

$$t^* = 2N_e \ln(1 + \Psi) \quad \text{where} \quad \Psi = \frac{\sigma_A^2(0)}{2N_e \sigma_m^2} \quad (26.31a)$$

Denoting the initial heritability by h^2 and recalling that $\sigma_E^2 = (1 - h^2)\sigma_z^2$ yields

$$\frac{\sigma_A^2(0)}{\sigma_m^2} = \frac{h^2 \sigma_z^2}{\sigma_m^2} = \frac{h^2}{\sigma_m^2 / \sigma_z^2} = \frac{h^2}{(1 - h^2)\sigma_m^2 / \sigma_E^2} = \frac{h^2}{(1 - h^2)h_m^2}$$

showing that

$$\Psi = \frac{h^2}{(1 - h^2) 2N_e h_m^2} \quad (26.31b)$$

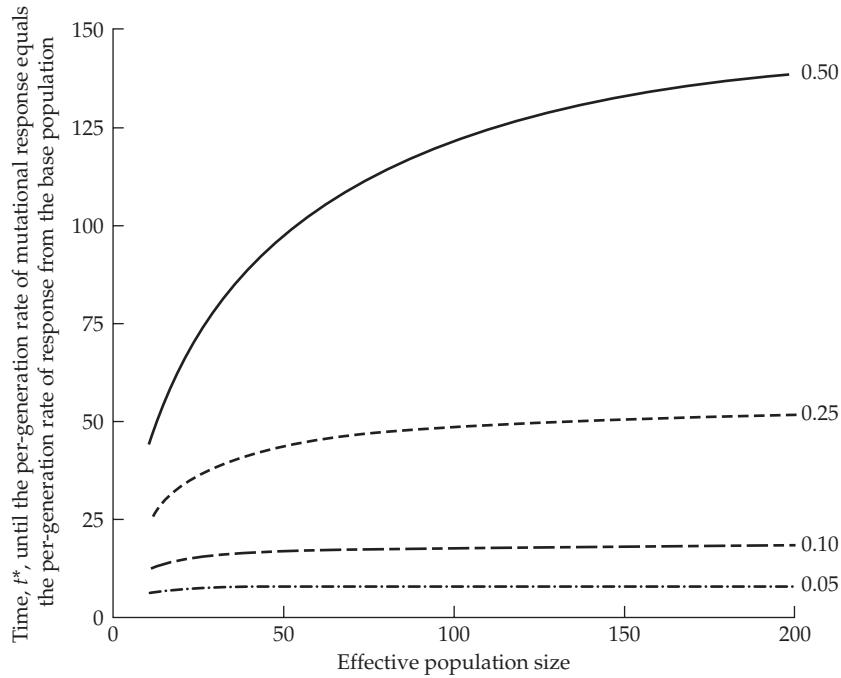

Figure 26.8 The expected generation, t^* , at which the per-generation response from mutational input equals the per-generation response from the initial variation in the base population (Equation 26.31a). We assume that $h_m^2 = \sigma_m^2/\sigma_E^2 = 0.005$, the average value in LW Table 12.1, from which Equation 26.31b yields $\Psi = 100h^2/[(1 - h^2)N_e]$. The four curves correspond to initial heritabilities of 0.05, 0.10, 0.25 and 0.50. For sufficiently large values of N_e , t^* becomes independent of N_e and approaches the approximation given by Equation 26.31c. Note when h^2 is modest to large that Equation 26.31c significantly overestimate t^* for small N_e .

The average value of the mutational heritability, $h_m^2 = \sigma_m^2/\sigma_E^2$, is approximately 0.005 (LW Table 12.1). With this value, t^* is only rather weakly dependent on N_e (Figure 26.8). If $\Psi \ll 1$, meaning that the expected additive variance at the mutation-drift equilibrium exceeds the initial additive variance ($\sigma_A^2(0) \ll 2N_e\sigma_m^2$), the approximation $\ln(1+x) \simeq x$ for small values of $|x|$ yields

$$t^* \simeq 2N_e\Psi = \frac{h^2}{(1 - h^2)h_m^2} \quad (26.31c)$$

Using $h_m^2 = 0.005$ yields $t^* \simeq 200h^2/(1 - h^2)$. For h^2 values of 0.05, 0.10, and 0.25, respectively, this translates into 11, 22, and 67 generations until the per-generation response from mutational input exceeds that due to initial variation. For $h_m^2 = 0.001$, these values increase approximately five-fold to 52, 111, and 250 generations. Comparing these approximate results (from Equation 26.31c) with their exact values (Equation 26.31a) shows that Equation 26.31c tends to overestimate the true value of t^* when N_e is small (see Figure 26.8).

Recalling the discussion following Equation 26.27, it is important to stress that our expression for the half-life of selection response (from the initial genetic variation) assumes that drift dominates and tends to yield overestimates when selection is moderate to strong. Likewise, we expect that the infinitesimal model underestimates the changes in allele frequencies of new mutations under moderate to strong selection. Thus, Equation 26.31a is best considered as an upper bound for the number of generations after which mutation is expected to dominate.

Example 26.5. Yoo (1980a) observed a steady, and reasonably constant, increase in *Drosophila*

abdominal bristle number over 80 generations of selection (Figure 25.8). In particular, an increase of about 0.3 bristles per generation was observed over generations 50 to 80. Assuming the infinitesimal model, how much of this response is due to mutational input? Yoo's base population had $\sigma_E^2 \simeq 4$, $\sigma_z^2 \simeq 5$, $h^2 \simeq 0.2$, and $\bar{t} \simeq 1.4$, with 50 pairs of parents chosen in each generation. Taking $\sigma_m^2 \simeq 0.001\sigma_E^2$ (the average for abdominal bristles in LW Table 26.1) gives $h_m^2 = 0.001$. Assuming $N_e \simeq 60$, Equation 26.31b yields

$$\Psi = \frac{0.2}{(1 - 0.2)2 \cdot 60 \cdot 0.001} = 2.083$$

Applying Equation 26.31a,

$$t^* = 2 \cdot 60 \ln(1 + 2.083) = 135$$

The approximation given by Equation 26.31c (which assumes that $\Psi \ll 1$) yields an overestimate of $t^* = 167$ generations. The expected asymptotic additive variance is

$$\tilde{\sigma}_A^2 = 2N_e\sigma_m^2 = 2 \cdot 60 \cdot 0.004 = 0.48$$

yielding an expected asymptotic rate of response of

$$r = \bar{t} \frac{\hat{\sigma}_A^2}{\hat{\sigma}_z^2} = \bar{t} \frac{\hat{\sigma}_A^2}{\sqrt{\hat{\sigma}_A^2 + \sigma_E^2}} = 1.4 \cdot \frac{0.48}{\sqrt{0.48 + 4}} \simeq 0.32$$

While the observed rate of selection response (0.3) over generations 50 to 80 is close to the expected asymptotic rate, the expected time for half of the response to be from new mutations, $t^* = 135$, exceeds 80, showing that (under the infinitesimal assumptions) most of the response is still from the initial variation. Applying Equation 26.28b, the expected single-generation response from new mutational input at generation 60 has only reached a fraction

$$1 - e^{-t/(2N_e)} = 1 - e^{-60/120} \simeq 0.40$$

of its expected asymptotic rate, yielding $0.4 \cdot 0.32 = 0.13$ as the expected response due to new mutants at $t = 60$. Assuming the phenotypic variance remains relatively constant, with $\sigma_z^2 \simeq 5$, the expected contribution at generation 60 from initial variation is

$$\bar{t} \frac{\sigma_{A,0}^2(t)}{\sigma_z} = \bar{t} \frac{h^2(0) \cdot \sigma_z^2 \cdot e^{-t/(2N_e)}}{\sigma_z} = 1.4 \cdot \frac{0.2 \cdot 5 \cdot e^{-60/120}}{\sqrt{5}} \simeq 0.38$$

Adding these two sources returns an expected total rate of response of $0.38 + 0.13 = 0.51$ bristles per generation, 75% of which is due to the initial variation. While the predicted rate of 0.51 is larger than the observed rate, opposing natural selection likely slowed down the selection response in Yoo's lines, as evidenced by the rather sharp decay in response upon relaxation of selection, as well as the presence of segregating lethals within responding lines (Yoo 1980b).

A complication with applying this theory is that the presence of major alleles both decreases the time to lose initial variation (when they reside in the base population) and increases the expected response from new mutants (when they arise as mutations). Both of these factors result in a larger role for mutational input than predicted from the infinitesimal model (i.e., a much shorter value for t^*). Applying the approximation for mutations of large effect (Equation 26.30b) using the parameters in this example, the per-generation response from mutation is 0.32. Assuming that the initial variation decays according to the infinitesimal model gives a total rate of response (at generation 60) of $0.38 + 0.32 = 0.70$, so mutation now accounts for a fraction, $0.32/0.70 = 0.46$, of the total response. Further, when major alleles are present in the base population, the initial variation declines even faster than predicted by Equation 26.15a (as selection augments the amount of allele-frequency change expected under drift alone), suggesting that an even higher percentage of response may be due to new mutation.

Expected Asymptotic Response Under More General Conditions

The infinitesimal model assumes that allele-frequency changes are due entirely to drift. Clearly, selection can also change allele frequencies, and in this case other methods of analysis are required. One approach (Hill 1982a, 1982b) is to consider the expected contribution resulting from the eventual fixation by drift and selection of some of the new mutations that arise in each generation. Provided mutation and selection remain constant over time, at equilibrium the rate of response equals this expected per-generation contribution. Assuming M adults are measured, the frequency of a new mutant allele, A^* , is $1/(2M)$. To allow for dominance, assume that the genotypic values of AA^* and A^*A^* are, respectively, incremented by $\alpha(1+k)$ and 2α relative to the value of AA . As before, we assume that the joint distribution of α and k is independent of the genotypic value of the parental allele. Let $f(\alpha, k)$ denote this joint probability density function and let $\mu = \sum \mu_i$ be the total gametic mutation rate for the trait of interest. The expected contribution to the total response from a new mutant appearing as a single copy becomes $2\alpha \cdot u(1/[2M], \alpha, k)$, the change in genotypic value if the new allele is fixed times its probability of fixation (the latter can be obtained by Equation 7.18a, using the fitnesses given by Equation 25.4). Because $2M\mu$ new mutants appear each generation, the asymptotic rate of response is

$$\begin{aligned} r_m(\infty) &= 2M\mu E \left[2\alpha \cdot u \left(\frac{1}{2M}, \alpha, k \right) \right] \\ &= 2M\mu \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} 2\alpha \cdot u \left(\frac{1}{2M}, \alpha, k \right) f(\alpha, k) d\alpha dk \end{aligned} \quad (26.32)$$

Note that the expected asymptotic rate depends critically on the exact shape of the distribution of mutational effects (a point echoed in Chapter 28). Fortunately, some fairly general results emerge by using simple approximations for the probability of fixation (similar to Equations 7.19a and 7.19b; see Hill 1982a, 1982b for details).

Consider first the case where all new mutants are additive ($k = 0$). Hill (1982b) found that, provided major alleles are not common among new mutants,

$$r_m(\infty) \simeq 2N_e \bar{\tau} \mu \frac{E^+[\alpha^2]}{\sigma_z} = \frac{4N_e \bar{\tau} \sigma_m^2}{\sigma_z} \frac{E^+[\alpha^2]}{E[\alpha^2]} \quad (26.33a)$$

where

$$E^+[\alpha^2] = \int_0^{\infty} \alpha^2 f(\alpha) d\alpha \quad (26.33b)$$

is the average squared increment of favorable alleles (i.e., those with $\alpha > 0$). If the distribution of mutational increments, $f(\alpha)$, is symmetric about zero, then $E^+[\alpha^2] = E[\alpha^2]/2$, as $\int_0^{\infty} f(\alpha) d\alpha = 1/2$, and the asymptotic response reduces to Equation 26.29. When major alleles are common among new mutants, correction terms involving $E^+[\alpha^3]$ appear; see Hill (1982b) for details. With divergent selection (the divergence between an up- and down-selected line; Chapter 25), effects due to asymmetry in $f(\alpha)$ cancel, and the asymptotic rate of divergence between high and low lines is simply twice the rate (for single-direction selection) predicted from the infinitesimal model, namely,

$$4N_e \bar{\tau} \frac{\sigma_m^2}{\sigma_z} \quad (26.33c)$$

independent of the shape of $f(\alpha)$. The effect of linkage on asymptotic response was examined by Keightley and Hill (1983, 1987), who found it to generally be small, with the relative effects of linkage increasing with σ_m^2 and N_e .

Hill and Keightley (1988) allowed for the possibility that new mutations are also influenced by natural selection. If both the trait and fitness effects of mutations are small, the distribution of α is symmetric, and natural selection effects are also symmetric in α (e.g.,

the change in fitness is a function only of $|\alpha|$, there is no change in the asymptotic rate of response. If these assumptions are violated, the asymptotic rate can be reduced.

To allow for dominance, we continue to assume the incremental mutation model. From LW Equation 4.12a, the additive variance contributed by a rare allele is

$$2p(1-p)\alpha^2[1+k(1-2p)]^2 \simeq 2p\alpha^2(1+k)^2$$

yielding a contribution to σ_A^2 from a single new mutation, where $p_0 = 1/(2M)$, of approximately

$$\alpha^2(1+k)^2/M$$

Because the expected number of new mutations per locus in any given generation is $2M\mu$, the expected additive variance contributed in each generation by new mutations at a given locus is

$$2M\mu E[\alpha^2(1+k)^2/M] = 2\mu E[\alpha^2(1+k)^2]$$

where the expectation is taken over the joint distribution of α and k values in new mutants. Summing over all loci, the expected new additive variance contributed each generation (in the absence of linkage disequilibrium) is

$$\sigma_m^2 = 2 \sum_{i=1}^n \mu_i E[\alpha^2(1+k)^2] = 2\mu E[\alpha^2(1+k)^2] \quad (26.34a)$$

as obtained by Hill (1982b). The last equality assumes the distribution of mutational values and rates to be the same at each locus. When all mutations are additive ($k = 0$) and symmetric ($E[\alpha] = 0$), this reduces to our previous definition of σ_m^2 . More generally, with complete additivity, but removing the assumption that $E[\alpha] = 0$, we have

$$\sigma_m^2 = 2\mu E[\alpha^2] \quad (26.34b)$$

while with complete dominance ($k = 1$),

$$\sigma_m^2 = 2\mu E[(2\alpha)^2] = 8\mu E[\alpha^2] \quad (26.34c)$$

For the same α and μ values, the mutational variance with complete dominance is four times larger than that for complete additivity (as the genotypic value of heterozygotes is doubled, which increases the variance by $2^2 = 4$).

For the case of complete dominance, Hill (1982b) found that the asymptotic rate of response is approximately

$$r_m(\infty) \simeq 16N_e \bar{t} \mu E^+ [\alpha^2] / \sigma_z \quad (26.35a)$$

where $E^+ [\alpha^2]$ is defined by Equation 26.33b. With a symmetric distribution of mutational effects, Equation 26.35a reduces to

$$r_m(\infty) \simeq N_e \bar{t} \frac{\sigma_m^2}{\sigma_z} \quad (26.35b)$$

where σ_m^2 is given by Equation 26.34c. For the same values of σ_m^2 , the response when all mutants are completely dominant is only half the expected response when alleles are additive (compare Equations 26.29 and 26.35b). However, for fixed values of μ and $E[\alpha^2]$, σ_m^2 is larger with complete dominance (compare Equations 26.34b and 26.34c), and the rate of response under dominance is twice as large as that expected for complete additivity.

If alleles are completely recessive, allelic effects are small, and the distribution of mutational effects is symmetric, the asymptotic response is approximately

$$r_m(\infty) \simeq 2N_e \bar{i} \mu E [\alpha^2] / \sigma_z \quad (26.36a)$$

(Hill 1982b). For recessives with large effects (cf. Equation 7.19b)

$$r_m(\infty) \simeq 2\mu E^+ [\alpha^{3/2}] \sqrt{\frac{2N_e \bar{i}}{\pi \sigma_z}} \quad (26.36b)$$

Thus, the limiting response when all new mutations are recessive is not predictable from σ_m^2 , even if mutational effects are symmetrically distributed. With recessive major alleles, the selection response scales as $\sqrt{N_e \bar{i}}$, and hence it increases much more slowly with $N_e \bar{i}$ than with complete dominance or additivity.

When loci are linked, the asymptotic response is reduced, but the effect is small unless linkage is tight, as might occur with a few small chromosomes (Keightley and Hill 1983). As mentioned previously, reduction in response also occurs if loci influencing the trait are linked to loci under natural selection.

Additional Models of Mutational Effects

A critical assumption in any analysis of mutational response is the mutational model. Given a current allelic effect of a , what can we say about the value, a^* , from a mutation in this allele? All of the above results make the incremental-mutation model assumption: $a^* = a + \alpha$, with the increment $\alpha \sim (0, \sigma_\alpha^2)$. This Brownian motion model (Appendix 1) implies that the additive variance (for neutral alleles) will be unbounded as N_e increases (Chapters 11 and 28).

As introduced in Chapter 11, the house-of-cards (HOC) is another potential mutation model. Here, each new allelic value is drawn from a constant distribution, *independent* of the current value of the parental allele, namely the HOC distribution: $a^* = \alpha$, with $\alpha \sim (0, \sigma_\alpha^2)$. Li and Enfield (1992) examined the long-term response under such a model. Starting with a population with no initial variation, they found that mutation increases the genetic variation up to some maximal value, after which it declines, with the time until this maximum is reached increasing with the number of loci. Li and Enfield only considered response over the first 120 generations, which was less than the smallest N_e value (150) in any of their simulations. Hence, the nature of any limit, or any asymptotic response, was not determined. The expectation under an HOC model is that an apparent selection limit is approached, although the population can still respond, but at an ever-diminishing rate, as further gains require random draws of ever-greater outliers from the HOC distribution of allelic-effects at a given locus. This view has connections with models of adaptive walks based on extreme-value theory, which are examined in the next chapter. A finite-value version of the HOC model, assuming that there are only k possible alleles at a locus, was examined by Zeng et al. (1989). As expected, the k -allele model results in an ultimate selection limit, as mutation cannot continue to generate better alleles indefinitely. In Chapter 11 we also introduced the Zeng-Cockerham model (Equation 11.23), $a^* = \tau a + \alpha$, which recovers Brownian motion when $\tau = 1$, and the HOC model when $\tau = 0$. To our knowledge, selection limits under the Zeng-Cockerham model have not been examined.

A second, very important, consideration is the role of pleiotropic fitness effects. These mutational models predict (for constant value of μ) that the equilibrium variance should linearly increase with N_e , at least when N_e is less than the reciprocal of the mutation rate (Chapter 11). However, even for modest N_e , the predicted equilibrium variances are too large to be comparable with observations (with heritabilities approaching 1.0, while most heritabilities in actual populations are below 0.5). This contradiction between theory and data as N_e increases is analogous to the limited observed range for molecular heterozygosity, which (assuming μ stays constant) should also approach one for large N_e (Chapter 2). If new mutations have pleiotropic fitness effects, the amount of usable variation will be overestimated at small N_e (the setting when σ_m^2 is measured). As detailed in Chapter 28, whether this results in a limiting value for $\tilde{\sigma}_A^2$ as $N_e \rightarrow \infty$ depends on very delicate features of the joint distribution of (s, α) for values of s near zero.

Optimizing the Asymptotic Selection Response

Because the asymptotic response is a function of $N_e \bar{t}$, response is maximized by selection strategies that maximize this product. As was the case for maximizing long-term response (the total response using only the initial variation), there is a tradeoff in that the optimal short-term response (maximizing \bar{t}) is in conflict with the optimal asymptotic response (because increasing \bar{t} decreases N_e). If our choice is simply the fraction of individuals to save, the previous discussion on the optimal selection intensity for long-term response also applies to considerations of the asymptotic response.

However, the breeder or experimentalist can use other design options beyond simply tuning the selection intensity. We have generally been assuming individual (or mass) selection, which is based solely on an individual's phenotype. There are, however, numerous other selection schemes, such as those incorporating information on the phenotypes of relatives (e.g., family-index and BLUP selection; Chapters 21 and 13, respectively). Schemes incorporating such information can improve the accuracy of an individual's breeding value estimate, and hence improve the accuracy of short-term response. This can be seen by recalling (Equation 13.11c) that the single-generation response, R , for any particular selection scheme is given by $R/(\bar{t}_x \sigma_A) = \rho(x, A)$, where selection occurs on some index, x , and $\rho(x, A)$ is the accuracy of the index (the correlation between an individual's index, x , and breeding values, A). Holding \bar{t} constant, the single-generation response increases with the accuracy, $\rho(x, A)$, of the selection method. While different schemes can improve the short-term response over mass selection, what is their effect on asymptotic response? Once again, the answer is that schemes improving the short-term response usually do so at the expense of the asymptotic response.

Optimal asymptotic response occurs by maximizing the fixation probabilities of favorable QTLs, which amounts to maximizing $N_e s$, where s is the selection coefficient on the QTL. For an additive trait, Hill (1985) and Caballero et al. (1996) generalized Equation 25.4 to show that

$$s = \left(\bar{t} \frac{a}{\sigma_z} \right) \frac{\rho(x, A)}{h} \quad (26.37)$$

Note that $\rho(x, A) = h$ for individual selection (the index is simply the trait value, $x = z$), recovering Equation 25.4. Fixation probabilities under different selection schemes with the same selection intensities are thus functions of the product $N_e s$, which is proportional to $N_e \rho(x, A)$. The tradeoff is that increasing $\rho(x, A)$ typically decreases N_e by increasing the among-family variance in trait value (and hence in fitness). Thus, as was the case in our previous discussion on the optimal selection intensity, the optimal selection scheme for short-term response may differ from the optimal scheme for long-term response.

The accuracy, ρ , depends on the genetic variance, and hence can change over time as these variances change. As shown in Chapters 24 and 25, predicting long-term changes in variances can be extremely difficult. Once again, the analysis is greatly simplified by assuming the infinitesimal model. Under this model, the additive genetic variance eventually converges to a value of $\tilde{\sigma}_A^2 = 2N_e \sigma_m^2$. The effect of different selection schemes on the equilibrium additive variance (and ρ) is then entirely determined by the effective population size that each scheme generates. In comparing two different selection schemes (i and j) with the same selection intensity, Wei et al. (1996) showed that the ratio of asymptotic responses becomes

$$\frac{\tilde{R}_i}{\tilde{R}_j} = \frac{\tilde{\rho}(i) \tilde{\sigma}_A(i)}{\tilde{\rho}(j) \tilde{\sigma}_A(j)} = \frac{\tilde{\rho}(i)}{\tilde{\rho}(j)} \sqrt{\frac{N_e(i)}{N_e(j)}} \quad (26.38)$$

where a tilde denotes an equilibrium value and $\tilde{\rho}(i)$ denotes the accuracy (at the equilibrium variances) of selection scheme i . The careful reader will note that the effect of N_e is twofold—there is a direct effect (the square root of the N_e ratio) and also an indirect effect through the ratio of the $\tilde{\rho}$ (which is a function of $\tilde{\sigma}_A$, and hence of N_e).

Example 26.6. Consider the asymptotic response to mass (m) versus within-family (w) selection. Under within-family (full-sib) selection, $N_{e(w)} \simeq 2N$, as the among-family variance is zero (Equation 3.4). In contrast, $N_{e(m)} < N$, with the difference between $N_{e(m)}$ and N increasing with the selection intensity and heritability (Equation 26.8), implying that

$$\sqrt{\frac{N_{e(w)}}{N_{e(m)}}} \geq \sqrt{2} \quad (29.39a)$$

The accuracy for mass selection is given by

$$\rho(z, A) = \frac{\sigma(z, A)}{\sigma_A \sigma_z} = \frac{\sigma_A^2}{\sigma_A \sigma_z} = \frac{\sigma_A^2}{\sqrt{\sigma_A^2 (\sigma_A^2 + \sigma_E^2)}} \quad (29.39b)$$

yielding an asymptotic accuracy as

$$\tilde{\rho}(m) = \frac{\tilde{\sigma}_A^2}{\sqrt{\tilde{\sigma}_A^2 (\tilde{\sigma}_A^2 + \sigma_E^2)}} = \frac{2N_{e(m)} \sigma_m^2}{\sqrt{2N_{e(m)} \sigma_m^2 (2N_{e(m)} \sigma_m^2 + \sigma_E^2)}} \quad (29.39c)$$

as obtained by Wei et al. (1996).

Turning to within-family selection, let \bar{z}_f denote the family mean. Selection decisions are based on the value of $z - \bar{z}_f$. Recalling our treatment of within-family selection from Chapter 21, the resulting accuracy for within-family (full-sib) selection becomes

$$\rho(w) = \rho(z - \bar{z}_f, A) \simeq \frac{\sigma(z - \bar{z}_f, A)}{\sqrt{\sigma^2(A) \sigma^2(z - \bar{z}_f)}} \simeq \frac{\sigma_A^2/2}{\sqrt{\sigma_A^2 (\sigma_{Gw}^2 + \sigma_{Es}^2)}} \quad (29.39d)$$

where the last step ignores the effect of the number of sibs (n) in each family by assuming that n is large (see Chapter 21 for expressions for when n is small). The within-family genetic variance, σ_{Gw}^2 , equals $\sigma_A^2/2$ for a full-sib family with only additive effects, while the within-family environmental variance, σ_{Es}^2 , equals σ_E^2 under the assumption of no common-family effects (Chapter 21). We make these simplifying assumptions here, but more general expressions easily follow. At equilibrium

$$\tilde{\rho}(w) = \frac{\tilde{\sigma}_A^2/2}{\sqrt{\tilde{\sigma}_A^2 (\tilde{\sigma}_A^2/2 + \sigma_E^2)}} = \frac{N_{e(w)} \sigma_m^2}{\sqrt{2N_{e(w)} \sigma_m^2 (N_{e(w)} \sigma_m^2 + \sigma_E^2)}} \quad (29.39e)$$

(Wei et al. 1996). Applying Equation 26.39a along with Equations 26.39c and 26.39e yields

$$\frac{\rho(w, \infty)}{\rho(m, \infty)} \geq \frac{1}{\sqrt{2}}$$

Thus,

$$\frac{\tilde{R}_w}{\tilde{R}_m} = \left[\sqrt{\frac{N_{e(w)}}{N_{e(m)}}} \right] \left[\frac{\tilde{\rho}(w)}{\tilde{\rho}(m)} \right] \geq \sqrt{2} \frac{1}{\sqrt{2}} = 1$$

and hence $\tilde{R}_w \geq \tilde{R}_m$. That is, for the same selection intensity, the asymptotic response is greater under within-family selection than under mass selection.

The effects of different selection schemes on the effective population size can be seen by considering the general weighted index of within- and among-family information,

$$I = (z - \bar{z}_f) + \lambda(\bar{z}_f - \bar{z}) = (\text{within-family}) + \lambda(\text{among-family}) \quad (26.40)$$

where z is an individual's phenotypic value, \bar{z}_f is the mean of its family, and \bar{z} is the grand mean. A number of selection schemes can be represented (either exactly or to a good approximation) by this index (Chapter 21). For example, $\lambda = 1$ corresponds to individual selection (as $I = z - \bar{z}$), while $\lambda = 0$ corresponds to strict within-family selection ($I = z - \bar{z}_f$). The accuracy of selection using this index with an appropriately chosen value of λ is greater than the accuracy of individual selection ($\rho(I, A) > \rho(z, A)$; Equation 21.53b), and hence selection using the optimal index gives a greater short-term response than mass selection. To a first approximation, BLUP selection corresponds to this optimal index.

Because the effective population size is reduced by inflating the among-family variance, the larger the value of λ in Equation 26.40, the greater is the reduction in N_e . Larger values of λ place more weight on family information, resulting in more individuals from the best families being coselected. The reduction in N_e is greatest when heritability is small, as in these cases the index places the most weight on the among-family component. Yet, however, it is exactly this setting under which index and BLUP selection have the greatest short-term advantage over individual selection. Conversely, when care is taken to equalize the amount of inbreeding across methods, individual selection can produce a larger single-generation response than index selection or BLUP (Quinton et al. 1992; Andersson et al. 1998).

Can one balance this tradeoff between increased accuracy for short-term response using information from relatives versus inflation of the among-family variance (and the resulting reduction in the long-term response via reduction in N_e) that these schemes produce? Several authors have proposed schemes for reducing the among-family variance following selection. Toro and colleagues (Toro and Nieto 1984; Toro et al. 1988; Toro and Pérez-Enciso 1990) suggested that selected individuals be mated in ways that minimize the coancestry between them. A slightly different strategy, **compensatory mating**, was suggested by Grundy et al. (1994). Here, individuals from families that are overrepresented following selection are mated to individuals from underrepresented families. This has the effect of reducing the cumulative effect of selection (Q_τ in Equation 26.6c) by reducing the variance in family contribution. Grundy et al. also suggested a more subtle approach. They noted that by using slightly biased selection parameters in the index (for example, using upwardly biased estimates of h^2 when computing the optimal λ), the slight reduction in the accuracy of the adjusted index from its optimal value is more than offset by a much smaller decrease in N_e . They suggested that this approach, combined with compensatory mating, provides a simple way for ameliorating the reduction in N_e . Verrier et al. (1993) also suggested that schemes placing slightly less emphasis on family information can, in small populations, give greater long-term response than BLUP selection. We examine the optimal control for inbreeding under BLUP in detail in Volume 3.

This tradeoff between optimal short-term versus optimal asymptotic response has economic consequences for breeders. While breeders are ultimately better off in the long run (in terms of total response) using selection schemes that are initially less accurate, competing breeders using the initially more accurate schemes will achieve a larger short-term response. Breeders must thus decide between staying in business over the short term versus experiencing a larger payoff (in terms of a greater response) over the long run.

Long-term Response:

3. Adaptive Walks

Real evolution may look less like an attempt to evolve uphill on a static landscape and more like an attempt to keep one's footing on an ever-changing landscape.

Orr (2009)

Our treatment of long-term selection response started by considering the role of existing genetic variation (Chapters 25 and 26). As such variation becomes exhausted through drift and selection, new mutations become increasingly more important (Chapter 26). Here we consider the logical conclusion of this second phase, the continual fixation of new mutations and their impact on long-term response over evolutionary time scales. In particular, our focus is on the nature of **adaptive walks**—the sequence of fixed mutational steps that underlie a specific adaptation. There is a rich (and growing) population-genetics literature on this subject which was nicely reviewed by Orr (2005a, 2005b). Much of this work starts with **Fisher's geometric model (FGM)** (Fisher 1930), an extremely influential model for the probability that a new mutation is adaptive (i.e., beneficial). A number of interesting results follow from this model, which assumes adaptation toward some optimal trait value (stabilizing selection). A second class of adaptive-walk models that we consider are based on extreme-value theory and focus on the *fitness effects* of new mutations (as opposed to the FGM focus on *trait values*). Surprisingly, both classes of models give the same general result: *the effect-size distribution of genetic factors fixed along an adaptive walk is often approximately exponential*.

FISHER'S MODEL: THE ADAPTIVE GEOMETRY OF NEW MUTATIONS

Fisher (1930) offered a highly simplified, yet elegant and powerful, geometric argument suggesting that the probability that a new mutation increases fitness is a simple function of the size of the mutational effect relative to the distance of the original phenotype from the optimal trait value. Fisher believed that his model, while idealized, captured the “statistical requirements of the situation” of adaptation: one complex thing (the organism) must fit into another complex thing (the environment). Although Fisher envisioned that adaptation requires a highly multivariate phenotype meshing with a highly multivariate fitness function, Figure 27.1A shows the basic structure of his model in two dimensions. Stabilizing selection is assumed, with the current phenotypic value at a distance d from a fitness optimum, θ . The two traits have been scaled and rotated to be independent, with equal selection intensity on both (this can be accomplished using a transformation along the lines suggested by Equation A5.16).

As depicted in Figure 27.1A, we assume stabilizing selection acting on two independent traits. Let the vector \mathbf{z} , at distance d from the optimal value, θ , represent the current multivariate phenotype associated with a particular genotype. The phenotypic change by a new mutation is given by a vector of length r (the **effect size** of the mutation) extended from the current value (\mathbf{z}) in some random direction (i.e., the incremental model). Any mutation whose distance to θ is less than d has increased fitness (and is said to be **beneficial** or **adaptive**), while a mutation whose distance from θ is greater than d has lower fitness. Drawing a circle of radius d around θ (a contour of equal fitnesses corresponding to that of the original phenotype), the probability that the new mutation is advantageous will be

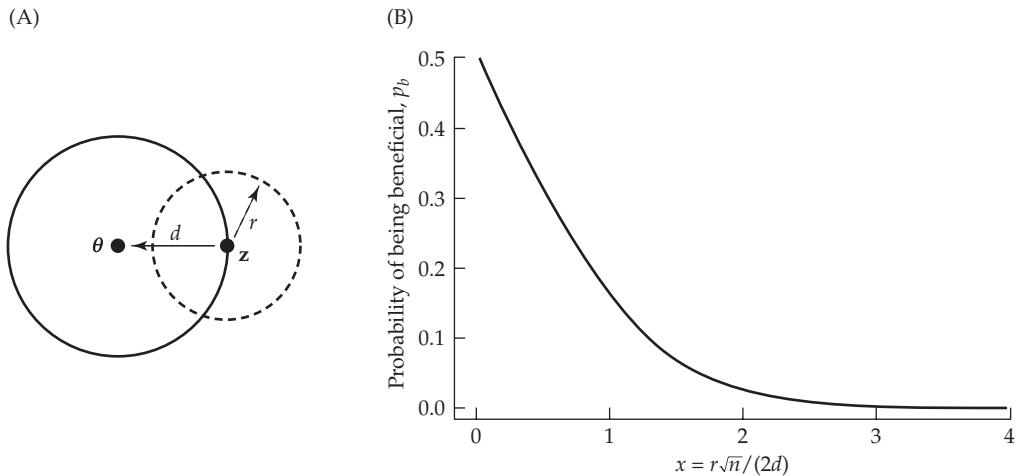

Figure 27.1 **A:** Fisher’s (1930) model for the probability that a new mutation increases fitness for the simple case of two independent traits under stabilizing selection. The optimal fitness value occurs at θ , while the mean phenotypic value of the genotype about to experience a mutation is \mathbf{z} , which is at distance d from the optimum. The solid circle denotes the fitness contour passing through the current value \mathbf{z} , meaning that all points inside this circle have higher fitness. The effect of a new mutation is to move the expected phenotype by some distance (r) in a random direction around \mathbf{z} , with the space of possible new phenotypes denoted by the dashed circle (the **isotropic** assumption of equal and independent mutational effects on both traits). The probability of increased fitness for a random mutation of effect r is the fraction of the circumference of the dashed circle that resides inside the solid circle (i.e., is closer to θ), namely, the fraction of all new mutations (whose range of possible phenotypes fall exactly along the circumference of the dashed circle) with a higher fitness than the original allele. More generally, under **anisotropic** conditions (correlated and/or unequal effects for selection, mutation, or both), these circles are replaced by ellipses in two dimensions, and the hyperspheres are replaced by hyperellipsoids in three or more dimensions. **B:** For an n -dimensional phenotype, the probability, p_b , that a new mutation is beneficial (has an increased fitness) is $1 - \Phi[r\sqrt{n}/(2d)]$, where $\Phi[x]$ is the cumulative density function of a unit normal (Equation 27.1b).

simply the probability that the mutation lies within this contour (i.e., is closer to θ).

To extend this simple two-dimensional model to n traits, let the vector \mathbf{z} denote the current (multidimensional) phenotype of an allele, which is at a (Euclidean) distance of d from the optimum, θ . We express this condition as $\|\mathbf{z} - \theta\| = d$, where $\|\mathbf{x}\|$ denotes the length of the vector \mathbf{x} (Equation A5.1a). Now suppose this allele mutates under the incremental model (Chapter 12), so that its new phenotype is $\mathbf{z}' = \mathbf{z} + \mathbf{m}$, where \mathbf{m} denotes the vector of mutational increments. In particular, the new value for trait i is $z'_i = z_i + m_i$, where $E[m_i] = 0$. Further, we assume the mutational increments are uncorrelated and homoscedastic, so that we can write their covariance matrix as $\mathbf{M} = \sigma_m^2 \mathbf{I}$. Fitness is increased if $\|\mathbf{z}' - \theta\| < \|\mathbf{z} - \theta\|$; namely, \mathbf{z}' is closer to the optimum than \mathbf{z} . Now consider a vector of random mutational inputs subject to the constraint that $r^2 = \sum m_i^2 = \|\mathbf{m}\|^2$. Fisher’s insight was that a single parameter, the **Fisher scaling parameter**,

$$x = \frac{r\sqrt{n}}{2d} \quad (27.1a)$$

is sufficient to compute the probability, p_b , that such a new mutation is beneficial, with

$$p_b = \frac{1}{\sqrt{2\pi}} \int_x^\infty \exp(-y^2/2) dy = 1 - \Phi(x) \quad (27.1b)$$

Here Φ is the cumulative density function of a unit normal. While Fisher did not present one, derivations of Equation 27.1b were provided by numerous authors (Kimura 1983; Leigh 1987; Rice 1990a; Hartl and Taubes 1996). Fisher's critical observation was that the probability (p_b) that a new mutation is beneficial is a decreasing function of the scaling parameter, x (Figure 27.1B). Increasing x decreases the chance that a mutation is beneficial, and conversely, decreasing x increases the chance it being beneficial. Indeed, as x approaches 0, the probability that a new mutation is beneficial approaches 0.5. The analogy Fisher used to explain this result was that of trying to improve the focus on a microscope. A very tiny change has close to a 50% chance of (very slightly) improving the focus, while a much larger change is far less likely to do so. This analogy led to the use of the term **Fisher's microscope** in the literature to describe this feature of the model.

Fisher's scaling factor (x) consists of two components. The first, r/d , is the ratio of the length of the vector of mutational increments to the distance from the optimum. Whether the mutational effect size (r) is regarded as large or small under Fisher's model depends on the distance of its progenitor allele from the optimum. Consider two mutations, both of which add a random vector of length 1 to the current phenotypic value. If $d = 50$, this is a mutation of small effect from the standpoint of x , while if $d = 2$, this is a large-effect mutation. Hence, the scaling of x accounts for the size of the mutation relative to the current distance from the origin. The second component of x , $\sqrt{n}/2$, accounts for the geometry of the fitness surface. As the dimensionality of the fitness surface increases, there are increasing numbers of constraints on a random mutation required for it to be beneficial. Hence, increasing the complexity of the phenotype (the number of independently selected traits, n , influenced by a new mutation) decreases the chance of mutations being beneficial. The original interpretation of Fisher's model was therefore twofold: small-effect mutations are the stuff of adaptation, and there is a “**cost of complexity**” (Orr 2000). As we will see, both of these initial assertions need significant refinement.

Orr (2006; also see Hartl and Taubes 1996, 1998; Waxman and Peck 1998) showed that Fisher's model provides a much richer description beyond simply predicting whether a mutation is beneficial—it can be used to generate the full distribution of fitness effects for the set of random mutations of a given size, r . Initially, this is performed under the assumption of equal and uncorrelated mutational and fitness effects (i.e., the distribution of trait displacements is a hypersphere of radius r and the fitness surface displays stabilizing selection with equal, and uncorrelated, selection along all trait dimensions). One can then integrate this result for a specific value of r over the assumed distribution of r values to obtain the unconditional distribution of fitness effects.

For the class of mutations that all have the same effect size, the fitness distribution is obtained by first computing the distribution of displacements toward the optimal value. Orr (198b) showed that this is approximately normal for large n , with a negative mean (on average, a random mutation moves the phenotype *away* from the optimum). Translating displacements into fitnesses under the assumption of Gaussian stabilizing selection, the resulting distribution of fitness effects of random mutations (again, all of the same size, r) is also approximately normal, with a mean less than the current fitness of the starting genotype. Martin and Lenormand (2006) and Tenaillon (2014) provided a more exact analysis, which yields a fitness distribution in the form of a modified gamma distribution (Appendix 2). Hence, most new mutations move a trait further away from its optimum, thereby lowering fitness. Only those mutations in the right tail of this displacement distribution (those with positive values, namely, those whose phenotypes following mutation are closer to θ) are advantageous. This important result foreshadows a rather different model of adaptation based on extreme-value theory (i.e., based on draws from the extreme right-hand tail of a fitness distribution), which will be examined in the second half of this chapter.

One might be concerned by the highly simplistic nature of Fisher's model: n independent traits with equal selection and mutation on each. However, these assumptions can be relaxed by replacing Fisher's assumed hyperspheres for fitness contours and mutational

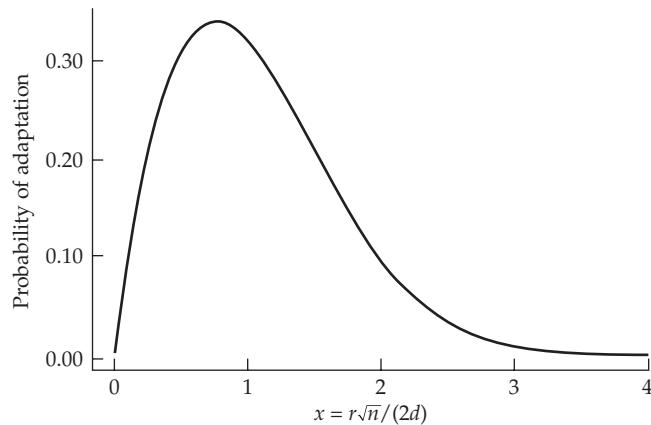

Figure 27.2 The probability of adaptation (the probability of being beneficial times the probability of fixation) for a new mutation with scaled effect $x = r\sqrt{n}/(2d)$. Figure 27.1B shows the probability, p_b , that such a mutation is *beneficial*, while the curve in this figure (which also incorporates the resulting selection coefficient) is the chance that it is beneficial and *fixed*.

effects (under the **isotropic assumption** of equal and uncorrelated effects) with hyperellipsoids, which allows for among-trait correlations and unequal traits effects in both fitness and mutation (e.g., Waxman and Welch 2005; Martin and Lenormand 2006, 2008; Waxman 2006, 2007). This **anisotropic assumption** of unequal and/or correlated pleiotropic mutational effects can be modeled by using a mutational covariance matrix, M , and unequal and/or correlated stabilizing selection (Chapter 30) can be accommodated with a semipositive-definite matrix, S (e.g., a matrix with no negative eigenvalues; Appendix 5). The resulting effective number of dimensions for x is given by $n/(1 + c_v^2)$, where c_v is the coefficient of variation of the eigenvalues of the matrix product of MS .

Fisher's model can also be derived from biological first principles. Martin (2014) showed that one can recover Fisher's model by starting with a complex metabolic network that influences a number of traits. Perhaps the best summary of Fisher's model is the comment by Fox (2014): "Sometimes, even really abstract mathematical models can make really good predictions about real-world biology. Further, they do so *because* of their abstractness, not *despite* it." Fisher's model is so powerful, not because it fully captures all of the biology, but rather because it *avoids* most of the biological details to make its critical points. Precisely because of this generality, there has been a recent resurgence of interest in Fisher's model as a framework for a number of evolutionary questions (reviewed by Tenaillon 2014).

Fisher-Kimura-Orr Adaptive Walks

A subtle feature, first noted by Kimura (1983), makes Fisher's smaller-is-better result misleading. An examination of Equation 27.1b and Figure 27.1B suggests that the majority of beneficial mutations are those with very small effects—those mutations whose length, r , satisfies $x \ll 1$, namely, $r \ll 2d/\sqrt{n}$. While this is indeed correct (under Fisher's model), Kimura noted that such small-effect mutations also have very small selective advantages, and therefore (while *beneficial*) are unlikely to be *fixed* by natural selection. Recall from Chapter 7 that the fixation probability of a favorable allele is $\approx 2s$, so that the magnitude of s , not only its sign, is important in determining which factors become fixed.

Under Fisher's model, and conditioning on a mutation being beneficial, the expected value of s is linearly proportional to x , as the distance from θ is an indicator of fitness (Kimura 1983; Orr 1998b). This can be more compactly written as $E[s] \propto x$. Thus, the probability that a mutation will be *fixed* is a function of both its selective advantage and its chance of being beneficial, $(2s) \cdot p_b \propto (2x) \cdot [1 - \Phi(x)]$. We call this the **probability of adaptation**. As shown in Figure 27.2, the outcome is a dramatic shift in our interpretation of Fisher's result: adaptation favors mutations of *intermediate* effect. A comparison of the difference

between Figures 27.1B and 27.2 highlights a critical distinction important throughout this chapter, namely, the difference between the distribution of effects (be they trait values or fitness) over *all* new beneficial mutations versus the distribution of effects restricted to *fixed* beneficial mutations.

There is an irony here in that although Fisher was a pan-selectionist, his initial analysis suggested that alleles of very small effect (i.e., nearly neutral) were more important for adaptation (i.e., comprise the majority of beneficial mutations). Conversely, Kimura, the founder of the neutral theory, showed that Fisher's model (when more carefully considered) argues for a role of stronger selection than envisioned by Fisher (i.e., fixing alleles of intermediate, rather than small, effect).

It is important to note that Figure 27.2 does *not* reflect the distribution of the x values for fixed mutations (i.e., the scaled lengths of fixed mutations). Rather, it describes the *filter of natural selection*, giving the chance that a mutation with effect x is fixed. The distribution of the x -scaled r values for fixed mutations depends on the product of the distribution of new mutational input (the distribution of r values among new alleles) and the chance that each is fixed (Figure 27.2).

To decouple the separate issues of the impact of selection (given a specific effect size) and the distribution of mutational effect sizes, both Kimura and Orr initially assumed a uniform distribution of effect sizes. This focuses discussion on the role of the filter of selection. The key finding, of a roughly exponential distribution of fixed trait effects, holds under rather general distributions of the effects of new mutations. For example, an exponential distribution of r , when compounded with an exponential distribution of fixed effects for a given value of r , returns an exponential. Orr's (1998b) simulations showed that the result of a roughly exponential distribution of the effect sizes of successful (i.e., fixed) mutations was remarkably robust to the assumed distribution of mutational effect sizes.

To examine the impact of selection on the pattern of successive fixations, we first consider the scaled length (x_1) of the initial successful (fixed) mutation at the start of a walk. The scaling from r into x accounts for both the initial distance from the optimum ($d_0 = ||\mathbf{z} - \boldsymbol{\theta}||$) and dimensionality (n) of the process (Equation 27.1a). Assuming a uniform distribution for the r values of new mutations, Kimura found that the expected value for $x_1 = r_1 \sqrt{n} / [2d_0]$ of this first successful mutation is $E[x_1] \simeq 1.06$. Hence,

$$E[x_1] = \frac{E[r_1]\sqrt{n}}{2d_0} \simeq 1.06, \quad \text{or} \quad E[r_1] \simeq \frac{2.12 d_0}{\sqrt{n}} \quad (27.2a)$$

where $E[r_1]$ is the expected value of r for the first-fixed mutation. For example, for $n = 10$, $E[r_1] = 0.67d_0$, while $E[r_1] = 0.3d_0$ for $n = 50$. Orr (1998b, 1999, 2000) noted that Kimura's result is simply the *first step* of the adaptive walk starting at distance d_0 from the optimum. Following this first fixation, the walk starts anew from distance $d_1 < d_0$ (Figure 27.3).

It is important to note that $E[r_1]$ is the expected total length of the vector of mutational increments (the distance between \mathbf{z} and its value, $\mathbf{z}' = \mathbf{z} + \mathbf{m}$, after the mutation, with $r = ||\mathbf{m}||$). Our real interest is not this length, but rather in how much of this displacement is toward $\boldsymbol{\theta}$, meaning that the new phenotype is actually closer (and more adaptive) than \mathbf{z} , i.e., $||\mathbf{z}' - \boldsymbol{\theta}|| < ||\mathbf{z} - \boldsymbol{\theta}||$. A large value of r_1 , by itself, does not imply a large jump closer to $\boldsymbol{\theta}$. Hence, to continue our analysis of the walk, we first need to compute the expected distance moved toward the optimum (i.e., the new distance, $d_1 = ||\mathbf{z}' - \boldsymbol{\theta}||$, from $\boldsymbol{\theta}$; Figure 27.3) after this first step of the walk (the first fixation event).

How much closer does fixing a mutation move us toward the optimum? The first fixed mutation almost never points exactly in the direction of the optimum, so that the actual amount of adaptation (distance moved toward $\boldsymbol{\theta}$) is less, and likely much less, than the length of the jump (Figure 27.3). Thus, instead of $E[x_1]$, we need to consider the length, $E[x_{p,1}]$, of the expected projection (Appendix 5) in the direction of the optimum. For large n , Orr (1998b) found that this projection is approximately

$$E[x_{p,1}] \simeq \frac{E[x_1]}{\sqrt{n}} \quad (27.2b)$$

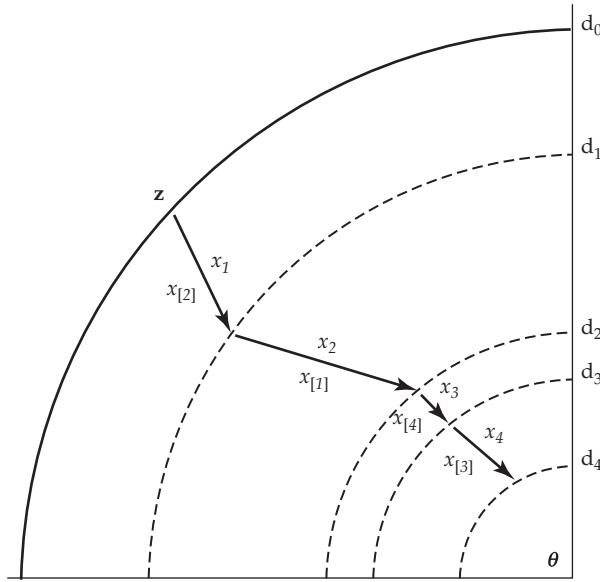

Figure 27.3 An example of an adaptive walk (in two dimensions), starting at \mathbf{z} and moving toward the optimal value, θ . Here x_i denotes the scaled mutational size of the i th fixed mutation (with $r_i = 2d_0x_i/\sqrt{n}$), while $x_{[i]}$ denotes the i th largest step (the i th largest x value over all mutations fixed during the walk). In this example, the largest jump, $x_{[1]}$, occurs at the second step (x_2), rather than at the first (x_1).

Scaling the phenotypes such that the initial distance from the optimum is one ($\|\mathbf{z} - \theta\| = d_0 = 1$), from Equation 27.1a the starting distance on the x scale is $\sqrt{n}/2$. Hence, following the first jump (the first fixation of a beneficial mutation), the population (on average) moves to a distance (in the x value scale) of

$$\sqrt{n}/2 - E[x_{p,1}] = \sqrt{n}/2 - E[x_1]/\sqrt{n}$$

which implies that the new distance to the optimum (on the x scale) following the first jump is a fraction,

$$\frac{\sqrt{n}/2 - E[x_1]/\sqrt{n}}{\sqrt{n}/2} = 1 - 2E[x_1]/n \quad (27.2c)$$

of the initial starting distance.

Orr's key insight was that the size distribution of the second jump (i.e., the distribution of x_2) is the same as that of the first jump, but with the distance to the optimum reduced an amount given by Equation 27.2c. Likewise, following the second jump, the distance to the optimum (as a fraction of the original distance) is the square of the value calculated by Equation 27.2c, and so forth, which generates a self-similar process for each step of the walk toward the optimum, for which $E[d_i] = (1 - 2E[x_1]/n)^i d_0$. It is this self-similar feature that generates the exponential distribution of effect sizes among fixed mutations. Orr (1998b) obtained the distribution for the Fisher-scaled effect size ($x = r\sqrt{n}/2$, taking $d = d_0 = 1$) of the new mutation (Equation 27.1a) during step k of the walk as

$$\psi(x, k) = C c_k^2 x [1 - \Phi(c_k x)] \quad \text{where} \quad c_k = \left(1 - \frac{2E[x_1]}{n}\right)^{1-k} \quad (27.3)$$

where C is a normalization constant. This expression is for a uniform distribution of mutation effects (the r values). More generally, the $C c_k^2$ terms in Equation 27.3 are replaced by $C \phi(c_k x) c_k^2 x$, where ϕ is the assumed distribution of mutational effects (Orr 1998b).

Assuming a uniform distribution of mutation effects (the r values), Orr showed that Equation 27.3 implies that the distribution of the $x_i = r_i \sqrt{n}/2$ is approximately exponential

with parameter $\lambda \simeq 2.9$ (i.e., with a mean value of $1/\lambda \sim 0.34$). Simulation studies by Orr (1998b, 1999) showed that this result is very robust to different assumptions about the distribution of mutational inputs, especially when large-effect mutations are not common.

Orr's simulations also showed that the exponential approximation may break down for mutations near the very end of the walk, where the fixed values of x_i are very small as the process very closely approaches θ . In part, this behavior arises because of the drift barrier, discussed in Chapter 7. As the fitness effects of a mutation become sufficiently small ($4N_e|s| \ll 1$), the fixation probability approaches the neutral expectation (i.e., the initial allele frequency, $1/[2N]$), rather than $2s$. Hence, even in a constant environment, perfect adaptation does not occur. Rather, as the drift barrier is approached, there is a constant fixation of mutations of very small effect, which are random in their direction toward, and away from, the optimum. Hence, Orr's key finding that the distribution of the effects of fixed mutations during a walk is roughly exponential is tempered somewhat by departures for fixed mutations with very small effects. However, given that this class of fixed mutations with very small effects would be very difficult to detect, from an empirical standpoint, the bulk of any detected substitutions during a walk would follow an approximately exponential distribution.

A critical point noted by Orr (1998b), and shown in Figure 27.3, is that the *largest* “jump” in the walk, $x_{[1]}$ (the largest scaled length for *any* of the fixed mutations), does not necessarily correspond to the *first* jump, x_1 (the scaled length of the vector of effects for the first fixed mutation). The expected value of the largest jump is approximately

$$E[x_{[1]}] \simeq \frac{1}{\lambda} \left[\ln \left(\frac{\lambda n}{2} \right) + 0.5772 \right] \quad (27.4a)$$

For example, taking $\lambda = 2.9$ and $n = 50$, Equation 27.4a yields the expected *largest* jump as $E[x_{[1]}] \simeq 1.68$, implying an expected total mutational size of $E[r_{[1]}] = 3.36d_0/\sqrt{n}$. Conversely, the expected value of the *first* jump is $E[x_1] \simeq 1.06$, or a mutation with $E[r_{[1]}] = 2.12d_0/\sqrt{n}$, which is $\sim 60\%$ of the expected size of the largest jump. More generally, the expected value of the k th largest jump is

$$E[x_{[k]}] \simeq \frac{1}{\lambda} \left[\ln \left(\frac{\lambda n}{2} \right) - \sum_{i=1}^{k-1} \frac{1}{i} + 0.5772 \right] \quad (27.4b)$$

and Equation 27.1a yields $E[r_{[k]}] = (2d_0/\sqrt{n})E[x_{[k]}]$. Using this result to consider the quantity $(E[x_{[k]}] - E[x_{[k+1]}])$ provides the expected difference in the scaled r values for the k and $k+1$ largest fixed mutations, which yields

$$E[x_{[k]}] - E[x_{[k+1]}] = E[\Delta_{[k]}] \simeq \frac{1}{\lambda} \left[\sum_{i=1}^k \frac{1}{i} - \sum_{i=1}^{k-1} \frac{1}{i} \right] = \frac{1}{\lambda k} = \frac{0.349}{k} \quad (27.4c)$$

for $\lambda \simeq 2.9$. For example, rearranging yields $E[x_{[2]}] = E[x_{[1]}] - 0.349 = 1.33$, and so on. This form of spacing will reappear in our discussion of walks modeled by extreme-value theory.

The careful reader might have noticed that Orr's finding of an approximate exponential distribution in the effects of fixed mutations refers to the lengths, r , of the vectors of these mutations. This is different from the actual phenotypic effect size for any *single trait*. Orr (1999) addressed this issue, and found that the projection of a favorable (but otherwise random with respect to direction) vector of length r onto any particular trait (say trait j) is roughly normally distributed, with an expected absolute value of

$$E[|z_j|] = \frac{2r}{\pi\sqrt{n}} \quad (27.5)$$

Hence, the distribution of the effect sizes for a single trait is the result of sampling from two distributions. First, the expected value of the effect size (Equation 27.5) is a function

of the random variable, r , which is roughly exponentially distributed for fixed mutations. Second, there is sampling noise around the expected value given by Equation 27.5, namely, the roughly normal distribution for the projection from a given value of r onto the mutational effect on any given single trait. It is therefore not surprising that Orr's simulations showed that the effect-size distribution on any particular single trait also shows a strong exponential trend (with Gaussian sampling noise around the expected trend). Thus, while the total *lengths* of the mutational displacement vectors associated with fixed mutations are roughly exponentially distributed, so too are the resulting changes in the phenotypic values of fixed mutations for any particular trait. Consequently, if we could score the phenotypic effects on a trait over the set of fixed mutations leading to the current adaptation, we would expect them to be roughly exponential (except for those fixed mutations with effects on a trait that are extremely small, and therefore difficult to detect).

The view of a random walk as a series of discrete, fixed steps is one extreme vision, and essentially a hard-sweep view (Chapter 8). The other extreme view is of the constant generation of mutations of small effect, which mount a continuous infinitesimal response (soft or partial sweeps; Chapter 8). Lande's analysis (Chapter 25) showed that polygenic response (changes in the trait mean through allele-frequency changes, and not necessarily fixations, at a large number of loci of small effect) is favored when major genes have negative pleiotropic effects on other traits, unless there is strong selection on a focal trait. Hence, adaptive walks that follow Fisher's model may be biased toward cases of traits that are under strong selection.

A second assumption of the Fisher-Kimura-Orr adaptive walk model is weak mutation, with only a single beneficial mutation segregating at any one time. With multiple segregating mutations, Hill-Robertson effects (Chapters 3, 7, and 8) reduce the effectiveness of selection, the most extreme example being **clonal interference** in asexuals (Gerrish and Lenski 1998; Rozen et al. 2002). When considering the fixation of mutations in clonal (asexual) populations, a new beneficial mutation must first avoid stochastic loss when rare. While such surviving cosegregating beneficial mutations (which we denote as **competing**) may be fixed in a sexual population, in an asexual population they are fully linked to genomes that may experience additional beneficial mutations before the initial mutation becomes fixed. When $N\mu \ll 1$, the presence of multiple segregating beneficial mutations is unlikely (where μ is now the genomewide beneficial mutation rate). However, when $N\mu \gg 1$, clonal interference can occur, wherein the most fit genomes compete with each other and only one is ultimately fixed (Gerrish and Lenski 1998; Elena and Lenski 2003; Barrick and Lenski 2013; Levy et al. 2015). As noted by Barrett et al. (2006a), the winning genome often accrues several beneficial mutations on its way to fixation (outcompeting genomes with potentially more favorable initial mutations that did not accumulate additional beneficial mutations), which can result in an investigator overestimating the fitness effects under the assumption of a single beneficial mutation driving the fixation.

Example 27.1. Annual wild rice (*Oryza nivara*) is a photoperiod-insensitive selfer adapted to seasonally dry habits. It is thought to have evolved from a progenitor with properties of its sister species, *Oryza rufipogon*, a photoperiod-sensitive, perennial outcrosser found in deep-water swamps. As a potential model system for adaptation to new conditions, Grillo et al. (2009) crossed these two species and mapped QTLs for flowering time, mating system, and life-history traits. The resulting distribution of the values of QTL effects for these traits was roughly exponential, as predicted from Orr's adaptive walk. If directional selection was an important factor in the divergence of these two species, one would expect to find an excess of the detected QTL alleles in *nivara* in the direction of the adaptive phenotypes (the QTL sign test; Chapter 12). Indeed, for flowering time and duration, all six of the *nivara* QTL alleles act in the direction of reduced photoperiod sensitivity and longer flowering. Likewise, all seven of the QTLs for mating system traits in *nivara* acted in the direction of increased selfing.

One prediction from the Fisher-Kimura-Orr model is that fixations of large-effect mutations are more likely when the current population is far from its adaptive peak. Rogers et al.

(2012) compared threespine stickleback fish (*Gasterosteus aculeatus*) from two different lake types. This species has a marine origin, but it colonized freshwater lakes at the end of the last ice age. Based on the presence of a sculpin predator, one lake type (sculpin-present) was judged as being closer to the ancestral marine optimum than a second type (sculpin-absent). A higher frequency of large-effect QTLs for morphology (related to general predator defense) was observed in the sculpin-absent lake type, consistent with the fixation of larger-effect mutations when the optimum is further away.

A corollary to this prediction is that larger fixed-effect sizes are expected at loci underlying traits that experience continual and sudden shifts in their fitness surfaces. Louthan and Kay (2011) suggested that this often happens in traits under biotic selection. They investigated this hypothesis with a meta-analysis of 1950 QTLs (1721 controlled traits presumed to be under abiotic selection, and the rest under biotic selection) from 10 plant families (but mainly Brassicaceae). They found larger QTL effect sizes for traits under presumed biotic, as opposed to abiotic, selection.

The Cost of Pleiotropy

We now turn to the second implication from an initial analysis of Fisher's model, which is the impact of n on x , and hence on p_b . Equation 27.1a shows that the scaling parameter, x , increases with \sqrt{n} , the number of traits (i.e., the complexity of an organism). For the same r/d values, the probability that a mutation is adaptive is lower in more phenotypically complex organisms (those with larger n values), which has been termed the cost of complexity. When considering the rate of adaptation, Orr (2000; also see Welch and Waxman 2003) noted that the cost of complexity is actually far greater than suggested by a superficial analysis of Fisher's model. Consider a rate of adaptation defined by the rate at which a trait approaches its optimal value. This rate is proportional to the product of three components: (i) the probability that a mutation is beneficial; (ii) the probability that such a mutation is fixed; and (iii) the length of a move (or displacement) toward the optimal value (the increase in fitness) when such a mutation is fixed. These last two factors each scale as $1/\sqrt{n}$ (Equations 27.2b and 27.5), so together they scale as $1/n$. Given that the probability of an adaptive mutation also decreases with n (in a monotonic, but nonlinear, fashion, as $p_b = 1 - \phi[\sqrt{nr}/(2d)]$), the net result is that the decrease in the rate of adaptation is faster than $1/n$, which suggests a far higher cost than under Fisher's initial analysis.

What exactly is n and what forces determine this number? The original Fisher model effectively assumed **universal pleiotropy**, namely, that all new mutations essentially influence *every* trait in an organism. Under this assumption, the number of independent trait combinations under selection (the dimension of the fitness surface; technically, this is the number of nonzero eigenvalues of the stabilizing selection matrix, S ; Appendix 5) in an organism is the factor that defines n . (The term universal pleiotropy first seems to have been used by Wright [1968], although, as noted by Wagner and Zhang [2011], Wright's usage appeared to be that every gene affects *more than one* trait, as opposed to the Fisherian notion that every gene affects *all* traits.) Under the Fisherian view of universal pleiotropy, the value of n is set by natural selection (n is the number of dimensions in the trait space that are under selection).

Given that Fisher's model is clearly biologically unrealistic, how valid is this concern of a cost of complexity (which, at face value, seems to imply that more complex organisms—those with more independent dimensions of trait space under selection—have a slower rate of evolution)? There are several potentially ameliorating factors. First, **mutational pleiotropy** is likely not universal, but rather more modular (the notion of **restricted pleiotropy**), wherein most mutations only influence traits within their developmental module (Wagner 1996b; Barton and Partridge 2000; Welch and Waxman 2003; Wagner et al. 2007; Wagner and Zhang 2011). Hence, the number of traits (on average) that a particular mutation influences is what determines n , not the overall dimension of the fitness surface. Notice that this shift in focus concerning the definition of n (from selection-driven to pleiotropy-driven)

immediately suggests that n can evolve (just as one can envision selection to increase, or decrease, developmental modularity).

Under restricted pleiotropy, the focus shifts from the complexity of an organism to the complexity of a module, with a **cost of pleiotropy** (Wagner and Zhang 2011), as the rate of adaptation is decreased in modules of higher complexity (i.e., modules in which single mutations impact a larger number of traits). As reviewed by Wang et al. (2010) and Wagner and Zhang (2011), evidence from extensive QTL mapping and gene-knockout studies in yeast, mice, and nematodes suggests that most mutations show restricted pleiotropy. For example, Wang et al. (2010) examined ~250 morphological traits in yeast and found that the median amount of pleiotropy for a given mutation was only 7 traits (2% of the traits examined) for the ~2500 gene knockouts that were examined. Hill and Zhang (2012a, 2012b), however, have suggested that we exercise some caution before accepting restricted pleiotropy. They performed simulation studies using a model with highly pleiotropic alleles (in which new mutations influence a large number of traits), and found that low power in the ability to detect effects on any particular trait can create the appearance of restricted pleiotropy (see Wagner and Zhang 2012 for a reply). Corrections for multiple comparisons, given the large number of tested traits (Appendix 4), is expected to result in low power for most of these mutant screens.

A second mitigating factor in determining the cost of complexity is that the intensity of selection likely varies over traits. This reduces the actual number of traits, n , in a module to an effective number of traits, n_e , where n_e decreases as the variance in trait selection intensity increases (Rice 1990a; Orr and Coyne 1992; Orr 2000; Waxman and Welch 2005; Martin and Lenormand 2006, 2008). If just a few traits in a module face the majority of the selective pressure, this significantly lowers the cost (i.e., it increases the rate of adaptation). A similar argument applies if mutational effects are very uneven over traits. Finally, the presence of highly correlated mutational effects within a module (e.g., mutations tend to affect traits in the same, as opposed to random, directions) also reduces the effective n (Wang et al. 2010). The joint impact from all these factors suggests that the effective dimensionality of a module is less, and likely far less, than the actual number of selectively independent traits that are influenced by a given developmental module.

The final mitigating factor in any cost of complexity is more subtle, as it deals with the relationship (if any) between the average incremental effect, m_i , of a mutation on a specific trait and the total effect, $r = \sqrt{\sum m_i^2}$, of that mutation over all the traits that it affects, and how this scales with n . Under the **invariant total-effect model** (Wagner et al. 2008), the total effect (r) of any given mutation is independent of the number of traits it influences. In that case, a mutation influencing more and more traits will, on average, see no change in its r value. Under this assumption, as a mutation influences more traits, its average effect on a given trait decreases with n (with r constant, m_i decreases with n). The complementary assumption is **Euclidean superposition** (Wagner et al. 2008), wherein the effect of a mutation on any given trait is independent of n (i.e., independent of how many other traits that mutation impacts). In this case, a mutation's total effect scales as

$$r = \sqrt{\sum_{i=1}^n m_i^2} = \sqrt{n} \sqrt{m^2}$$

where m^2 is the average squared effect of a mutation on a random trait (with m^2 constant, r increases with n). Both of these models are special cases of the more general scaling, $r \simeq a n^b$, where $b = 0$ corresponds to the invariant model and $b = 0.5$ to the superposition model (Wang et al. 2010). With a large number of pleiotropic mutations in hand, one can regress their total effect over all traits, r , on their degree of pleiotropy, n , to estimate b . Surprisingly, studies in mice (Wagner et al. 2008) and yeast (Wang et al. 2010) suggest that the data are best fit by a model with $b > 0.5$, implying that the per-trait effect of a mutation *increases* with the amount of pleiotropy, n . Wang et al. showed that the consequence of $b > 0.5$ is that while the probability that a new mutation is advantageous decreases with increasing

n , its fixation probability, and its effect on fitness if fixed, both increase with n , resulting in the rate of adaptation being maximized at some intermediate value of n (akin to Kimura's observation of an intermediate value of x maximizing the probability of adaptation).

However, the observation of $b > 0.5$ needs to be treated with care. Hermisson and McGregor (2008) noted that QTL studies can result in inflated estimates of b in the presence of linked loci. While the results of Wang et al. (2010) avoid this concern (being based on single-gene knockouts), caution is still in order. Simulation studies by Hill and Zhang (2012b) found that a true value of $b = 0.5$ can easily generate data with b values greatly in excess of 0.5 if the traits and/or measurement errors are correlated.

Our conclusion from all of the above results is that any cost of complexity is based, not on organismal dimensionality per se, but rather on the amount of pleiotropy that a typical mutation experiences. There are reasons to suggest that this is often modest or small. Further, variances in the strength of selection, or in the distribution of mutational effects over individual traits, will lower the effective value of n , further reducing this cost. Finally, unresolved scaling issues (e.g., the relationship between total and individual-trait effects of new mutations) can further reduce this cost, provided they occur in the appropriate direction. While all of these issues can mitigate the cost of complexity, one may still remain. Cooper et al. (2007) used an extensive single-gene deletion dataset in yeast (*Saccharomyces cerevisiae*), where 501 morphological traits were measured for roughly 4800 single-gene deletions, along with the fitness effects for each deletion. There was a strong and significant negative correlation between the amount of pleiotropy (number of traits influenced) and fitness of the deletion (a squared correlation coefficient of roughly 0.18), meaning that organisms with greater numbers of pleiotropic mutations tend to be less fit.

Adaptive Walks Under a Moving Optimum

One critical assumption of Orr's analysis is that the change in the optimal value is sudden, large ($E[r] \ll d$), and effectively permanent. While this can happen following a sudden shift in the environment, an equally plausible scenario is that the optimal value slowly changes over time, e.g., $\theta(t) = \nu t$. In this setting, Bello and Waxman (2006), Collins et al. (2007), and Kopp and Hermisson (2007, 2009a, 2009b) found situations in which alleles of small to intermediate effect tend to be fixed before large-effect alleles. This is in contrast to the constant-optimum prediction that large-effect substitutions occur when the population is far from the optimum. Kopp and Hermisson (2009a, 2009b) made the key observation that the substitution pattern critically depends on the speed, ν , of environmental change relative to the genetic potential of the population. If the environmental change is sufficiently rapid, large-effect alleles are favored, as the population is waiting for the appearance of new mutations to help it keep up (and is said to be **genetically limited**). Conversely, when the environmental change is sufficiently slow, small-effect mutations tend to be fixed (and the population is said to be **environmentally limited**). For a single trait with a moving-optimum, Kopp and Hermisson (2009b) obtained a simple composite parameter

$$\gamma = \frac{\nu}{\omega^2 s N \mu \sigma_\alpha^2} \quad (27.6a)$$

to determine which region (environmentally, or genetically, limited) a population is in. Here μ is the haploid genomic mutation rate for the trait, while ν and ω^2 are, respectively, the rate of change in the optimum and the strength of stabilizing selection (larger values of ω^2 imply weaker selection; Equation 28.3b). Finally, σ_α^2 is the variance of the effects of new mutations (which are examined in detail in Chapter 28). The denominator in Equation 27.6a represents the genetic potential of the population (being a measure of the amount of new variation introduced into the population in each generation), while the numerator represents the speed of environmental change. When γ is small (as can happen in a large population), evolution is environmentally limited, while when γ is large, it is genetically limited.

Matuszewski et al. (2014) generalized this result to a multivariate vector of optima changing over time. The multivariate mutational structure is described by a pleiotropy

mutation matrix, \mathbf{M} , while the multivariate nature of selection is described by a stabilizing selection matrix, \mathbf{S} , with the vector $\boldsymbol{\nu}$ showing the per-generation change in each component of $\boldsymbol{\theta}$. The basic results from the univariate optimum analysis hold, where the composite parameter determining which domain a population resides in (genetically or environmentally limited) is given by

$$\gamma = \frac{\sqrt{\boldsymbol{\nu}^T \mathbf{S}^{-1} \boldsymbol{\nu}}}{(N\mu)(\tilde{s}/\tilde{m})^{-3/2}}, \quad \text{where } \tilde{s}^2 = \sqrt[n]{\det(\mathbf{S})} \quad \text{and} \quad \tilde{m}^2 = \sqrt[n]{\det(\mathbf{M})} \quad (27.6b)$$

Recall that the determinant (\det) of a matrix is the product of its eigenvalues (Appendix 5), and thus \tilde{s}^2 and \tilde{m}^2 are the geometric means of the eigenvalues of the stabilizing selection, \mathbf{S} , and mutation, \mathbf{M} , matrices, which can be thought of as the average widths of these processes. When both matrices are isotropic (a constant times the identity matrix), Equation 27.6b reduces to Equation 27.6a. Matuszewski et al. (2014) showed that in the environmentally limited range (where γ is sufficiently small), there is an optimal mutation size, with the distribution of the effects of fixed mutations being unimodal (like Kimura’s distribution for the first-fixed factor; Figure 27.2), as opposed to Orr’s exponential model.

There is also an interesting cost-of-complexity within the environmentally limited domain. Apparently at odds with Orr’s result, Matuszewski et al. (2014) found that the size of the first fixed effect *increases* with the number of characters (n). However, a cost is imposed because the waiting time for a beneficial mutation that is destined to become fixed also increases with n . Because one has to wait longer for a beneficial mutation as complexity increases, the optimum has traveled further away, now making larger-effect mutations easier to fix. In the words of Matuszewski et al., “the moving-optimum model does not contradict the cost-of-complexity argument, but reveals yet another aspect of it.”

WALKS IN SEQUENCE SPACE: MAYNARD-SMITH-GILLESPIE-ORR ADAPTIVE WALKS

Quantitative geneticists have historically been interested in the phenotypic effects of alleles, while the focus of population geneticists has been on their effect on a very particular trait, fitness. The power of Fisher’s geometric model is that it addresses both of these concerns, as trait effect sizes can be translated into fitnesses (Martin and Lenormand 2006; Orr 2006; Tenaillon 2014). While the distribution of phenotypic values under Fisher’s geometry is both unconstrained and continuous, a second class of adaptive walks, based on the much more constrained geometry of **sequence space**, has also been widely examined. The analysis of such models is strictly concerned with the sequence of fitness increases from beneficial alleles fixed during a walk, rather than their phenotypic effects (Maynard-Smith 1970; Gillespie 1983, 1984b, 1994; Orr 2002, 2003a). Further, they focus on evolution at a *particular locus* (or more generally, a tightly linked region, such as an entire bacterial genome), while Fisher’s model is concerned with the *genome-wide response* in a continuous trait, potentially involving a very large number of loci. Sequence-space walk models have several potentially very robust features, making them perhaps more general than FGM results.

One emerging feature in studies of molecular fitness spaces is the use of experimental tests of many of the assumptions and models. We will touch on this briefly here, and encourage the reader to work through the more technical sections that serve as leadins to experimental tests, as (is detailed below) much of this theory can be directly applied to model systems, especially in microbes. For example, the combination of high-throughput combinatorial DNA/RNA synthesis (tens of millions of base-pair combinations can be generated) coupled with high-throughput scoring (such as chip-based binding assays) is starting to open up the exploration of the fitness surfaces associated with single genes (reviewed in Conrad et al. 2011; de Vass and Krug 2014). There is a rich literature—spanning statistical physics, computational theory, experimental molecular biology, and evolutionary biology—on mutational and fitness landscapes over sequence space beyond

the models examined here. See Miller et al. (2011), Szendro et al. (2013), and de Vasser and Krug (2014) for brief overviews and an entrée into deeper modeling issues under more complex mutational-fitness surfaces.

SSWM Models and the Mutational Landscape

As first noted for protein sequences by Maynard-Smith (1962b, 1970), while phenotypic space is continuous, underlying evolutionary modifications involving changes in DNA sequences impose a discrete, and constrained, geometry. For a DNA sequence of length L , while there are 4^L possible states, each single point mutation can only move to one of $3L$ possible states. Under the strong selection ($Ns \gg 1$), weak mutation ($N\mu \ll 1$), assumption (the **SSWM**, or “swim,” model), each new mutation will either be fixed or lost before the next one appears, meaning that double-mutations are not segregating. This shortened horizon in the sequence space leads to Gillespie’s (1983) **mutational landscape model (MLM)**, which constrains the possible geometry of evolutionary paths in sequence space to those that are one mutational step away (our discussion in Chapter 7 on mutations with contextual effects deals with some of the issues arising when the horizon is two, or more, mutations away). Given a starting allele, the set of “local” alleles are those $3L$ new sequences that are located one mutational step away. When one such adaptive mutation is fixed, there is now a new space of $3L - 1$ sequences ($3[L - 1]$ sequences when ignoring the just-mutated site, which [ignoring the back mutation] can itself contribute 2 new sequences), and the walk continues until the most fit local allele is fixed and the walk stops. As we will detail shortly, Gillespie’s (1983, 1984b) analysis of such models draws on the use of **extreme-value theory (EVT)**, which treats the distribution of extreme draws from some underlying distribution (Gumbel 1958; Leadbetter et al. 1989).

Extreme-Value Theory (EVT)

Under Gillespie’s model, fitness values for new mutations are drawn from some unknown, and complex, underlying fitness distribution. However, the current allele is likely rather fit (even if moved to a new environment) relative to all of the possible $3L$ alleles that are one step (a single-base change) removed. Hence, its current fitness value is already in the right-hand tail of the fitness distribution, with new favorable alleles being drawn from values that are even more extreme (farther to the right); see Figure 27.4. In such settings, EVT states that one of three possible limiting distributions (referred to as **domains**) will occur (Example 27.2). Gillespie (1983, 1984b) assumed the **Gumbel domain**, which arises for a very wide range of underlying distributions. Joyce et al. (2008) examined the properties of adaptive walks under the two other EVT limiting distributions, the **Weibull** (truncated right tails) and **Fréchet** (tails heavier than exponential) **domains**. They did so by extending many of the results that we present below (which assume a Gumbel), under a generalized Pareto distribution as a function of its tail parameter (κ), which sets the domain (Example 27.2). Joyce et al. found that results based on the Gumbel ($\kappa = 0$) assumption are fairly robust for biologically realistic Fréchet distributions ($0 < \kappa < 0.5$), and for moderate Weibull distributions ($-0.5 \leq \kappa < 0$). However, for more extreme Weibull distributions ($\kappa < -0.5$), significant departures in behavior from Gumbel-assumption results can occur.

Example 27.2. The body of extreme-value theory that deals with the largest draws from a distribution provides very powerful machinery for the analysis of new beneficial mutations. Gillespie’s (1983, 1984b) key insight was that the current alleles are likely rather fit (relative to all possible local alleles), and are therefore in the rightmost tail of the unknown, and likely very complex, distribution of potential fitnesses at a given locus (or over a very tightly linked region). More fit alleles represent even more extreme draws from this distribution (Figure 27.4), allowing many of their features to be derived from the extreme-value distribution of fitnesses at the target gene or region. There is another Fisherian irony here in that the field of EVT, which

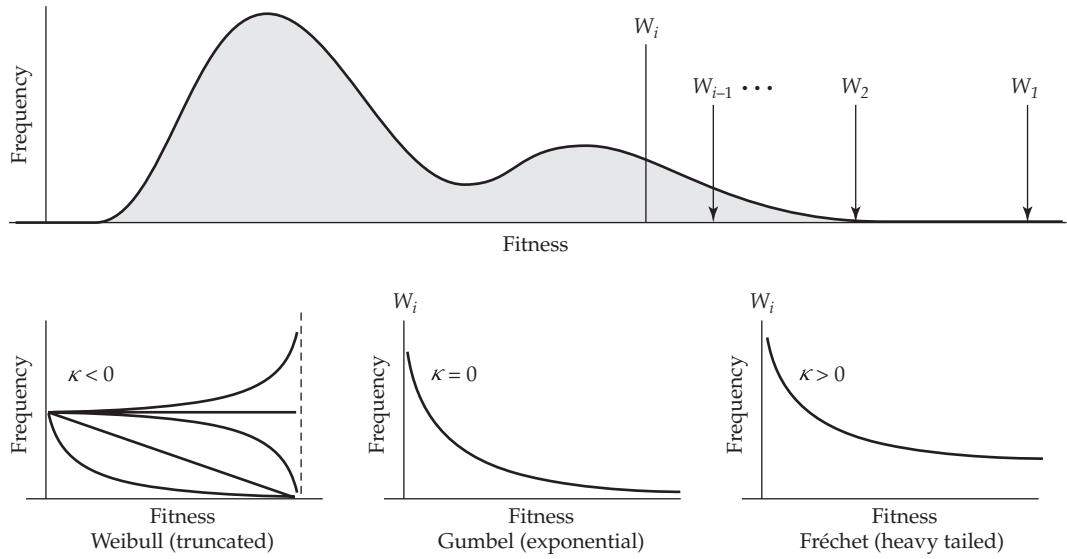

Figure 27.4 **Top:** Extreme-value theory applied to the distribution of fitness effects of new beneficial alleles. Assume some arbitrary, and unknown, fitness distribution for possible alleles at a given locus. Provided the current allele is fairly fit, it is a draw from the righthand tail (extreme upper values) of this distribution. Let W_i denote its current fitness, with i denoting the fitness rank of the current allele relative to the set that it can mutate to. W_1 is the most fit possible allele at this locus, W_2 is the next most fit, and so on. **Bottom:** The **trinity theorem** (Example 27.2) states that the limiting distribution of draws from the extreme tail of a distribution is one of only three possible types (or **domains**), depending upon a shape parameter, κ (see Equation 27.7). The figure displays the form of the density function for these three limiting cases. Under the **Gumbel domain**, the limiting extreme-value distribution is exponential. If there is a finite upper limit on the original distribution, its extreme-value distribution is from the **Weibull domain** (which, as depicted in the figure, can have a wide variety of shapes depending on the value of κ). Finally, if the tail of the original distribution is heavier (falls off more slowly) than an exponential, its limiting extreme-value distribution is in the **Fréchet domain**. (After Beisel et al. 2007.)

provides the basis of an alternative model to Fisher's geometric model, was first introduced by Fisher (Fisher and Tippett 1928). Leonard (L. H. C.) Tippett, a statistician working in the textiles industry, was a leading figure in the early development of quality-control methods and was also the first to publish a table of random numbers (Tippett 1927).

The critical result from EVT is the so-called **trinity** (or **Fisher-Tippett-Gnedenko theorem**), which states that the distribution of draws of extremes (the **extreme-value distribution**) from any underlying distribution are given by the **generalized Pareto distribution** (Pickands 1975), a family of distributions determined by a scale parameter, τ , and shape parameter, κ (also called the **tail index**), which falls into one of three limiting types (or **domains**), depending on the value of κ (Equation 27.7). Because our interest is in the distribution of fitness values for new beneficial alleles, setting the fitness of the current allele to 1, then the fitness of a beneficial allele is $1 + X$, where the fitness increase, X , is drawn from the tail of the underlying distribution to the right of zero. Following Beisel et al. (2007), the families of extreme-value distributions for such draws are given by

$$\Pr(X \leq x | \tau, \kappa) = \begin{cases} 1 - (1 + \kappa x / \tau)^{1/\kappa}, & x \geq 0 \quad (\text{Fréchet}) \\ 1 - (1 + \kappa x / \tau)^{1/\kappa}, & 0 \leq x < -\tau/\kappa \quad (\text{Weibull}) \\ 1 - \exp(-x/\tau), & x \geq 0 \quad (\text{Gumbel}) \end{cases} \quad (27.7)$$

Most common distributions (normal, gamma, etc.) have a **Gumbel** EV distribution ($\kappa = 0$), which has an exponential tail. This is the most commonly assumed EV distribution for beneficial mutations. When the underlying distribution is truncated to the right (the upper bound of $-\tau/\kappa > 0$, as $\kappa < 0$), the extreme-value distribution is in the **Weibull domain**.

Such an upper-truncated underlying distribution may hold for loci that are near their fitness optimum, as the fittest possible allele simply moves to the optimal value (Martin and Lenormand 2008). The final possible EV distribution (arising when $\kappa > 0$) is the **Fréchet domain**, which has much heavier tails than an exponential. Biologically, this implies that highly beneficial new mutations are rather likely to occur, and hence it is generally not used (Orr 2006), although some experimental data are consistent with the underlying fitness distribution being in the Fréchet domain (Table 27.1). By noting that κ determines the domain family, Beisel et al. (2007) developed a likelihood-ratio test for $\kappa = 0$. They found that the power to detect the Weibull domain alternative ($\kappa < 0$) versus a Gumbel null ($\kappa = 0$) is reasonable if ten or more beneficial mutations are scored.

One alternative approach to modeling walks is based upon the **Fisher–Kolmogorov equation** (Fisher 1937; Kolmogorov 1937), which was originally used to model the speed of the traveling wave of advance of an advantageous mutation over a linear cline (the analysis of allelic surfing is based on this approach; Chapters 8 and 9). As applied to an adaptive walk, one treats the “wave” of advance as the rate at which mean population fitness increases due to increases in the frequency of new advantageous mutations (see Hallatschek 2011 and Neher 2013 for reviews). The leading edge of this traveling wave of advance (the most fit alleles, namely, the extreme right tail of the fitness distribution) is often called the **nose** of the distribution, leading to the term **nose theory** being used to describe this modeling approach. The connection with EVT is that if the distribution of fitnesses in the nose (the extreme values of the distribution) falls off more quickly than an exponential, the distribution of fitness effects is in the Weibull domain, with the fitnesses of new advantageous alleles tending to be somewhat uniform (in the words of Neder 2013, their distribution “tends to be smooth”). Conversely, if the tail of the underlying fitness distribution declines at a rate slower than an exponential, extreme fitnesses are drawn from the Fréchet domain and the behavior of the walk can be dominated by a few large-effect mutations.

Structure of Adaptive Walks Under the SSWM Model

Given that the limiting EVT distribution is largely independent of the details of the underlying distribution generating it, several interesting results follow when the distribution of fitnesses for new mutations falls into the Gumbel domain. First, let s_j denote the fitness advantage of a new allele relative to the current one. Gillespie (1984b) showed that under strong selection and weak mutation (SSWM), the probability of allele j being the next one to be fixed during the walk is

$$\pi_j = \frac{s_j}{\sum_{\ell=1}^k s_\ell} \quad (27.8a)$$

where there are k alleles that are more fit than the current one (the set of potential alleles is typically taken as the set of all possible mutations that are one step away from the current allele). Hence, the chance that a mutation is fixed is proportional to its fitness advantage, but the most fit allele is by no means guaranteed of being the next allele fixed. Mutation rates do not appear in Equation 27.8a, as it makes the assumption that mutational change to any of the $3L$ adjacent sequences is equally likely (Equation 7.38 recovered a similar result for a somewhat different problem).

Gillespie (1983) also showed that the mean number of substitutions during a walk is small, with the mean number of steps until the most favorable allele is fixed, given the walk starts with the k th fittest, being

$$\frac{1}{2} \left(1 + \sum_{j=1}^{k-1} \frac{1}{j} \right) \quad (27.8b)$$

The simplification given in Equation 27.8b of Gillespie’s original result is due to Orr (2002). Because Equation 27.8b scales as $\sim \ln(k)$, the mean number of steps (substitutions) typically ranges between two and five (Gillespie 1994). This sequential series of fixations until the best

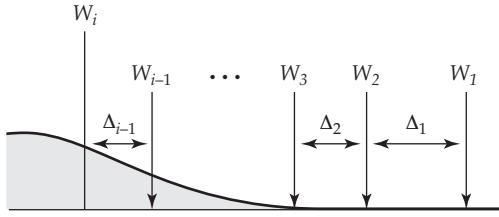

Figure 27.5 Let $\Delta_i = W_i - W_{i+1}$ denote the spacing (difference) in fitnesses between the genotype of fitness rank i and $i + 1$. When the current genotype has a high fitness (its rank, i , is not too large) and the underlying fitness distribution is in the Gumbel domain, then the values of Δ_i follow an exponential distribution (Gillespie 1983; Orr 2003b).

allele is fixed yields a burst of substitutions followed by stasis (unless there is a significant change in the environment, and thus in the fitness function). The result is an overdispersed molecular clock (a higher variance than expected from the Poisson distribution for substitutions that is generated under drift). Remember that extreme-value theory walks focus on the substitution patterns in a single gene or tightly linked genetic region. Hence, many such walks may simultaneously be ongoing within a (recombining) genome. We return to the important issue of context-specific fitness (i.e., epistasis), and how it alters the walk, shortly.

Orr (2002) used Gillespie's SSWM process as an adaptive-walk model, making use of a key result from EVT on the **spacing** between extreme values. Let $\Delta_i = W_i - W_{i+1}$ denote the spacing between the fitness values for alleles of fitness ranks i and $i + 1$ (Figure 27.5). When the fitness extreme-value distribution is in the Gumbel domain, then $E[\Delta_j] = E[\Delta_1]/j$ (Gumbel 1958; Weissman 1978), meaning that there is a regular pattern in the spacing that only depends on the fitness rank, j , of a given allele and on the expected spacing, $E[\Delta_1]$, for the most fit allele. (Recall that Equation 27.4c showed that a similar scaling of spacing, C/j , occurs between steps in an FGM walk.) This result leads to a dramatic simplification of Equation 27.8a. If the current allele has a fitness rank of i , the selection coefficient on a higher-ranked ($j < i$; i.e., more fit) allele is

$$s_j = \frac{\Delta_j}{W_i} = \frac{E[\Delta_1]/j}{W_i} = \frac{C_i}{j} \quad (27.9a)$$

where $C_i = E[\Delta_1]/W_i$. If we substitute $s_j = C_i/j$ into Equation 27.8a and note that the common C_i term in the numerator and denominator terms cancels, gives the transition probability (starting with an allele with a fitness rank of i) that the next allele to be fixed has a rank of $j < i$, as

$$\pi_{j,i} = \frac{1}{i-1} \sum_{k=j}^{i-1} \frac{1}{k} \quad \text{for } j < i \quad (27.9b)$$

Using this expression, if the current sequence is the i th-fittest local allele, the mean fitness rank of the next fixed allele is

$$\sum_{j=1}^{i-1} j \cdot \pi_{j,i} = \sum_{j=1}^{i-1} j \left(\frac{1}{i-1} \sum_{k=j}^{i-1} \frac{1}{k} \right) = \frac{i+2}{4} \quad (27.9c)$$

Using Equation 27.9b, the corresponding variance in the fitness rank of this next fixed allele was obtained by Rokyta et al. (2006)

$$\frac{(i+2)(7i+6)}{144} \quad (27.9d)$$

For example, if the wild-type is the 10th-fittest (its rank is ten), Equation 27.9c calculates the expected rank following one substitution as three (the third-fittest), rather than the most fit (an allele of rank 1), as naively might be expected. From Equation 27.9d, the standard

error on this expected rank is 2.5. Thus, while large jumps in fitness rank occur during the walk, these are typically not to the most fit allele. Orr (2002) noted that the adaptive process over this walk is the average of **perfect adaptation** (the best mutation, $i = 1$, is fixed in the first substitution; this is called **gradient adaptation** in the physics and computer science literature) and **random adaptation** (a randomly chosen fitter allele is fixed, for an average rank of $i/2$), as $(1 + i/2)/2 = (i + 2)/4$, recovering Equation 27.9c.

Unlike Fisher's model, Orr (2002) found that jumps under the SWMM model are few, and substantial, with over 30% of the total fitness change from the walk occurring on the first jump, and over 50% occurring from the largest jump. Orr also showed that the distribution of fixed selective effects over a number of such walks (ignoring the very smallest final steps) is again roughly exponential under certain conditions, a statement that we will refine below. Hence, adaptive walks over two very different geometries (continuous phenotypic vs. discrete sequence space), operating on different genetic scales (genomewide vs. a single gene or region), and treating rather different quantities (trait values vs. fitness effects), can both generate the same rough pattern of substitution effects. They differ in that a random walk in sequence space typically has only a few, mostly substantial, steps.

We have already discussed how the abstract nature of Fisher's model is perhaps its greatest strength, as it frees one from the tyranny of the idiosyncratic details for any particular trait. A similar feature occurs in sequence space through the use of EVT, to again obtain fairly general statements for an unknown distribution of the fitness effects of new alleles at a particular locus. What are some of the potential weaknesses of the sequence-space walk model? We can classify these as weaknesses as assumptions about mutation and assumptions about selection. An obvious issue concerning mutation is bias, in that the models assume that all (single-step) mutations are equally likely. However, the focus of these models is on how selection shapes the outcome under assumptions of equal mutation.

The first and foremost weakness with respect to assumptions about selection is that the fitness distribution may not be in the Gumbel domain, a point which will be discussed further below. Second, strong selection (the SS in SSWM) assumes that no slightly deleterious mutations can be fixed, while the weak-mutation assumption (the WM in SSWM) considers only two segregating alleles (the original and the mutation) at any point in time. Under these conditions, advantageous mutations that must be accessed through the fixation of a deleterious intermediate cannot be reached. A **selectively accessible** sequence is one that can be reached through a series of single-step substitutions, each of which is adaptive. This need not be the case when **sign epistasis** is present (epistasis that results in a change in the sign of fitness, meaning that an allele is deleterious in one background and favored in another). Here, one can have a mutation landscape with a series of fitness peaks that are inaccessible from one another through single mutations (Weinreich et al. 2005). As examined in Chapter 7, such peaks can potentially be reached (even under strong selection) when the weak mutation assumption is violated, such as in very large populations. This can occur via stochastic tunneling, wherein the second (advantageous) mutation can arise in the small fraction of segregating, initially deleterious, mutations. Finally, the weak mutation assumption ignores the important concern of clonal interference in asexual species.

The strong selection assumption also implies that no neutral (or even effectively neutral) alleles are fixed, but this is not a serious issue for the question being addressed by the model, namely the expected change in fitness from fixation of progressively more fit alleles (although it may be an important issue in terms of which adaptive peaks are accessible). For positively selected alleles, as selection coefficients become progressively smaller (but still positive), the drift barrier (Chapter 7) will be reached, and numerous substitutions of small (and effectively neutral) effect can occur. EVT theory ignores these as they all have essentially the same fitness (and hence are lumped into the same fitness class).

Example 27.3. Evolution in experimental microbial populations offers the opportunity to test certain features of the mutational landscape model (MLM), and in particular, the expected

small number of steps during a walk and the prediction of rapidly diminishing fitness returns from new beneficial mutations (provided the initial genotype is itself reasonably fit). Holder and Bull (2001) examined the pattern of fitness increases (measured by doubling time) during adaptive walks for growth at high temperature in the bacteriophages ϕ X174 and G4. The response seen for ϕ X174 fit the pattern expected from MLM theory: the first mutation accounted for roughly 75% of the total gain in fitness, and the first two mutations accounted for 85%. A more complicated picture was seen for G4, which grows at lower temperatures than ϕ X174. G4 showed no initial response for high-temperature (44°C) tolerance, and had to first be selected (for 50 generations) for adaptation to an intermediate temperature (41.5°C) before subjecting it to 44°C. While one of the first two mutations for growth at 44°C had a large fitness effect, there was otherwise no evidence of diminishing returns in the fitness in subsequently fixed beneficial mutations. In part this could be due to the essentially zero fitness of the initial genotype in the target environment (44°C), which violated the technical assumption that the starting value is itself from the extreme value distribution.

Adaptive walks in the fungus *Aspergillus nidulans* were studied by Schoustra et al. (2009) and Gifford et al. (2011). The observed number of steps in the walk was short (a mean of ~2), with diminishing fitness returns for fixed sites. By placing the original genotype in different environments with very different starting fitnesses, Gifford et al. were able to show that the length of the walk (which was still ~2 steps) was insensitive to the starting fitness.

Perhaps the most direct test of Orr's model was performed by Rokyta et al. (2005), who examined 20 single-step adaptations (for rapid replication under standard culture conditions) in the single-strand DNA bacteriophage ID11 (a relative of ϕ X174). Genome sequencing showed that these 20 single-step events were comprised of nine different mutations. Based entirely on the fitness ranks of these mutations (with the wildtype having rank 10 and the most fit mutation having rank 1), Equation 27.9b gives a probability of 0.28 that the fitness-rank 1 mutation is fixed first. Hence, we expect that this will occur \sim 6 ($20 \cdot 0.28 = 5.6$) times in 20 random trials. However, it was only fixed once. Rokyta et al. used a multinomial distribution (Equation A2.37a) to assess whether there was a significant lack-of-fit between the observed probabilities for a mutation with fitness rank k being fixed first and the expected probability of this event under Equation 27.9b. The fit was poor ($p = 0.10$), but not significantly different from the null (which could simply reflect low power). The authors noted that the rank-1 mutation required a transversion mutation (these occur at lower rates than transition mutations, thus violating the equal-mutation assumption of Equation 27.8a). A much better fit ($p = 0.67$) was seen after correcting Equation 27.8a to allow for known differences in mutation rates.

Example 27.4. The examination of adaptive walks in sequence space between naturally occurring alternative sequences, and the possibility of local peaks that are not accessible through a series of single-step adaptive mutations, began with Malcolm et al. (1990). Game bird species (*Galliformes*) display one of two protein sequences for lysozymes, either Thr at position 40, Ile at position 55, and Ser at position 91 (the ancestral TIS sequence) or Ser 40, Val 55, Thr 91 (the derived SVT sequence). Malcolm et al. generated synthetic proteins representing all possible single-replacement pathways between these two states (e.g., TIS→SIS→SIT→SVT, TIS→TVS→SVS→SVT, and so on) and examined their thermostability (as a proxy for functional fitness). In all possible single-step pathways between TIS and SVT, an intermediate showed thermostability that was significantly outside the narrow range seen in either TIS or SVT, suggesting that these intermediate steps were deleterious.

A more direct study was performed by Weinreich et al. (2006), who examined penicillin resistance associated with the *E. coli* β -lactamase gene. Five point mutations (four nonsense and one 5' noncoding) separate the resistant allele (TM^*) from its wild-type ancestor (TM^{wt}). By constructing the appropriate strains, Weinreich et al. examined the fitnesses of each intermediate sequence in all possible $5! = 120$ single-step walks between TM^{wt} and TM^* . They found that 102 of the possible 120 trajectories (85%) were selectively inaccessible, involving transition through an intermediate of lower fitness, via sign epistasis. Using the estimated selection coefficients for each intermediate genotype, the authors applied Equation 27.8a to compute the expected probability of state transition (among those sites that are one mutational step away from the current state), and found that the 18 selectively accessible trajectories were not equally likely to occur, with just 6 accounting for half of all expected successful trajectories.

Table 27.1 Summary of several bacterial and viral experiments on the distribution of fitness effects among beneficial mutations. These studies either considered only *fixed* (Fixed = Yes) beneficial effects or considered *all* detected beneficials (Fixed = No). In order to detect all (as opposed to only fixed) beneficial mutations appearing in some interval during the walk, some experiments looked for rescue mutants that allow a strain to grow in a nonpermissive environment (Low = Yes). The Gillespie-Orr model predicts an exponential distribution (Gumbel domain of the EV distribution) when *all* beneficial mutations are considered (Fixed = No) and the genotype starts out at a high fitness (Low = No). Distributions indicated with the term “domain” used the formal likelihood-ratio approach of Beisel et al. (2007) to test the null (EV distribution shape parameter $\kappa = 0$; in the Gumbel domain) versus κ as significantly negative (Weibull domain) or significantly positive (Fréchet domain). The Barrett et al. study found a Weibull *distribution* of effects, which is unimodal, and *different* from the Weibull EV *domain* (indeed, if the underlying distribution is Weibull, its EV domain is actually Gumbel), and which is denoted by an asterisk to remind the reader of this difference.

Species	Fixed?	Low?	Beneficial Fitness Effects	Auhors
<i>Escherichia coli</i>	Yes	No	Exponential distribution	Imhof & Schlötterer 2001
	Yes	No	Normal distribution	Rozen et al. 2002

The Fitness Distribution of Beneficial Alleles

Much of our discussion on walks (especially under Fisher’s model) has been on the distribution of *fixed* beneficial mutations. We can use extreme-value theory to provide insight into a second issue: the distribution of effects for *all* beneficial mutations that appear at a given stage in the walk, not just those that are fixed (Orr 2003b, 2006, 2010; Martin and Lenormand 2008). When the fitness of an initial allele is high and the fitness distribution is in the Gumbel domain, the distribution of fitness values in new *beneficial* mutations is expected to be close to an exponential (Gillespie 1983; Orr 2003b). A remarkable feature about this distribution of effects is **Orr’s invariance result**: at any stage of the walk, a new advantageous allele has the same mean fitness increase *independent* of the fitness of the current allele, as long as that allele’s fitness is high (Orr 2003b).

As summarized in Table 27.1, a number of experiments with microbes have attempted to test the Gillespie-Orr prediction of an exponential distribution of fitness effects for all beneficial mutations. There are two important caveats when considering these results. First, the Gillespie-Orr prediction applies to the distribution of *all* newly beneficial mutations, *not* the distribution of those beneficial mutations that are *fixed* (although as mentioned above, the fixed distribution can itself be exponential in certain cases, a point that will be addressed shortly).

Second, the use of EVT assumes that the starting genotype already has a high fitness. A number of studies detect beneficial mutations by the rescue of deleterious mutations or by placing the genotype in a radically new, and very deleterious, environment. While this strategy provides a rapid screen for adaptive mutations (i.e., those that grow), the starting genotypes may not be sufficiently extreme in the fitness distribution for EVT to apply. As summarized in Table 27.1, all three EVT domains (Gumbel, Weibull, and Fréchet) are seen

in the experimental data. As noted by Seetharaman and Jain (2014), there are qualitative differences in adaptive walks over these different domains. In particular, the expected fitness differences between successive substitutions are decreased under the Weibull domain, but they are increased under the Fréchet, and (as we have seen) they are constant under the Gumbel domain. When the selective effects are small (but still strong in a population-level sense, as we assume $4N_e s \gg 1$), the number of substitutions during a walk under the Fréchet domain is smaller than under the Weibull or Gumbel domains. However, when selective effects are large, the adaptive walk is shortest in the Gumbel domain.

Example 27.5. While detecting the vast majority of new beneficial mutations is an extremely challenging endeavor, it is not impossible, as an elegant study by Levy et al. (2015) demonstrated. By inserting $\sim 500,000$ random DNA barcodes into a clonal founder yeast (*Saccharomyces cerevisiae*) population, they were able to track the appearance on new, favorable mutations by increases in the frequency of a specific barcode that was greater than expected from drift. In a population of $\sim 10^8$ cells descendant from this founding collection of random barcodes, the authors were able to ascertain that $\sim 25,000$ lineage had gained a beneficial mutation within the roughly 170 (asexual) generations that they followed. By examining the rate of increase of a barcode, they were able to estimate its s value using the equations for allele-frequency change from Chapter 5. While there was a lower-limit in the s values that could be estimated (in particular, only those **established** mutants that escaped early stochastic loss were followed), this is still a remarkable system for tracking favorable mutations.

The findings from this study are at odds with much of the above theory. The distribution of detected beneficial fitness effects was not exponential. In fact, it was not even monotonic, but rather a multimodal distribution, with the bulk of (detected) mutations with modest effects ($0.02 < s < 0.05$), and then a rather flat (uniform) distribution for large effects, but with slight peaks around 0.07 and 0.10. Most beneficial mutations were lost, as their initial fitness advantage declined as the mean population fitness increased due to other clones acquiring beneficial mutations. This resulted in the small-effects mutations that dominated at the start of selection being overtaken by rarer mutations of large effect.

FISHER'S GEOMETRY OR EVT?

Fisher's geometric model (FGM) and the mutational landscape model (MLM) and its corresponding EVT results are, on the surface, very different views of adaptation. The former looks at the evolution of mutational-effect size for a trait under stabilizing selection, while the latter examines the evolution of fitness (a trait under strict directional selection) during a walk in a single linked region. However, at some fundamental level, we should be able to connect results from these models, as (ideally) the MLM is modeling the loci that result in phenotypes adapting under FGM. The results of Orr (2006) and, especially, Martin and Lenormand (2008), start to bridge this gap.

Recall for the FGM that Orr (2006) showed the distribution of fitness effects for *all* alleles (and not only the beneficial ones) to be roughly normal. As a result, under FGM, the underlying fitness distribution of new mutations is in the Gumbel domain (the EV domain associated with a normal distribution), and the fitness distribution for beneficial alleles (when they are rare, i.e., drawn from the extreme-value region of the distribution) is exponential. Thus, when beneficial mutations are rare, EVT results also apply to FGM. Provided the initial genotype starts at a sufficient distance from the optimum, so that many steps are needed in the walk, both the distribution of the phenotypic values of fixed mutations and the fitnesses of new beneficial mutations are exponential under FGM.

Likewise, the fitness distribution of *all* beneficial mutations is also exponential under a Gillespie-Orr walk when the Gumbel EV conditions hold (the starting genotype has high fitness and the fitness distribution is in the Gumbel domain). The distribution of fitness

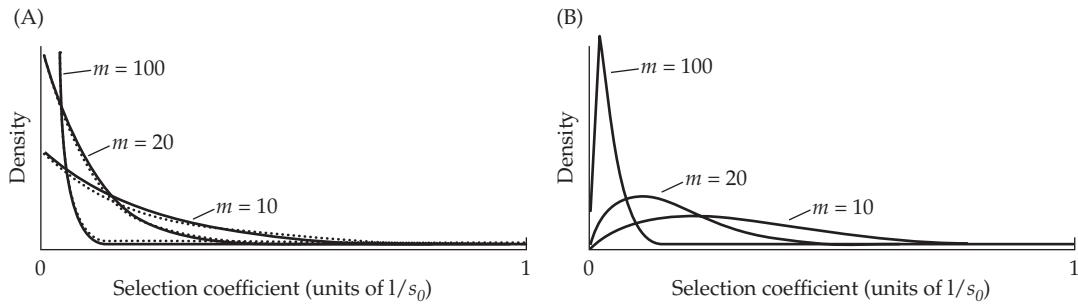

Figure 27.6 The distribution of the fitness effects for beneficial mutations at a locus underlying a phenotype under stabilizing selection, with the current allele close to the optimum. Let $s_0 \ll 1$ denote the maximal fitness advantage for any new mutation (which occurs when a mutation jumps the phenotype exactly to the optimum). **A:** The distribution of fitness effects among *all* beneficial mutations follows a beta distribution, $\text{Beta}(1, m/2)$, where m is a measure of pleiotropy. The dotted curves show the corresponding exponential distributions, with the two distributions being very similar for values of m modest to large (>10). **B:** The distribution of fitness effects among *fixed* beneficial mutations also follows a beta distribution, but now with the first beta shape parameter changing from one to two, returning a unimodal distribution, $\text{Beta}(2, m/2)$. Note that the exponential provides a very poor fit to this distribution unless m is very large and small values are ignored.

values among mutations that are *fixed* during the walk, however, departs from an exponential (Rozen et al. 2002; Barrett et al. 2006b; Martin and Lenormand 2008; Good et al. 2012). One reason is seen in Figure 27.2—while beneficial mutations with small fitness advantages are expected to be more common (given that they follow an exponential distribution), they also have lower fixation probabilities. Thus, the set of mutations surviving stochastic loss has a distribution that is shifted toward higher values (Figures 27.2 and 27.6).

Can we account for this difference in the distribution of fixed effects for trait values under FGM versus that for fitnesses under EVT? Likewise, what happens when the fitness distribution is not in the Gumbel domain? As Martin and Lenormand (2008) showed, these questions are connected. Recall that the trinity theorem (Example 27.2) states that when an underlying distribution has a limiting extreme-value distribution, it must reside in one of three domains. Most of our focus has been on results for the Gumbel domain. The Fréchet domain, with its heavier-than-exponential tails, has an excess of high fitness mutations (over the Gumbel domain). As such, Orr (2006) felt that fitness distributions were unlikely to fall in the extreme Fréchet domain (large values of κ). However, when the starting fitness is very low (such as when a genotype is very far from its optimal phenotype under FGM), there may indeed be an excess of high fitness mutations relative to the situation when the genotype is close to its optimal value.

Likewise, the Weibull domain is biologically quite feasible, simply requiring an upper limit on fitness (the underlying fitness distribution is truncated on the right). Indeed, this is exactly the domain that would be expected for a locus underlying a trait experiencing stabilizing selection, namely, the conditions for FGM. An allele at such a locus can have no higher fitness than that of a mutation that exactly jumps the genotype to the optimum, thus setting a strict upper limit on the fitness distribution. Let s_0 denote the selection coefficient for such a maximally beneficial mutation. Martin and Lenormand (2008) showed that when $s_0 \ll 1$ (the population is near an optimum), the distribution of fitness effects of *all* beneficial mutations is in the Weibull domain and is a beta (Equation A2.38), with

$$\frac{s}{s_0} \sim \text{Beta}(1, m/2) \quad \text{for } 0 < s < s_0 \quad (27.10a)$$

where m is a measure of pleiotropy (m is the rank of the product of the mutational covariance matrix, \mathbf{M} , and the stabilizing selection matrix, \mathbf{S}). Figure 27.6A plots this distribution and

shows that it is close to an exponential for m modest to large (indeed, a beta with a large m converges to an exponential). This convergence follows from the fact that the EVT shape parameter when Equation 27.10a holds is $\kappa = -2/m$, which approaches zero (and hence the Gumbel domain) for large m (see Equation 27.7). In this setting, the FGM generates a distribution of beneficial mutations that is roughly exponential, in accordance with EVT. This relationship also suggests an approach for estimating m , using the ML approach of Beisel et al. (2007) to estimate κ , with $\hat{m} = -2/\hat{\kappa}$.

Applying Equation A2.38b (the mean value for a beta distribution) yields a mean fitness value of all newly arising beneficial mutations of

$$E(s_b) = \frac{2s_0}{2 + m} \quad (27.10b)$$

Note the cost of pleiotropy, with the expected fitness decreasing with m . Martin and Lenormand found that the distribution of selection coefficients for *fixed* beneficial alleles is also a beta, but now with a shape parameter that generates a unimodal distribution (see Figure 27.6B), with

$$\frac{s}{s_0} \sim \text{Beta}(2, m/2) \quad \text{for } 0 < s < s_0 \quad (27.11a)$$

From Equation A2.38b, the mean fitness value of fixed beneficial mutations becomes

$$E(s_b) = \frac{4s_0}{4 + m} \quad (27.11b)$$

which shows both a cost of pleiotropy among fixed mutations, as $E(s_b)$ decreases as m increases, and also that the mean of fixed mutations is larger than the mean of all beneficial mutations (as would be expected). Although this distribution is unimodal, if m is sufficiently large (a great number of weakly correlated traits are under selection) and small effects are ignored (the assumptions made by Orr), then it can be reasonably approximated by an exponential (Figure 27.6B). Outside of this range, however, the use of an exponential overestimates the fraction of fixed beneficial mutations with large fitness effects. Experimental support for Equation 27.11a was offered by the work of Sousa et al. (2012) on the distribution of fitness effects of compensatory mutations in *E. coli* that recover antibiotic resistance (also see Trindale et al. 2012).

THE IMPORTANCE OF HISTORY IN WALKS: LESSONS FROM LENSKI'S LTEE

The above theory of adaptive walks shows the importance of evolutionary history, with large steps in the walk typically occurring early and smaller steps typically occurring later (under constant selection). Empirically, the role of historical events can be clearly seen in Lenski's long-term evolution experiment, LTEE, which was introduced in Chapter 25 (Lenski et al. 1991; Lenski and Travisano 1994; Barrick et al. 2009; Wiser et al. 2013). The LTEE consists (as of this writing) of over 55,000 generations (the equivalent of over a million years of human evolution) of selection on 12 replicate populations of *Escherichia coli*. One unique feature of this experiment is that because material from every 500 generations is frozen, one can go back and "replay" evolution. We consider just three of the interesting features or examples that have come from this experiment. These empirical results highlight some of the nuances that were missed by the above theory of single-step mutational walks and also by the stochastic tunneling results for adaptations that require multiple steps to pass through deleterious intermediate genotypes (discussed in Chapter 7).

One feature is the general appearance of hypermutators (Elena and Lenski 2003; Barrick and Lenski 2013). This is not surprising given the lack of recombination in *E. coli*, as a hypermutator allele can generate a completely linked adaptive mutation, resulting in selection on this more favorable clone (as the adaptation counters the deleterious effects of the mutator, at least transiently). Once the beneficial site is fixed, the mutator is now deleterious, and

it generates (weak) selection to reduce the mutation rate back toward more normal levels. Such a spike in mutation rates followed by a reversion to normal levels is routinely seen in the LTEE and other microbial experiments (reviewed in Barrick and Lenski 2013).

An interesting example from the LTEE is the evolution of the use of citrate as a carbon source, which serves as a potential model for the evolution of innovations (Blount et al. 2008, 2012). The growth medium for the LTEE contains abundant citrate, which was initially intended primarily as a chelating agent, and generally not accessible (under aerobic conditions) as a carbon source for *E. coli*. In one of the 12 replicates, a citrate-using strain (Cit^+) arose around generation 30,000 and became dominant around generation 33,000. Blount et al. (2008) found that the appearance of the initial Cit^+ mutation depended on one or more mutations in the population's history. When evolution was replayed, clones from the first 15,000 generations did not go on to produce Cit^+ mutations, while some clones chosen from later generations did. One or more potentiatting events occurred at around generation 20,000, which led to conditions allowing for Cit^+ mutations to appear some 10,000 generations later, and these events did not result from a general increase in the mutation rate. Blount et al. (2012) partitioned the evolution of this trait into three phases: **potentiation, actualization, and refinement**. Events that occurred before generation 20,000 set up the conditions for the *potential* of Cit^+ mutations, which was *actualized* at around generation 30,000. Blount et al. (2012) detailed some of the molecular features leading to *refinement* from the initial extremely weak Cit^+ mutation, including duplication of *cit* genes.

A final example from the LTEE, which shows the full power of being able to “replay” evolution, is from Woods et al. (2011), who compared the fitnesses of four clones from generation 500. Two of these clones (EW1, EW2) were eventual winners, going on to become fixed, while two (EL1, EL2) were eventual losers. Surprisingly, when measured at generation 500, the fitness of the EL clones was significantly higher (by about 6%) than that of the EW clones. Indeed, these fitnesses predict that the EW clones would have gone extinct in roughly another 350 generations. Why, then, did the EW clones succeed? When evolution was replayed in several replicate experiments starting with these clones, eventually the majority of the EW clones went on to accrue higher fitnesses than the EL clones (presumably due to subsequent mutations), even though initially they had lower levels of fitness. The authors ruled out higher mutation rates among EW clones and determined instead that the key was a mutation in the EW clones in the *spoT* gene, a master regulator. In the EW background, this mutation conferred a large beneficial fitness effect, but it was essentially neutral in the EL background. Thus, differences in fitness epistasis between the two types of clones (EL and EW) and the *spoT* gene resulted in the initially higher-fitness EL clones closing off access to a higher fitness peak via *spoT* mutations that the EW clones could achieve. In the very large population sizes of the LTEE, this inability of EL to access this fitness peak, while EW could do so, allowed secondary mutations to occur before the initial EW clones went extinct, which eventually led to an ancestor of the EW clones becoming fixed. This is an example of **second-order selection** (Tenaillon et al. 2001), whereby the fate of a new mutation is dependent on its ability to accrue secondary mutations, namely, the notion of stochastic tunneling, which is examined in Chapter 7.

Maintenance of Quantitative Genetic Variation

Empirical studies of quantitative genetic variation have revealed robust patterns that are observed both across traits and across species. However, these patterns have no compelling explanation, and some of the observations even appear to be mutually incompatible. Johnson and Barton (2005)

How wonderful that we have met with a paradox. Now we have some hope of making progress.

Niels Bohr

Genetic variation is a ubiquitous feature of natural populations. The nature of the forces responsible for the maintenance of this variation, be it the distribution of allele frequencies, the level of heterozygosity, the amount of additive variation in a trait, or the joint distribution of allele frequencies and their effects, have long been of concern to both population and quantitative geneticists. The basic explanation is some balance of evolutionary forces: mutation/migration introducing new variation, which is removed by drift and/or selection against deleterious alleles. In some cases, selection by itself can maintain variation, such as when heterozygotes are advantageous. These various explanations are not mutually exclusive, and theorists have spent a great deal of effort in building models to examine the plausibility of each scenario. If the required parameter space to maintain variation is very narrow, a particular mechanism may account for the maintenance of variation in specific cases but is unlikely to be a general explanation.

Despite a wealth of possible explanations for the maintenance of variation, this is an area of some frustration among quantitative geneticists. At present, there are difficulties in reconciling most (some would say all) of the proposed explanations with estimates of observable parameters (such as the strength of the apparent stabilizing selection on a trait, its heritability, and the mutational variance). As this is a subject with a substantial body of complex theory, we present many of the derivational details in examples, which allows us to focus on the key results while still presenting the logic and assumptions behind the models. Reviews of the struggle to explain quantitative-genetic variation can be found in Nagylaki (1984), Turelli (1984, 1986, 1988), Barton and Turelli (1989), Bulmer (1989), Bürger (1998, 2000), Barton and Keightley (2002), Johnson and Barton (2005), Zhang and Hill (2005b, 2010), and Mitchell-Olds et al. (2007). Bürger (2000) is the standard reference for much of the theory developed here, and should be consulted by the more mathematically inclined reader.

OVERVIEW: THE MAINTENANCE OF VARIATION

Earlier chapters explored the roles of the major evolutionary forces (drift, mutation, and selection) and important modifiers (recombination and migration) in the maintenance of polymorphisms at individual loci. The effects of drift (removing variation) and mutation (generating variation) are straightforward (Chapter 2), while the effects of selection are more complicated, as it either retains or removes variation, depending on its nature (Chapter 5). With constant selection coefficients, overdominance (heterozygote advantage) retains variation in large populations, while all other constant-fitness schemes remove it (Figure 5.1). Selection can retain variation under a variety of circumstances when fitnesses vary, which we loosely lump together under the umbrella term of **balancing selection**. These conditions include frequency-dependent selection when rare alleles are favored, tradeoffs among different fitness components, sex-specific differences, and fitness changes over time and/or space ($G \times E$). The conditions necessary to maintain variation can be rather delicate

for many of these strictly selective explanations.

The result of interactions between evolutionary forces can be straightforward—such as the mutation-drift equilibrium (Equation 2.24) or mutation-selection balance for deleterious alleles (Equation 7.6)—or they can be subtle and counterintuitive, such as the joint impact of selection, mutation, drift and recombination on the levels of variation under selective sweeps (Chapter 8). The goal in this chapter is build on these results in an attempt to explain the nature of the evolutionary forces maintaining quantitative-trait variation.

Maintaining Genetic Variation for Quantitative Traits

Most of our previous results on the maintenance of genetic variation were for population-genetic models, wherein the focus was solely on allele *frequencies*, and usually quantified by summary statistics such as the heterozygosity or the number of segregating alleles (Chapter 2). In this setting, the most complete equilibrium solution is given by the distribution of allele frequencies, such as Wright's result for a diallelic locus under mutation-selection-drift (Equation 7.31a) or the Watterson distribution for the site-frequency spectrum for mutation-drift balance under an infinite-sites model (Equation 2.34a). For quantitative traits, the allele-frequency distribution, by itself, is not sufficient to describe the equilibrium variation. Instead, one needs the full *joint* distribution of allele frequencies and their *effect sizes*, although we typically work with the additive-genetic variance as an appropriate summary statistic. Given the number of scenarios outlined above, it should not be surprising that a plethora of models have been proposed for the maintenance of genetic variation in quantitative traits. Figure 28.1 attempts to bring a little structure to this vast menagerie.

The simplest models are fully neutral: the trait, and its underlying loci, have no effects on fitness, leading to **mutation-drift models** (Chapters 11 and 12). Their problem is that they generate *too much* variation if the population size is modest to large. The most obvious correction is that there is some selection on the trait and/or on the underlying loci (independent of their effect on the focal trait). Models incorporating selection can be broken into two categories: those with at least some **direct selection** on the focal trait, and **pleiotropy models** that assume a neutral focal trait whose underlying loci have pleiotropic effects on fitness.

A central issue concerning direct-selection models is that stabilizing selection on a trait usually generates *underdominance* in fitness at its underlying loci, thus *removing* variation (Example 5.6). Hence, **strict stabilizing selection**, by itself, cannot account for quantitative-trait variance. This removal of variation could be countered by either mutation (**mutation-stabilizing selection balance**) or by selectively favored pleiotropic fitness effects. Under the latter scenario, loci underlying the trait under stabilizing selection are also under balancing selection for some other independent component of fitness (**balancing-stabilizing selection**). The central issue concerning mutation-selection balance is that the estimated strengths of stabilizing selection and polygenic mutation appear to be inconsistent with observed levels of heritability.

A critical question in the maintenance of genetic variation is just how much of observed stabilizing selection is actually real. Pleiotropic models can easily generate **apparent** (or **spurious**) **stabilizing selection** by returning a signature of stabilizing selection in a quadratic regression of fitness on the phenotypic value of a neutral trait (Chapters 29 and 30). Hence, it is possible that some (or perhaps much) of the observed stabilizing selection in nature is not real, but rather is instead due to pleiotropic fitness effects. Under pleiotropic models, the variation at the loci underlying a neutral trait is assumed to be maintained by either overdominant effects on fitness (**pleiotropic overdominance**) or because the underlying loci are slightly deleterious, but in mutation-selection equilibrium (**pleiotropic deleterious mutation-selection balance**). The problem with pleiotropy models is that the strength of selection on the underlying loci required to recover the observed strength of apparent stabilizing selection seen in nature is usually inconsistent with some other observable feature of the model. Various combinations of elements of these basic models have been proposed, as

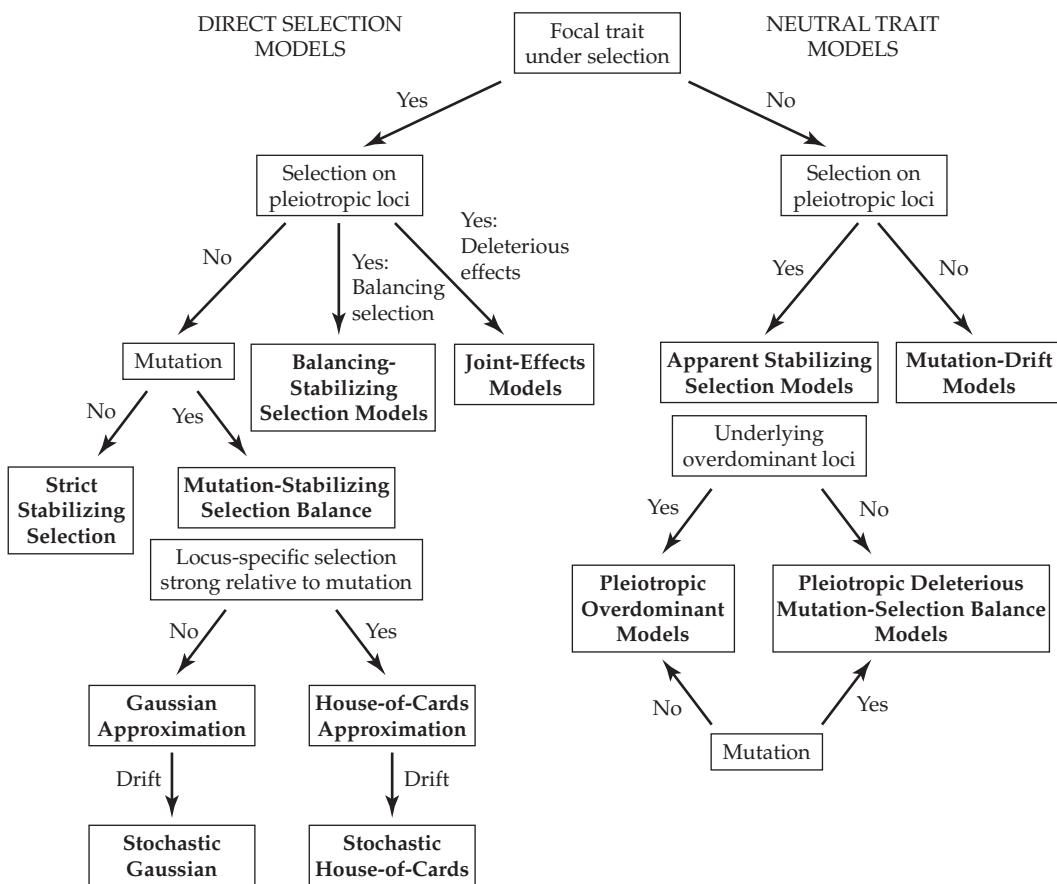

Figure 28.1 Flow chart of the various classes of models for the maintenance of quantitative-genetic variance. Roughly speaking, there are **direct-effect models** that assume that selection is acting on the phenotype of the focal trait (whose variation we are trying to explain) and models that assume that this trait is neutral. **Pleiotropic models** assume that loci underlying a trait have fitness effects *independent* of their impact on the focal trait (which is often assumed to be strictly neutral). As detailed below, models also vary in the importance assigned to mutation in countering the removal of genetic variation by selection and drift.

have refinements adding additional forces (such as drift), but most give inconsistent results when trying to simultaneously account for observed amounts of selection and variation.

Finally, differences in the assumed *granularity* of the underlying genetic architecture of a trait can significantly impact the results. If a few loci, each with only a few alleles, underlie a trait, the resulting genotypic values have a fairly granular distribution. The dynamics under stabilizing selection are different when one of these genotypic values matches the optimal stabilizing selection value compared to those of the situation when none do. Likewise, with just a few alleles at a few loci, the opportunity for independent selection on many traits is constrained. Conversely, under continuum-of-alleles (COA) models (Chapter 24), with their large number of alleles at each locus, there is a distribution of allelic effects and the potential for significantly more fine-tuning. A key point of this chapter is that the relative strengths of the underlying evolutionary forces dictates which genetic architecture is more appropriate. If drift is strong relative to the other forces, then at most, only a few alleles at a locus are likely (beyond a constellation of very rare new mutations). The same is true when selection is strong relative to mutation. Conversely, when the strength of mutation is greater than the strength of selection or drift at a locus, we expect it to harbor a number of alleles in a large population. As we will see, differences in the strength of mutation relative to selection at a locus lead to qualitatively different results.

The (often fairly technical) analysis of the large number of models given in Figure 28.1

comprises the bulk of the chapter. There are several possible schemes by which to organize and discuss all of these alternative models. Our presentation is centered around increasing the complexity of evolutionary forces and their interactions. We start with drift interacting with neutral mutation, which serves as a useful baseline. We then consider models invoking only selection, either stabilizing selection on the focal trait or balancing selection on loci with pleiotropic effects on a strictly neutral focal trait.

These selection-only considerations provide the background for the major classes of models, those involving *both* selection and mutation. Much of the discussion on these models focuses on stabilizing selection countered by mutation, including the incorporation of drift. Most of the work on stabilizing selection has assumed either a Gaussian (Equation 28.3b) or quadratic (Equation 28.3a) fitness function. How these results translate to more general fitness functions with a stabilizing component remains a rather open question.

We conclude by discussing models in which a large fraction of the trait variance is assumed to result from pleiotropic effects of deleterious alleles, which are maintained by mutation-selection balance. Our analysis of this last class of models starts with a neutral focal trait, followed by **joint-effect models** allowing for *both* stabilizing selection on a focal trait *and* pleiotropic contributions from deleterious alleles.

To aid the more casual reader, Table 28.3 (near the end of the chapter) summarizes the major inconsistencies for each model, followed by an examination of the current data. This allows the reader to bypass the more technical discussions below, while still obtaining a general overview of the problem. The conclusion from this extensive analysis is that all of the models have significant inconsistencies with current estimates of strength of selection, mutational inputs, and amounts of standing genetic variation. The typical pattern seen is that for a model to accommodate one known feature (e.g., the observed strength of stabilizing selection), the required parameter values result in another known aspect (say, amount of standing variation) being inconsistent with observed values.

MUTATION-DRIFT EQUILIBRIUM

The most basic model for the maintenance of variation considers two universal (and counterbalancing) forces, drift and mutation. Chapter 2 examined the distribution of neutral allele frequencies and reviewed various resulting summary statistics under mutation-drift balance. At equilibrium, neutral allele frequencies are given by the Watterson distribution (Equation 2.34a), and the expected heterozygosity (for an infinite-alleles model) is $\tilde{H} = \theta/(1 + \theta)$, where $\theta = 4N_e\mu$ is the product of the effective population size and the mutation rate (Equation 2.24b). The problem with this expression, as noted by Lewontin (1974), is that heterozygosity should quickly approach one in large populations ($\theta \gg 1$), yet this is not seen. One possible explanation is that the mutation rate inversely scales with population size, so that θ is always $\ll 1$ (Chapter 4). Another, not necessarily exclusive, explanation is that selection at linked sites depresses variation by decreasing N_e (Chapters 3, 8, and 10). The impact on N_e from a pattern of recurrent sweeps is greatest in very large asexual populations, which otherwise would be predicted to have very high values of \tilde{H} .

Mutational Models and Quantitative Variation

Chapters 11 and 12 developed the quantitative-genetic analog of \tilde{H} by considering the expected additive variance, $\tilde{\sigma}_A^2$, that is maintained by neutral alleles in mutation-drift equilibrium. Two extensions, both concerning mutation, are required when moving from allelic frequencies to quantitative-trait variation. The first is that the **mutational variance** (the total amount of genetic variation arising in each generation), σ_m^2 , replaces the mutation rate, μ (Chapter 11). The mutational variance contributed by (diploid) locus i is $2\mu_i\sigma_{\alpha_i}^2$, the product of its mutation rate and $\sigma_{\alpha_i}^2$, the **variance of mutational effects** (or **mutational-effects variance**). We use σ_{α}^2 to denote an unspecified locus and $\sigma_{\alpha_i}^2$ to denote a specified one. With n equivalent loci, $\sigma_m^2 = 2n\mu\sigma_{\alpha}^2$, while $\sigma_m^2 = 2\sum_i \mu_i\sigma_{\alpha_i}^2$ when mutational effects vary over loci.

Table 28.1 Models for the effect of a new mutation on a quantitative trait. All make the infinite-alleles assumption that each new mutation creates a new allele. The effect, x' , of this new allele is a function of its current value, x , and a random variable, $\alpha \sim (0, \sigma_\alpha^2)$. The incremental and house-of-cards (HOC) models are special cases of the Zeng-Cockerham regression model, corresponding to $\tau = 1$ and $\tau = 0$, respectively. Derivations can be found in Chapter 11, and in Zeng and Cockerham (1993).

Model	New Effect	$\tilde{\sigma}_A^2$	$\tilde{\sigma}_A^2$ as $N_e \rightarrow \infty$
Incremental, Random-walk, Brownian-motion	$x' = x + \alpha$	$4N_e\mu n\sigma_\alpha^2 = 2N_e\sigma_m^2$	Unbounded
House-of-cards	$x' = \alpha$	$\frac{8N_e\mu n\sigma_\alpha^2}{1 + 4N_e\mu} = \frac{4N_e\sigma_m^2}{1 + 4N_e\mu}$	$2n\sigma_\alpha^2 = \frac{\sigma_m^2}{\mu}$
Regression	$x' = \tau x + \alpha$	$\frac{8N_e\mu n\sigma_\alpha^2}{(1 + \tau)[1 + 4N_e\mu(1 - \tau)]} = \frac{2n\sigma_\alpha^2}{1 - \tau^2} = \frac{\sigma_m^2}{\mu(1 - \tau^2)}$ $= \frac{4N_e\sigma_m^2/(1 + \tau)}{1 + 4N_e\mu(1 - \tau)}$	

As reviewed in LW Chapter 12, the mutational variance can be estimated from the accumulation of additive variance in inbred lines. Such estimates are usually scaled by the environmental variance to yield the **mutational heritability**, $h_m^2 = \sigma_m^2/\sigma_E^2$, and a typical value is $h_m^2 = 10^{-3}$ (LW Table 12.1). Estimates of the component features of the mutational variance—the number of loci, n ; the per-locus mutation rate, μ ; and the variance of mutational effects, σ_α^2 —are far more difficult to obtain. This is unfortunate, as many of the following models require the values of these components (n , μ , and σ_α^2), rather than their composite measure, σ_m^2 . Some crude estimates follow from the widespread observation that h_m^2 is typically on the order of 10^{-3} . If we assume that $\sigma_\alpha^2/\sigma_E^2 = 1$, then the total trait mutation rate, $2n\mu$, will be on the order of 10^{-3} . For $n = 100$ loci, this implies a per-locus mutation rate (to new trait alleles) of $\mu = 5 \cdot 10^{-6}$. If the scaled variance of mutational effects is lower, then either the number of loci and/or the per-locus mutation rate must be correspondingly higher. Lyman et al. (1996) estimated a value of $\sigma_\alpha^2/\sigma_E^2 \approx 0.1$ for *Drosophila* bristle number mutations generated by *P*-element insertions. For $h_m^2 = 10^{-3}$, this implies $2n\mu = 0.01$ (assuming that σ_α^2 and μ for *P*-element insertions are representative of the wider mutational spectrum, which is unlikely).

The second required extension is some assumption relating the current effect of an allele, x , with its effect, x' , after mutation (Table 28.1). (While we typically use a to denote allelic effects, given the close similarity to our use of α for the mutational effect, for clarity we will often use x in this chapter to denote an allelic effect.) The most widely used construct is the **incremental model** (also referred to as the **Brownian-motion** or **random-walk** model). Initially introduced by Clayton and Robertson (1955), and more formally by Crow and Kimura (1964) and Kimura (1965a), this model assumes that $x' = x + \alpha$, the pre-mutation value plus a random increment, where $\alpha \sim (0, \sigma_\alpha^2)$. When all mutations are additive, Equation 11.20c gives the (diploid population) mutation-drift equilibrium variance under this model as $\tilde{\sigma}_A^2 = 2N_e\sigma_m^2$. Equation 11.22a shows the expression for the additive variance when dominance is present. From Equation 11.21a, the expected equilibrium heritability becomes

$$\tilde{h}^2 = \frac{2N_e h_m^2}{1 + 2N_e h_m^2} = 1 - \frac{1}{1 + 2N_e h_m^2} \quad (28.1)$$

Note the connection with the expression for neutral allelic heterozygosity, \tilde{H} , as both are of the form $2N_e y / (1 + 2N_e y)$, with $y = h_m^2$ for heritability and $y = 2\mu$ for heterozygosity. As with \tilde{H} , even modest values of N_e (~ 1000) return \tilde{h}^2 values over 0.5, while larger values return heritabilities of close to one. For example, when $h_m^2 = 0.001$, N_e is constrained to be in the range of 50–1200 in order to recover typical heritability values (0.1 to 0.6).

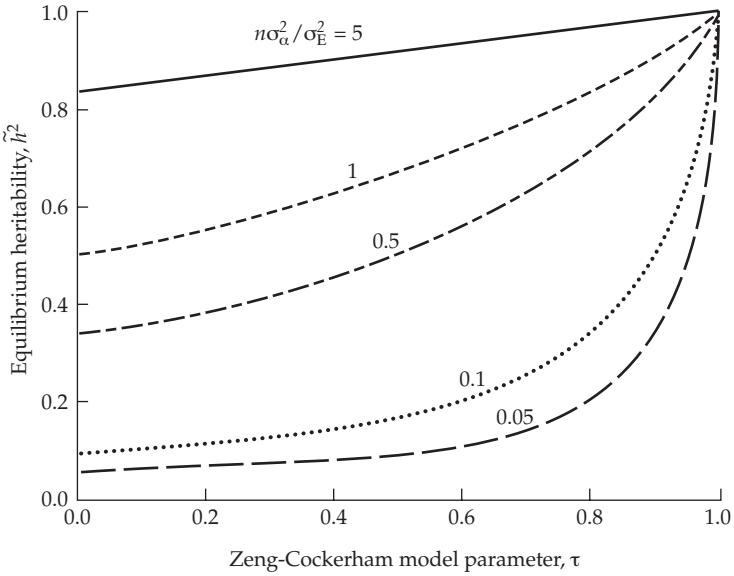

Figure 28.2 The expected heritability, \tilde{h}^2 , for large N_e , at mutation-drift equilibrium under the mutational regression model of Zeng and Cockerham (Equation 28.2a). This model includes the incremental ($\tau = 1$) and HOC ($\tau = 0$) models as special cases. Curves denote different values of $h_m^2/(2\mu) = n\sigma_\alpha^2/\sigma_E^2$, the ratio of the mutational heritability to the per-locus mutation rate.

As noted in Chapter 11, the incremental mutational model represents one extreme, wherein the value of the new mutation is closely tied to the evolutionary history (x) of its parental allele. The other extreme is the **house-of-cards** (HOC) model, which was formally developed by Kingman (1977, 1978; although also assumed by Wright 1948b, 1969). Under HOC, $x' = \alpha$, independent of an allele's starting value x , where again $\alpha \sim (0, \sigma_\alpha^2)$, so that past evolutionary history is completely irrelevant.

The incremental and HOC models present two extremes, one strongly influenced by evolutionary history and the other completely indifferent to it. Zeng and Cockerham (1993) proposed a more general **regression model**, $x' = \tau x + \alpha$, where $0 \leq \tau \leq 1$ and $\alpha \sim (0, \sigma_\alpha^2)$ (Table 28.1). The regression coefficient, τ , indicates the importance of past evolutionary history, recovering the incremental ($\tau = 1$) and HOC ($\tau = 0$) as special cases. This regression model is an Ornstein-Uhlenbeck process (Equation A1.33), as $E[\Delta x] = E[x' - x] = -(1 - \tau)x$. The parameter τ counters the diffusive effects of Brownian motion (the incremental random α) by exerting a restoring force toward the origin, and thus producing a bounded equilibrium distribution for $\tilde{\sigma}_A^2$ (for $\tau < 1$). Under the regression model (provided $\tau \neq 1$), the equilibrium additive variance in a large population is bounded by $\sigma_m^2/[\mu(1 - \tau^2)]$, with a resulting heritability of

$$\tilde{h}^2 = \frac{\sigma_m^2/[\mu(1 - \tau^2)]}{\sigma_m^2/[\mu(1 - \tau^2)] + \sigma_E^2} = 1 - \frac{1}{K + 1} \quad (28.2a)$$

where

$$K = \frac{h_m^2}{\mu(1 - \tau^2)} = \frac{2\mu n \sigma_\alpha^2 / \sigma_E^2}{\mu(1 - \tau^2)} = \frac{2n\sigma_\alpha^2 / \sigma_E^2}{1 - \tau^2} \quad (28.2b)$$

Figure 28.2 plots \tilde{h}^2 as a function of τ and $h_m^2/(2\mu) = n\sigma_\alpha^2/\sigma_E^2$ (the scaled variance of mutational effects over all loci). The expected heritability increases as the role of past evolutionary history of an allele becomes increasingly important in predicting its mutated value (i.e., \tilde{h}^2 increases with τ). Likewise, \tilde{h}^2 increases with the total variance of mutational effects, $n\sigma_\alpha^2$. Assuming a typical value of $h_m^2 = 0.001$, an underlying per-locus mutation rate of $\mu = 10^{-3}$

(implying $2n\sigma_\alpha^2 = \sigma_E^2$) and a value of $\tau = 0.5$ gives $K = 2$ and $\tilde{h}^2 = 0.67$. This decreases to 0.5 as we approach the HOC model ($\tau = 0$), and increases to one as we approach the incremental model ($\tau = 1$). Assuming that $h_m^2 = 0.001$ is a standard value for many traits, for large N_e this model requires a very high per-locus mutation rate ($\mu > h_m^2 \sim 0.001$; implying $K < 1$), otherwise the predicted heritabilities are too large. As with the incremental model, Equation 28.2a ignores the impact of deleterious mutations, and thus gives an upper limit on the equilibrium heritability.

MAINTENANCE OF VARIATION BY DIRECT SELECTION

As shown in Figure 28.1, a number of models for the maintenance of variation assume stabilizing selection on the focal trait. We start by examining stabilizing selection per se on both one, and n , traits. The conclusion is that only very limited amounts of genetic variation can be maintained in such settings, especially if a large number of genes, each of modest to small effect, underlie the trait. One potential counteracting selective force will arise if trait loci have overdominant pleiotropic effects on fitness, and this is discussed next. Such overdominance can arise when homozygotes have a higher environmental variance than heterozygotes for a trait under strict stabilizing selection. Fitness overdominance can also be generated when the underlying loci show $G \times E$ in the trait under selection, and we will examine both of these situations. Finally, the impacts of a changing optimum phenotypic value and frequency-dependent selection will be examined to see if these can help retain variation. As we detail, all of these models fall short in their attempt to account for observed levels of variation.

Fitness Models of Stabilizing Selection

Two standard fitness models of phenotypic stabilizing selection with trait value z appear in the literature: Wright's (1935a, 1935b) quadratic optimal model

$$W(z) = 1 - s(z - \theta)^2 \quad (28.3a)$$

and the Gaussian (or nor-optimal) model of Haldane (1954; also Weldon 1895)

$$W(z) = \exp \left[\frac{-(z - \theta)^2}{2\omega^2} \right] \quad (28.3b)$$

Recalling that $e^{-x} \simeq 1 - x$ for $|x| \ll 1$, the Gaussian reduces to the quadratic model under weak selection ($\omega^2 \gg 1$), as

$$W(z) \simeq 1 - \frac{(z - \theta)^2}{2\omega^2} \quad (28.3c)$$

As a result, these two models are used somewhat interchangeably, with $s \simeq 1/(2\omega^2)$. This is quite reasonable under the assumption of weak selection ($\omega^2 \gg 2\sigma_z^2$), but inappropriate under strong selection ($\omega^2 < 2\sigma_z^2$). While the Gaussian fitness function imposes no restrictions on the strength of stabilizing selection, the quadratic model does (to ensure that fitnesses are not negative at extreme values of z), which results in the two models showing very different behavior for loci under strong selection (Gimelfarb 1996b; see Example 5.11).

Discussions on the maintenance of variation often involve the mean fitness generated by a particular strength of selection. Under the quadratic model, this is a function of the mean and variance of z . If $z \sim (\bar{z}, \sigma_z^2)$, then

$$\overline{W}(z) = E[w(z)] = 1 - s(E[z^2] - 2\theta E[z] + \theta^2) = 1 - s[(\bar{z} - \theta)^2 + \sigma_z^2] \quad (28.3d)$$

where the last simplification follows from $E[z^2] = \bar{z}^2 + \sigma_z^2$. For Gaussian selection, if we assume that z is normal with $z \sim N(\bar{z}, \sigma_z^2)$, then

$$\begin{aligned} \overline{W} &= \frac{1}{\sqrt{2\pi\sigma_z^2}} \int \exp \left[\frac{-(z - \bar{z})^2}{2\sigma_z^2} \right] \exp \left[\frac{-(z - \theta)^2}{2\omega^2} \right] dz \\ &= \sqrt{\frac{\omega^2}{\omega^2 + \sigma_z^2}} \exp \left[\frac{-(\bar{z} - \theta)^2}{2(\omega^2 + \sigma_z^2)} \right] \end{aligned} \quad (28.3e)$$

(Kimura and Crow 1978). Equations 28.3d and 28.3e are special cases of our previous Equations 17.7b and 17.8a. An important application of Equation 28.3e is the expected fitness associated with a genotypic value of G . Assuming environmental effects are normally distributed around G , then $z|G \sim N(G, \sigma_E^2)$, and the resulting strength of stabilizing selection on G becomes

$$V_s = \omega^2 + \sigma_E^2 \quad (28.3f)$$

Larger values of V_s correspond to weaker selection, so (as expected) variation in the phenotype around a genotypic value weakens the strength of selection ($V_s > \omega^2$). V_s is a central parameter in the maintenance-of-variation literature, and it is usually scaled in units of σ_E^2 , with $V_s = \omega^2/\sigma_E^2 + 1 \simeq \omega^2/\sigma_E^2$ under weak selection ($\omega^2 \gg \sigma_E^2$).

Assuming that the fitness function is given by Equation 28.3b, Equation 16.18a yields the phenotypic variance following selection as

$$\sigma_{z^*}^2 = \sigma_z^2 - \frac{\sigma_z^4}{\sigma_z^2 + \omega^2} \quad (28.3g)$$

When $\omega^2 \gg \sigma_z^2$ (weak selection), then for low heritability, $\sigma_z^2 + \omega^2 \simeq \sigma_E^2 + \omega^2 = V_s$, which rearranges to give an estimate of the strength of stabilizing selection as

$$\hat{V}_s \simeq \frac{\sigma_z^4}{\sigma_z^2 - \sigma_{z^*}^2} \quad (28.3h)$$

This is a biased estimate in the presence of directional selection, which also reduces the phenotypic variance following selection (Equation 29.16a). Less biased estimates can be obtained from the quadratic term in the Pearson-Lande-Arnold fitness regression (Equation 29.29a),

$$w(z) = 1 + \beta(z - \mu_z) + \frac{\gamma}{2} \left[(z - \mu_z)^2 - \sigma_z^2 \right] + e \quad (28.3i)$$

which adjusts for the reduction in variance from directional selection. Matching terms with Equation 28.3c, we find that $\gamma = -1/\omega^2$ (Keightley and Hill 1990). Under weak selection, $V_s = \omega^2 + \sigma_E^2 \simeq \omega^2$, returning an estimate of V_s as $\simeq -1/\gamma$.

Turelli (1984) suggested a typical value of $V_s/\sigma_E^2 \simeq 20$, which corresponds to $V_s/\sigma_A^2 \simeq 20$ when $h^2 = 0.5$. Under this strength of stabilizing selection (which implies that $V_s \simeq 10\sigma_z^2$), a phenotype two standard deviations from the mean has around 80% of the fitness at the phenotypic optimum. While Turelli's values are widely used in the maintenance-of-variation literature, more recent estimates (Kingsolver et al. 2001; summarized in Figure 30.5) are less clear. On the one hand, the average value of V_s among traits experiencing stabilizing selection (those with estimated negative γ values) is stronger than Turelli's assumed value, with a mean V_s of $\simeq 5\sigma_z^2$ ($\simeq 10\sigma_E^2$ when $h^2 \simeq 0.5$). Under this strength of selection, a phenotype two standard deviations from the mean has around 70% of the optimal fitness. On the other hand, Figure 30.5 shows that the distribution of estimated γ values from natural populations is largely symmetric around zero, implying that disruptive selection is as common as stabilizing selection. Although these results are colored by a lack of information on the statistical significance of many of the γ values plotted in Figure 30.5, they still raise the possibility that a typical trait may be under much weaker, or even nonexistent, stabilizing selection. Conversely, the long-term stasis of many traits over evolutionary time suggests that stabilizing selection is indeed a major force shaping evolution (Charlesworth et al. 1982; Maynard Smith 1983; Estes and Arnold 2007; Hunt 2007). Haller and Hendry (2013) discuss a variety of factors that might make stabilizing selection difficult to detect (Chapter 30).

An even larger issue, which frames much of the discussion on the maintenance of variance, is whether an observed amount of stabilizing selection on a trait is **real** or **apparent**. As we saw in Chapter 20 (and discuss extensively in Chapter 30), selection acting on a hidden feature correlated with the trait of interest will impart a signature of selection on that trait. Direct selection models assume that there is real selection on the focal trait. As we

will see, their problem is that reasonable assumptions about the components of σ_m^2 predict heritabilities that are too small, given the observed values of V_s . Conversely, pleiotropic models that can account for the observed levels of heritability predict much larger apparent values of V_s (weaker selection) than are typically seen.

Stabilizing Selection on a Single Trait

In Chapter 5 we examined constant-fitness population-genetic models for alleles under strict selection (no mutation or drift) and showed that while heterozygote advantage can stably maintain both alleles at a diallelic locus, most forms of selection tend to remove variation. At first glance, an additive QTL for a trait under stabilizing selection seems to be an example of such a heterozygote advantage, as the heterozygote is intermediate in phenotype and an intermediate phenotype is preferred by selection. However, it is critical to recall that this is *not* the case. Example 5.6 showed that a QTL underlying a trait under stabilizing selection generally experiences selective *underdominance*, and hence the *removal*, rather than the maintenance, of variation by selection.

While Fisher (1930) was the first to suggest that stabilizing selection will remove, rather than retain, variation, the initial formal demonstration of this was due to Wright (1935a, 1935b) and Robertson (1956), and a vast literature has since followed. Assuming Gaussian stabilizing selection, and if the genotypes $q_i q_i$, $Q_i q_i$, and $Q_i Q_i$ at locus i have effects of $-a_i$, 0, and a_i , respectively, then the dynamics for frequency p_i of allele Q_i are calculated by

$$\Delta p_i \simeq \frac{a_i}{V_s} \left[\frac{p_i(1-p_i)}{2} \right] \left[a_i(2p_i - 1) + 2(\theta - \bar{z}) \right] \quad (28.4a)$$

(derived in Example 5.6). A useful way to understand these dynamics is to express them in the form of a weakly selected allele with additive effects (Equation 5.2), $\Delta p \simeq s_i p_i(1 - p_i)$, where the selection coefficient becomes

$$s_i = \frac{a_i}{2V_s} \left[a_i(2p_i - 1) + 2(\theta - \bar{z}) \right] \quad (28.4b)$$

The first term in the square brackets, $a_i(2p_i - 1)$, represents stabilizing selection to reduce the variance generated by this locus, while the second term, $2(\theta - \bar{z})$, is the impact from directional selection. When $|\theta - \bar{z}| > a_i/2$, directional selection determines the dynamics. When this second term is negligible, selective underdominance occurs, as $\Delta p_i < 0$ for $p_i < 1/2$ and $\Delta p_i > 0$ for $p_i > 1/2$ (with $p = 1/2$ being an unstable equilibrium point). When $\bar{z} \simeq \theta$, the initial selection coefficient on a new allele ($p_i \simeq 0$) is

$$s_i \simeq -\frac{a_i^2}{2V_s} \quad (28.4c)$$

as found by Latter (1970), Kimura (1981), Bürger et al. (1989), and Houle (1989).

This is the crux of the problem with stabilizing selection per se—it drives allele frequencies towards fixation, *removing, rather than retaining*, variation at underlying loci (Robertson 1956). Additional analysis of single-locus models (ignoring linkage disequilibrium) showed that partial dominance (Kojima 1959; Lewontin 1964; Jain and Allard 1965; Singh and Lewontin 1966; Bulmer 1971a) or the presence of loci with unequal additive effects (Gale and Kearsey 1968; Kearsey and Gale 1968) can result in the maintenance of several polymorphic loci at equilibrium, although the parameter space for this to happen is extremely narrow for unlinked loci.

Analyses of two- and multiple-locus models (where LD is fully considered) again lead to the conclusion that selection removes variation for additive loci of equal effect. However, when selection is strong relative to recombination, multiple-locus polymorphisms can be maintained by stabilizing selection on a single trait when loci have unequal effects, or when dominance or epistasis is present in the trait under selection (Gimelfarb 1989, 1996b; Nagylaki 1989a; Zhivotovsky and Gavrilets 1992; Gavrilets and Hastings 1993, 1994a, 1994b).

Example 5.11 detailed Bürger and Gimelfarb's (1999) analysis of the general two-locus model under quadratic selection, and Willensdorfer and Bürger (2003) presented a similar analysis for Gaussian selection. The conditions under which stabilizing selection on a single trait can maintain polymorphisms at multiple loci are fairly stringent and generally result in high negative levels of disequilibrium, and hence small additive variances (Gimelfarb 1989; Zhivotovsky and Gavrilets 1992). Further, the genetic variance that can be maintained under such models generally decreases very rapidly with the number of loci, reflecting diminished selection coefficients on the individual loci (Bürger and Gimelfarb 1999). One subtle issue is the granularity of these models, in that if no genotype exists whose value exactly equals the optimal value under stabilizing selection, then small amounts of directional selection ($|\theta - \bar{z}| > 0$) can be present at equilibrium, and multilocus polymorphism (often with alleles at extreme values, and hence contributing little variation) can be maintained (Barton 1986).

Given that most traits seem to be controlled by a moderate to large number of loci of moderate to small effect (Chapter 24), strong selection on *individual loci* (distinct from strong selection on the *trait*) is generally unlikely. Thus, the weak selection results suggest that, at best, only very modest amounts of additive variation are maintained by single-trait stabilizing selection in the absence of other forces.

Stabilizing Selection on Multiple Traits

The assumption that a gene only influences a single trait is biologically rather unrealistic, as it ignores the likely situation that *the amount of standing variation at a given locus reflects the action of selection acting on multiple traits*. One model of such pleiotropic fitness effects assumes that a locus influences n independent traits, each under stabilizing selection. Hastings and Hom (1989) showed that when selection on individual loci is weak relative to recombination, at most k loci are polymorphic when k independent traits are under selection. Hence, under weak selection, the addition of pleiotropic stabilizing selection on a nonfocal trait does little to increase the amount of standing variation at a focal trait.

The effect of strong selection was examined by Gimelfarb (1986a, 1992, 1996a) and Hastings and Hom (1990). Gimelfarb (1986a) constructed a model with independent selection on two phenotypically uncorrelated traits (1 and 2, with phenotypic values of z_1 and z_2), which were determined by two additive loci with alleles A/a and B/b , whose joint allelic effects on the traits are $A : (z_1 = z_2 = 0)$, $a : (z_1 = z_2 = 1)$, $B : (z_1 = 0, z_2 = 1)$, and $b : (z_1 = 1, z_2 = 0)$, respectively. Fitness is assumed to be a function of the phenotypic values of each trait, and $W(z_1, z_2) = [1 - s_1(z_1 - \theta_1)][1 - s_2(z_2 - \theta_2)]$. Under this model there is pleiotropy (as the A locus influences both traits), and although Gimelfarb showed that, at equilibrium, both loci are polymorphic, the traits are phenotypically and genetically uncorrelated, and selection occurs independently on each. The result, in the words of Gimelfarb, is that "even if the investigator will be lucky enough to come across character 2, he is almost certain to discard it as having no biological connection with the character 1." The worrisome implications of this model foreshadow additional complications from pleiotropy, which are discussed below. While multiple-trait stabilizing selection can maintain variation at a number of loci, with selection strong relative to recombination, there is significant negative disequilibrium and often little additive variance in each trait (Gimelfarb 1992).

Barton (1990) raised several additional points on the limitations of multiple-trait stabilizing selection. First, simple genetic load arguments (the decrease in mean population fitness relative to the fittest possible genotype) place upper limits on the number of independently selected traits. Assume k traits, each under Gaussian selection with a common value of $V_s = \omega^2 + \sigma_E^2$. For populations at equilibrium ($\mu = \theta$), Equations 28.3e and 28.3f imply that genetic variation reduces the mean population fitness by $\sqrt{V_s/(V_s + \sigma_A^2)}$ for each trait. For $V_s \gg \sigma_A^2$ (weak selection), a Taylor-series argument shows that

$$\sqrt{\frac{V_s}{V_s + \sigma_A^2}} = \sqrt{\frac{1}{1 + \sigma_A^2/V_s}} \approx 1 - \sigma_A^2/(2V_s) \approx \exp\left[-\frac{\sigma_A^2}{2V_s}\right]$$

Assuming multiplicative fitnesses across the k independently selected traits, this yields a load of $\simeq \exp(-k\sigma_A^2/[2V_s])$. For $V_s = 20\sigma_A^2$, the mean fitness is around 8% of the highest fitness with $k = 100$ traits. For weaker selection, $V_s = 100\sigma_A^2$, this same load occurs for $k = 500$, while for stronger selection ($V_s = 5\sigma_A^2$) it occurs for $k = 25$. Thus, one quickly approaches an upper limit on the number of traits before the fitness load becomes unbearable.

As discussed in Chapter 7, such load arguments can be delicate because departures from the assumed multiplicative fitness model can either lessen the load (synergistic epistasis) or enhance it (diminishing-returns epistasis). However, the point remains that selection itself places a limit on the number of independent traits with segregating variance. There are also limits on the number of alleles at a given locus, again constraining the ability to evolve in an unlimited number of directions in phenotypic space (at least k alleles are required for a locus to evolve in independent directions at k traits).

Barton (1990) suggests there may be a modest number of phenotypic dimensions experiencing significant real stabilizing selection, which results in apparent stabilizing selection on any trait phenotypically correlated to one, or more, of these dimensions (Example 28.1). Further, we have shown that stabilizing selection per se, be it on a single or multiple traits, is unlikely to account for significant additive variance. Coupling these points suggests that stabilizing selection, by itself, is unlikely to explain more than a trivial amount of the genetic variance for a trait that appears to be under stabilizing selection, and that additional factors (such as mutation and pleiotropy) are critical. As succinctly stated by Barton “*heritable variation in any one trait is maintained as a side effect of polymorphisms which have nothing to do with selection on that trait*,” an idea more fully explored throughout this chapter.

Example 28.1. As illustrated in Chapter 20, traits may show signs of directional selection (a covariance between trait value and fitness) without being the actual target of selection. The same is true for stabilizing selection, which appears as a negative covariance between the squared trait value and fitness (Chapters 29 and 30). Wagner (1996a) emphasized this point by considering two genetically uncorrelated traits, 1 and 2, that are phenotypically correlated through some shared environmental effect. Trait 1 is neutral (its trait value, z_1 , has no effect on fitness), while trait 2 is under Gaussian stabilizing selection with a strength parameter of ω_2^2 . Wagner showed that if ρ_z is the phenotypic correlation between the two traits, the expected fitness of phenotype z_1 is

$$W(z_1) = \exp\left(-\frac{z_1^2 \rho_z \sigma_{z_2}^2}{2\sigma_{z_1}^2 [\omega_2^2 + \sigma_{z_2}^2 (1 - \rho_z^2)]}\right) \quad (28.5a)$$

Matching terms with Equation 28.3b shows that trait 1 experiences apparent stabilizing (Gaussian) selection around an apparent optimum of 0 and with a strength of

$$\omega_1^2 = \frac{\sigma_{z_1}^2 [\omega_2^2 + \sigma_{z_2}^2 (1 - \rho_z^2)]}{\rho_z \sigma_{z_2}^2} \quad (28.5b)$$

Note that $\omega_1^2 \rightarrow \infty$ (no selection) as $|\rho_z| \rightarrow 0$. Scaling both traits to have an environmental variance of one, then $\sigma_{z_i}^2 = \sigma_{G_i}^2 + 1$, where $\sigma_{G_i}^2$ is the (environmentally scaled) genetic variance of trait i . Using this scaling, Wagner rearranged Equation 28.5d to find a lower bound of

$$\omega_1^2 \geq 2\omega_2^2 (\sigma_{G_1}^2 + 1)^2 \quad (28.5c)$$

This sets an upper limit on the strength of apparent stabilizing selection (as smaller ω_1^2 values imply stronger selection), with ω_1^2 increasing (selection becoming weaker) as the fraction of genetic variance in trait 1 increases. This is not surprising, as the apparent selection arises through the environmental component, which is decreased by increasing the genetic contribution.

What is surprising, however, is that the joint fitness for the genotypic values for both traits, (A_1, A_2) , is

$$W(A_1, A_2) = \exp\left(-\frac{A_2^2}{2[\omega_2^2 + \sigma_{E_2}^2]}\right) \quad (28.6)$$

showing that there is no selection on the genotypic values of trait 1, which therefore evolves neutrally. Hence, the equilibrium heritability in trait 1 is entirely independent of the strength of the apparent selection on trait 1 (i.e., ω_1^2 does not appear in this expression).

Stabilizing Selection Countered by Pleiotropic Overdominance

Extensions of direct-selection models to include pleiotropy assume that the loci underlying a trait under stabilizing selection also have independent effects on other fitness components. For example, an allele might influence the value of a trait under stabilizing selection (such as height), but might also influence fecundity, independent of any impact of height on fecundity. The motivation for this idea traces back to Lerner (1954), who suggested that “inheritance of metric traits may be considered, at least operationally, to be based on additively acting polygenic systems, while the totality of traits determining reproductive capacity and expressed as a single value (fitness) exhibits overdominance.” While the support for overdominance has diminished over time (Lewontin 1974; Hedrick 2012; but see Manna et al 2011; Sellis et al. 2011; and Charlesworth 2015), a number of the initial pleiotropy models assumed overdominance (Robertson 1956; Lewontin 1964; Bulmer 1973; Gillespie 1984a). As we will see, such models can still be meaningful even in the absence of classical overdominance.

The basic structure of the **pleiotropic-overdominance-stabilizing-selection model** is as follows. For locus i , the genotypes $q_i q_i : Q_i q_i : Q_i Q_i$ have effects of $-a_i : 0 : a_i$ on a trait under stabilizing selection, and fitness effects of $1 : 1 + t_i : 1$ on an independent (and multiplicative) fitness component, with total fitness calculated as the product of $W(z)$ from stabilizing selection (e.g., Equation 28.3b) and the pleiotropic fitness of the genotype. Under this model, the change in allele frequency from weak overdominance alone is

$$\Delta p_i \simeq -t_i p_i (1 - p_i)(2p_i - 1) \quad (28.7)$$

This form of selection maintains variation, as $\Delta p_i > 0$ when $p_i < 1/2$, while $\Delta p_i < 0$ when $p_i > 1/2$. Under the assumption of weak selection on the focal trait, we can add the change from stabilizing selection to obtain the approximate total allele-frequency change. Assuming Gaussian stabilizing selection, Equation 28.4a yields

$$\begin{aligned} \Delta p_i &\simeq -t_i p_i (1 - p_i)[2p_i - 1] + \frac{a_i}{V_s} \left(\frac{p_i(1 - p_i)}{2} \right) [a_i (2p_i - 1) + 2(\theta - \bar{z})] \\ &= p_i(1 - p_i) \left([2p_i - 1] \left[-t_i + a_i^2/(2V_s) \right] + [a_i(\theta - \bar{z})/V_s] \right) \end{aligned} \quad (28.8)$$

which has a stable polymorphic equilibrium if $t_i > a_i^2/(2V_s)$, provided the population mean is close to the optimal trait value, θ (stability analyses are given by Gillespie 1984a; and Turelli and Barton 2004). Recalling Equation 28.4c, this condition can be restated as a stronger selection coefficient from overdominant selection than from stabilizing selection alone, namely, $t_i > a_i^2/(2V_s) = s_i$. If the phenotypic mean is sufficiently far away from the optimum value, then directional selection dominates (fixing Q_i if \bar{z} is sufficiently below θ , and fixing q_i if \bar{z} is sufficiently above θ). When $\bar{z} \simeq \theta$, balancing selection occurs, in which the net balance of the two selective forces maintains variation, resulting in intermediate allele frequencies at equilibrium.

While the preceding arguments are mathematically correct, the biological relevance of this model is less clear, especially given the difficulty of finding examples of loci that

display classic fitness overdominance. However, there are several realistic settings involving stabilizing selection per se that also result in fitnesses that mimic heterozygote advantage. Zhivotovsky and Feldman (1992) noted that pleiotropic overdominance naturally arises when the environmental variance associated with a genotype decreases along with the number of heterozygous loci (Whitlock and Fowler 1999; Chapter 17). To see this, consider quadratic selection. The fitness associated with genotype g , where $z|g \sim (G, \sigma_{E(g)}^2)$ is given from Equation 28.3d as

$$W(G) = 1 - s(G - \theta)^2 - s\sigma_{E(g)}^2$$

As the environmental variance, $\sigma_{E(g)}^2$, decreases, the fitness increases. This creates pleiotropic overdominance, as heterozygous individuals have a higher fitness than do more homozygous individuals with the same genotypic value (G) due to their smaller values of $\sigma_{E(g)}^2$ (also see Curnow 1964).

Gillespie and Turelli (1989, 1990) found that certain patterns of $G \times E$ (allelic effects change over environments, while the optimum phenotypic value, θ , remains unchanged) can also result in heterozygotes having higher fitnesses than homozygotes, which again recovers pleiotropic overdominance. However, Gimelfarb (1990) noted that the association between fitness and heterozygosity critically depends on strong $G \times E$ symmetry assumptions. A more general analysis of both spatial and temporal $G \times E$ models was provided by Turelli and Barton (2004), who found that a necessary condition for balancing selection to maintain polymorphisms in the face of stabilizing selection is that the coefficient of variation of allelic effects over environments exceed one. If the standard deviation of allelic effects over environments is less than their mean value, the loci are fixed. An interesting consequence of this condition is that sex-specific differences in allelic effects are not sufficient to maintain significant variation (i.e., more than one polymorphic locus) in polygenic models of stabilizing selection. While we showed, in Chapter 5, that antagonistic selection between the sexes can maintain variation in a single-locus model, moving to a polygenic model maintains no additional polymorphic loci.

Fluctuating and Frequency-dependent Stabilizing Selection

Balancing polymorphisms can potentially be maintained by **fluctuating selection**. The $G \times E$ models that we just considered assumed constant selection (θ fixed), with allelic effects changing over environments. In contrast, fluctuating stabilizing selection models assume constant allelic effects with the optimum value, θ , varying over time. Variation in θ can be random or include some periodicity. Starting with Dempster (1955a) and Haldane and Jayakar (1963), a large body of theoretical literature (reviewed by Felsenstein 1976; Hedrick 1986; Frank and Slatkin 1990a; Gillespie 1994; Lenormand 2002) showed that the conditions for temporal variation to retain a polymorphism at a single locus are delicate. Are the conditions any less restrictive with a polygenic trait under fluctuating stabilizing selection? Not substantially.

The simplest model involves random (uncorrelated) fluctuations in θ , and was considered by Ellner and Hairston (1994) and Ellner (1996). They showed that polymorphisms are maintained provided that $\gamma\sigma^2(\theta)/V_s > 1$, where $\sigma^2(\theta)$ is the temporal variance in θ and γ is a measure of the amount of population carryover when overlapping generations are present. Hence, rather large fluctuations are required. Are the conditions less restrictive when the change in θ is periodic? Bürger and Gimelfarb (2002) examined the impact of a fluctuating optimum under a model with built-in periodicity (the expected value of θ varied according to a sine function) plus additional stochasticity (the realization of θ at a particular time is its expected value plus a random increment). An autocorrelated moving optimum had little impact (relative to constant stabilizing selection) on maintaining genetic variation or increasing polymorphism. Further, the longer the periodicity of oscillation, the less was the impact on polymorphisms or on the level of genetic variation. As we will see later, when mutation is also allowed, fluctuating selection can significantly increase the amount of standing variation over models that assume a constant value of θ .

Spatial variation in θ can also maintain at least some variation. A simple example was

given by Felsenstein (1977), who assumed a continuum-of-alleles model, with a Gaussian distribution of allelic effects at each locus (Chapter 24). Under Felsenstein's model, the optimal phenotypic value at position x along some linear cline (such as a river bank) is $\theta(x) = \beta x$. Individuals disperse along this cline with a mean distance of zero and a variance of σ_d^2 . When selection is strong relative to migration ($V_s \ll \sigma_d^2$), the equilibrium additive variance is approximately $\beta^2 \sigma_d^2$. When selection is weak relative to migration, the equilibrium variance is roughly $\beta(\sigma_d^2 V_s)^{1/2}$. More detailed analyses of this problem were presented by Tufto (2000) and Spichtig and Kawecki (2004).

Frequency-dependent selection is another possible mechanism for generating balancing selection. As discussed in Chapter 5, frequency dependence can maintain variation under selection alone (i.e., no other evolutionary forces need be invoked), and aspects of this process have been modeled by a number of researchers (Roughgarden 1972; Bulmer 1974b, 1980; Felsenstein 1977; Slatkin 1979; Clarke et al. 1988; Mani et al. 1990; Kopp and Hermisson 2006). The most comprehensive analysis (in terms of maintenance of variation when stabilizing selection is occurring) is that of Bürger and Gimelfarb (2004). These authors assumed constant stabilizing selection on a trait that was also involved in intraspecific competition (as did Bulmer 1980). Individuals with increased differences in trait values from each other experienced reduced competition, and hence higher fitness, thus generating disruptive selection on the trait. Stabilizing selection on the focal trait was modeled by a quadratic fitness function with a selection effect of s (Equation 28.3a), whereas the amount of competition between phenotypes g and h also follows a quadratic, $1 - s_c(g - h)^2$. Assuming that these two components of fitness are multiplicative, Bürger and Gimelfarb found that the key parameter is $f = s_c/s$, the ratio of selection from competition to stabilizing selection. If f is below a critical value, the model essentially behaves like a standard model of stabilizing selection in removing variation. If f exceeds this critical value, however, there will be no stable monomorphic equilibria, and the genetic variance and amount of polymorphism will rapidly increase with f (since disruptive selection dominates).

Summary of Direct-selection Models

When the focal trait is under direct stabilizing selection, very little variation is maintained in the absence of other forces (such as mutation or countering selection). Likewise, stabilizing selection on multiple traits has little impact on increasing the amount of genetic variance that is at a focal trait, especially under weak selection (i.e., when selection on any given underlying locus is small relative to recombination). When the loci underlying a trait under stabilizing selection are also overdominant for an independent fitness component, sufficiently strong balancing selection can maintain significant variation. However, given the apparent scarcity of widespread fitness overdominance, this is an unlikely candidate to provide a general explanation for the maintenance of variation. Certain strictly stabilizing selection scenarios can mimic pleiotropic overdominance, such as environmental variances that decrease as a function of the total heterozygosity, or $G \times E$ when the genotypic values (but not the fitness optimum) change over time or space. A fluctuating optimum (a varying θ) is unlikely to retain significant variation by itself, but there are conditions under which density-dependent selection can maintain significant variation. As with any explanation presented here, demonstrating a potential to account for a pattern, even over a very wide parameter space, is not sufficient, as one also needs to have some idea about how common a particular mechanism actually is in nature.

NEUTRAL TRAITS WITH PLEIOTROPIC OVERDOMINANCE

In the preceding overdominance models, the removal of genetic variation for a trait under stabilizing selection is countered by advantageous pleiotropic fitness effects at the underlying loci. A natural extension of this idea is to imagine that there is *no* selection on a focal trait, but rather that trait variation is maintained *entirely* as a result of pleiotropic fitness effects at the underlying loci (e.g., Robertson 1956, 1967). These underlying polymorphisms could be

maintained by advantageous fitness effects, such as overdominance or balancing selection, where the nature of selection is independent of the value of the focal trait. Another, more intriguing, possibility is that the underlying pleiotropic loci may have *deleterious* fitness effects, with variation now being maintained by mutation-selection balance. Given that strictly neutral models (i.e., in which none of the underlying loci are under any selection) maintain *too much* variation, perhaps making them slightly deleterious (for reasons other than their associated trait values) might allow them to generate the observed amounts of trait variation. Alas, however, as we will show later in the chapter, this is not the case.

An obvious concern that the careful reader might have with neutral-trait models is the widespread observation of apparent stabilizing selection on many traits. However, pleiotropic selection models can generate associations between the values at a neutral focal trait and fitness, thus generating false signals of stabilizing selection on that trait. In the case of underlying overdominant loci, more homozygous individuals have both lower fitness and more extreme trait values (Example 5.8). Likewise, under the pleiotropic deleterious mutation-selection balance model, individuals carrying more deleterious mutations also have more extreme trait values. In both settings, the neutral trait will show **apparent stabilizing selection** (Robertson 1956, 1967; Barton 1990; Kondrashov and Turelli 1992). Gavrilets and de Jong (1993) found that the conditions required for underlying pleiotropic loci to generate apparent stabilizing selection on a neutral trait are rather minimal. This has led to the suggestion that a significant fraction of apparent stabilizing selection on traits in natural populations is the result of selection on features other than the scored traits (e.g., Example 28.1; Gimelfarb 1996a). The limitation of pleiotropic-fitness models is that they cannot simultaneously account for the observed levels of variation (h^2) and the observed strengths of stabilizing selection (V_s). When one value matches the observations (say h^2), the corresponding value that the model generates for the other parameter (V_s) will be at odds with our current understanding of the data.

To see this last point, we turn to an analysis of Robertson's (1956, 1967) **pleiotropic overdominance** model, wherein loci under overdominant selection also have pleiotropic effects on a *neutral* focal trait (Example 5.8). This is in contrast to the previous pleiotropic overdominance model, in which the focal trait was under *stabilizing selection*, as opposed to being neutral. Consider the i th such pleiotropic locus, and assume that there are two alleles (the conditions for maintaining more than two alleles by overdominance at a locus are very delicate, so this is not an unreasonable assumption; Lewontin et al. 1978). Let the genotypes $Q_i Q_i : Q_i q_i : q_i q_i$ have fitnesses of $1 - s_i : 1 : 1 - t_i$, yielding (Example 5.4) an equilibrium frequency for Q_i of $\tilde{p}_i = t_i/(s_i + t_i)$. Under an additive model in which the pleiotropic effects of this locus on the focal trait are $a_i : 0 : -a_i$, the equilibrium additive variance for the focal trait from this locus is $2a_i^2 \tilde{p}_i (1 - \tilde{p}_i)$. When summed over n overdominant loci, the expected equilibrium additive variance is

$$\tilde{\sigma}_A^2 = 2nE[a_i^2 \tilde{p}_i (1 - \tilde{p}_i)] \quad (28.9)$$

The expectation is taken over all segregating overdominant loci influencing the trait. If homozygotes have rather similar fitnesses ($s_i \approx t_i$), the equilibrium allele frequencies are intermediate ($\tilde{p} \approx 1/2$), resulting in $\tilde{\sigma}_A^2 \approx (n/2)E[a_i^2]$. If alternative homozygotes have very different fitnesses, the equilibrium frequencies will be close to zero or one, which results in drift quickly fixing one of the alleles (Figure 7.4). Consequently, under balancing selection models, segregating alleles are expected to be maintained at moderate frequencies.

Example 28.2. While pleiotropic overdominance models can maintain significant amounts of variation (Equation 28.9), they have limitations as a general explanation for quantitative-trait variation. The first problem is the scarcity of examples of actual overdominant selection in the wild (Lewontin 1974). However, one could argue that overdominance is widespread but overlooked, as very weak selection against both homozygotes still results in overdominance but would be difficult to detect in natural populations. Barton (1990) noted a second limitation:

the genetic load under a multilocus overdominance model constrains the expected response to artificial selection. We sketch this argument here.

Our starting point is Barton's (and Robertson's 1956) demonstration that the overdominance model with fitnesses of $1 - t_i : 1 : 1 - s_i$ (and phenotypic effects of $-a : 0 : a$) generates a strength of apparent stabilizing selection on the neutral focal trait of

$$V_s \simeq \sigma_A^2 / \bar{\ell} \quad (28.10a)$$

where σ_A^2 is the focal-trait additive variance, $\bar{\ell}$ is the average of the locus-specific segregation loads (the reduction in fitness from the optimal value) where

$$\ell_i = \frac{s_i t_i}{s_i + t_i} \simeq \frac{s_i}{2} \quad \text{when } s_i \simeq t_i \quad (28.10b)$$

and $1 - \ell_i$ is the equilibrium mean fitness at locus i . Equation 28.10a implies that $\bar{\ell} = 0.05$ for a trait to have a typically assumed value of $V_s = 20\sigma_A^2$. Assuming n independent overdominant loci and multiplicative fitnesses, the expected mean population fitness becomes

$$\prod_{i=1}^n (1 - \ell_i) \simeq \exp(-\bar{\ell}n)$$

For $\bar{\ell} = 0.05$, around 20 such loci will result in the mean population fitness being about a third of its maximum possible value, so the number of such loci has to be modest for the load to remain reasonable. If loci have weaker effects ($\bar{\ell} < 0.05$), more polymorphisms can be maintained, but Equation 28.10a shows that the associated strength of apparent stabilizing selection on the neutral trait will be correspondingly weaker (V_s is larger).

Now consider the selection response (in the mean) when the focal trait is subjected to artificial directional selection that is strong enough to overpower any natural selection from overdominance. Assuming that the starting equilibrium allele frequencies (from overdominance) are $\tilde{p}_i \simeq 1/2$ (i.e., $s_i \simeq t_i$), Equation 25.2a predicts that the fixation of all favorable alleles will result in an increase in the mean (measured in terms of standard deviations of the initial additive variance) of $\sqrt{2n}$ (this corrects the value given by Barton 1990). Hence, an observed response of R standard deviations requires $R^2/2$ such overdominant loci. Coupling this with the above load calculations suggests that for a population to show $5\sigma_A$ of response in a short-term selection experiment (a fairly typical result; Chapter 18), a lower bound of $5^2/2 = 13$ overdominant loci is required. Given a typical value of observed strength of (in this case, apparent) stabilizing selection of $\simeq 20\sigma_A^2$, $n = 13$ implies that the mean population fitness needs to be $(1 - 0.05)^{13}$, or roughly 50%, of the optimal fitness, to support such a response. For 10 standard deviations of response, the required reduction in fitness in the base population to support the required 50 overdominant loci is over 90% of the fitness of the optimal genotype.

Several factors can modify these results. First, as mentioned in Chapter 7, load can be diminished (and more loci can be maintained) under synergistic epistasis (as opposed to multiplicative fitnesses). Second, Equation 25.2a gives a lower bound on the required number of loci. The actual number of loci is much larger when their frequencies depart from 1/2 (homozygotes have unequal fitnesses), increasing the load. Finally, when homozygote fitnesses are rather unequal, the two alleles are maintained at more extreme frequencies (i.e., closer to 0 or 1), and thus potentially lost to drift in the small populations that characterize selection experiments (Chapter 26), resulting in an undercount of the number of overdominant loci.

MUTATION-STABILIZING SELECTION BALANCE: BASIC MODELS

Recurrent mutation can maintain at least some genetic variation even in the face of strong selection (Chapter 7). For example, if μ is the mutation rate to a deleterious allele whose fitnesses are given by $1 : 1 - hs : 1 - s$, the infinite-population equilibrium frequency of the deleterious allele is $\tilde{p} \simeq \mu/(hs)$ for $h \gg \sqrt{\mu/s}$ (Equation 7.6d) and $\tilde{p} = \sqrt{\mu/s}$ for a recessive

($h = 0$; Equation 7.6d). While it is obvious that at least some variation can be maintained by the balance between stabilizing selection and mutation, the critical question is just how much. This apparently simple query has generated a huge amount of rather technical theory, with some surprising results.

We start our treatment by first considering the very different conclusions reached by Latter (1960) and Bulmer (1972) for diallelic models versus those by Kimura (1965a), Lande (1975, 1977a, 1980a, 1984a), and Fleming (1979) for continuum-of-alleles models. We show how these apparently disparate results are connected, with the different outcomes due, not to the number of assumed alleles per locus (two versus many), but rather to the relative strengths of mutation and selection (Turelli 1984). Given the rather complex nature of some of the theory, we have placed most of derivations, and many of the more technical details, in Examples 28.4–28.8 at the end of this section.

Latter-Bulmer Diallelic Models

While diallelic models of mutation and stabilizing selection trace back to Wright (1935a, 1935b), it was Latter (1960) and Bulmer (1972, 1980) who first considered the predicted equilibrium additive-genetic variance. To obtain their results, we start by slightly rewriting Equation 28.4a for the change in allele frequency due to Gaussian stabilizing selection as

$$\Delta p_i(\text{sel}) \simeq p_i(1 - p_i) \frac{a_i^2(p_i - 1/2) - a_i(\bar{z} - \theta)}{V_s} \quad (28.11a)$$

where a_i is the allelic-effect for locus i (assuming additive loci) and θ is the optimum phenotypic value. Assuming a simple diallelic model with equal mutation rates between alleles, the change from mutation becomes

$$\Delta p_i(\text{mut}) = -2\mu_i(p_i - 1/2) \quad (28.11b)$$

Assuming that $\bar{z} = \theta$ at equilibrium (a subtle assumption that requires sufficient granularity in the allelic effects at the underlying loci; Barton 1986) and setting $\Delta p_i(\text{sel}) + \Delta p_i(\text{mut}) = 0$ gives one equilibrium solution as

$$\tilde{p}_i(1 - \tilde{p}_i) a_i^2 = 2\mu_i V_s \quad (28.11c)$$

The solutions to this quadratic equation are

$$\tilde{p}_i = \frac{1}{2} \left(1 \pm \sqrt{1 - \frac{8\mu_i V_s}{a_i^2}} \right) \quad (28.11d)$$

An admissible solution ($0 < \tilde{p} < 1$) requires that the strength of selection ($s_i = a_i^2/[2V_s]$; Equation 28.4c) on a locus be strong relative to mutation μ_i (Bulmer 1980; Slaktin 1987), namely, that

$$a_i^2 > 8\mu_i V_s, \quad \text{implying} \quad s_i > 4\mu_i \quad (28.11e)$$

Notice that the left-hand term in Equation 28.11c is just one half the additive variance contributed by the i th locus. Ignoring the contribution from linkage disequilibrium (which will be slightly negative; Chapter 16), summing over n loci yields an additive variance of

$$\tilde{\sigma}_A^2 \simeq 4n\bar{\mu}V_s \quad (28.12a)$$

where $\bar{\mu} = n^{-1} \sum \mu_i$ is the average allelic mutation rate. Equation 28.12a is due to Latter (1960), who obtained it by a different approach. The surprising result is that the size of allelic effects (a_i) does not appear in $\tilde{\sigma}_A^2$. This follows from Equation 28.11d, as increasing a_i results in a more extreme value of \tilde{p} , and hence a smaller value for $\tilde{p}(1 - \tilde{p})$; the two effects (larger effect size versus more extreme equilibrium frequencies) cancel, as is seen in Equation 28.11c.

If we consider the contribution from a single locus and then recall Equation 28.4c for the strength of selection against a new mutation ($2V_s = a_i^2/s_i$), Equation 28.11c yields the contribution from locus i to the additive variance as

$$\tilde{\sigma}_{A(i)}^2 = 2a_i^2 \tilde{p}_i[1 - \tilde{p}_i] = (2\mu_i)(2V_s) = \frac{2\mu_i a_i^2}{s_i} = \frac{\sigma_{m_i}^2}{s_i} \quad (28.12b)$$

showing that the contribution from the i th locus is the ratio of its mutational variance, $\sigma_{m_i}^2$, and the strength of selection against new mutations, s_i ; namely, the ratio of the rate of input of new variation to the rate of its removal (the analog of Equation 7.6b).

One interesting consequence of Equation 28.12a is that the mean fitness at equilibrium is independent of the strength of phenotypic selection, V_s . Substitution of Equation 28.12a into Equation 28.3e yields

$$\begin{aligned} \overline{W} &= \sqrt{\frac{V_s}{V_s + \tilde{\sigma}_A^2}} = \sqrt{\frac{V_s}{V_s + 4n\bar{\mu}V_s}} \\ &= 1/\sqrt{1 + 4n\bar{\mu}} \simeq 1 - 2n\bar{\mu} \quad \text{for } 4n\bar{\mu} \ll 1 \end{aligned} \quad (28.12c)$$

This is another example of Haldane's principal (Chapter 7), namely, that the selective load is simply a function of the mutation rate, independent of the strength of selection.

Equation 28.12a ignores linkage disequilibrium, as it is simply the sum of the single-locus results. A more careful analysis by Bulmer (1980) accounting for gametic-phase disequilibrium (among unlinked loci) found that

$$\tilde{\sigma}_A^2 \simeq \frac{4n\bar{\mu}V_s}{1 - 8n\mu} \quad (28.12d)$$

which closely approximates Equation 28.12a unless the total mutation rate is large. More generally, Turelli (1984) found that the impact of linkage is typically small, unless it is very tight.

With $\tilde{\sigma}_A^2 = 4n\bar{\mu}V_s$, the equilibrium heritability becomes

$$\tilde{h}^2 = \frac{\tilde{\sigma}_A^2}{\tilde{\sigma}_A^2 + \sigma_E^2} = \frac{\tilde{\sigma}_A^2/\sigma_E^2}{\tilde{\sigma}_A^2/\sigma_E^2 + 1} = \frac{4n\bar{\mu}(V_s/\sigma_E^2)}{4n\bar{\mu}(V_s/\sigma_E^2) + 1} \quad (28.12e)$$

Using Turelli's (1984) value of $V_s/\sigma_E^2 \simeq 20$ (moderate selection), $n = 100$, and $\bar{\mu} = 10^{-5}$ returns an equilibrium heritability of 0.07. Increasing the per-locus mutation rate to 10^{-4} gives a value of 0.44. A total haploid mutation rate of $n\bar{\mu} = 0.0125$ is required to account for a heritability of 0.50 under $V_s/\sigma_E^2 = 20$. Hence, unless stabilizing selection is weaker than it appears ($V_s/\sigma_E^2 \gg 20$), the per-locus mutation rates are higher than expected ($\mu \gg 10^{-5}$), or the number, n , of loci is very large, the Latter-Bulmer model cannot account for the typically observed levels of heritability, a point made by Latter (1960).

A cautionary note on the Latter-Bulmer model was offered by Barton (1986). Due to the symmetry of the model (all loci have the same effect and heterozygote values equal the optimum value) and its diallelic nature, the above analysis assumes that the mean equals the optimum (set at $\theta = 0$) at equilibrium, such that there are an equal number of loci with equilibrium values of \tilde{p} and $1 - \tilde{p}$, (contributing $2a(2\tilde{p} - 1)$ and $2a(1 - 2\tilde{p})$, respectively, to the overall mean). Barton showed that when the number of loci is large, equilibria exist at the underlying loci where the population mean *does not* equal the optimum, and in such settings the amount of additive variance exceeds the value predicted by Equation 28.12a, in some cases by a considerable amount. However, while such equilibria can indeed exist, they tend not to be reached, especially in the face of drift (Barton 1989; Hastings 1988, 1990d).

Turelli (1984) generalized the Latter-Bulmer result to a triallelic model, assuming additive effects and no epistasis, with Gaussian stabilizing selection occurring on n loci assumed

to be in linkage equilibrium. At locus i , the alleles $A_{-1}^{(i)} : A_0^{(i)} : A_1^{(i)}$ have values of $-a_i : 0 : a_i$, with the following mutational structure

$$A_{-1}^{(i)} \xrightleftharpoons[\mu_i/2]{\mu_i} A_0^{(i)} \xrightleftharpoons[\mu_i/2]{\mu_i} A_1^{(i)} \quad (28.13a)$$

This model also has a symmetry assumption, namely, that allele A_0 corresponds to the optimal value ($\theta = 0$). Provided that $\mu_i \ll a_i^2/V_s \ll 1$, the equilibrium allele frequencies are

$$\tilde{p}_1^{(i)} = \tilde{p}_{-1}^{(i)} \simeq \mu_i V_s / a_i^2 \quad (28.13b)$$

with $\tilde{p}_0^{(i)} = 1 - 2\tilde{p}_1^{(i)}$ (see Turelli 1984 for details). The resulting additive variance for locus i is

$$\tilde{\sigma}_{A(i)}^2 = 2 \left[(-a_i)^2 \tilde{p}_{-1}^{(i)} + 0^2 \tilde{p}_0^{(i)} + a_i^2 \tilde{p}_1^{(i)} \right] = 4a_i^2 (\mu_i V_s / a_i^2) = 4\mu_i V_s \quad (28.13c)$$

Under the assumption of linkage equilibrium, summing over loci recovers Equation 28.12a.

Kimura-Lande-Fleming Continuum-of-alleles Models

In contrast to the Latter-Bulmer two-allele model, starting with Kimura (1965a), a number of continuum-of-alleles models (Chapter 24) have been proposed that allow for a large number of alleles at a locus (Lande 1975, 1977a, 1980a, 1984a; Fleming 1979). Kimura's original analysis followed the distribution, $p_i(x)$, of allelic effects (x) at a given locus, i , assuming the incremental model of mutation (Table 28.1). As detailed in Example 28.4, by assuming small mutational effects, Kimura was able to use a Taylor-series approximation (Equation 28.22a) to show that the distribution of effects at an individual locus are normally distributed, with mean zero and variance $\sqrt{\mu_i \sigma_{\alpha_i}^2 V_s}$. Kimura's result is for a haploid model, where $\sigma^2(a_i) = \sqrt{\mu_i \sigma_{\alpha_i}^2 V_s}$ denotes the variance in allelic effects from locus i in a haploid gamete. Because of their similar notation, we remind the reader that $\sigma^2(a_i)$ denotes the equilibrium variance in allelic effects, while $\sigma_{\alpha_i}^2$ denotes the variance in mutational effects. Assuming additivity, the additive variance from locus i becomes $\tilde{\sigma}_{A(i)}^2 = 2\sigma^2(a_i)$. Assuming no LD, Example 28.4 shows that summing over loci gives Kimura's expression for the additive variance with n equivalent underlying diploid loci as

$$\tilde{\sigma}_A^2 = \sqrt{2nV_s \sigma_m^2} \quad (28.14a)$$

When effects vary over loci, the above expression holds, with the effective number of loci

$$n_e = 2 \left(\sum_{i=1}^n \sqrt{\mu_i \sigma_{\alpha_i}^2} \right)^2 / \sigma_m^2 \quad (28.14b)$$

replacing n .

Lande (1975) extended Kimura's model to a full multilocus analysis to allow for linkage disequilibrium (Example 28.7). He did so by assuming that the vector of allelic effects for the n loci in a gamete is multivariate normal, and he obtained a slightly different expression for n equivalent underlying loci,

$$\tilde{\sigma}_A^2 = \sqrt{2n\sigma_m^2(V_s + n\sigma_m^2/2)} + n\sigma_m^2 \quad (28.14c)$$

which essentially reduces to Kimura's result (Equation 28.14a) when $n\sigma_m^2 \ll 1$. As with Equation 28.14a, when loci differ, n_e (Equation 28.14b) replaces n . Unlike Latter (1960),

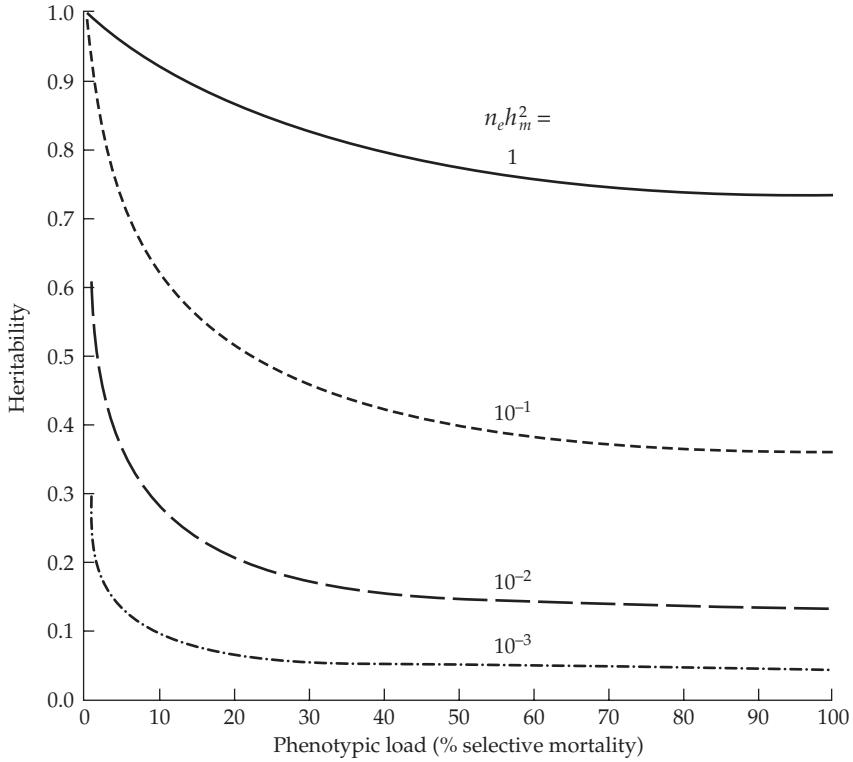

Figure 28.3 The equilibrium heritabilities expected under the Lande model (Equation 28.14c).

Percent selective mortality is $100 \cdot (1 - \bar{W})$, where $\bar{W} = \sqrt{\omega^2 / (\omega^2 + \sigma_E^2 + \tilde{\sigma}_A^2)}$, assuming $\bar{z} = \theta$ (Equation 28.3e). Taking a typical value of $h_m^2 = 10^{-3}$, the plotted curves correspond (from top to bottom) to effective number of loci (n_e) values of 1000, 100, 10, and 1. Note that modest selection (low selective mortality) with a reasonable number of loci (n_e from 10 to 100, implying that $n_e h_m^2$ is 0.01 to 0.1) can account for the observed heritabilities in natural populations ($0.2 \leq h^2 \leq 0.7$). (After Lande 1975.)

Lande concluded that mutation-selection balance *could* indeed account for high levels of additive variation (Figure 28.3). Nagylaki (1984) and Turelli (1984) noted that with weak selection, Equation 28.14c slightly overestimates the genetic variance and is slightly less accurate than Equation 28.14a.

One can also recover Equation 28.14a using results from Chapter 24 on the Gaussian continuum-of-alleles model (which, as in Lande 1975, assumes the distribution of allelic effects at a locus to be normal). Equation 24.2a gave the dynamics for the change in genic variance, $\Delta \sigma_a^2(t)$, under the Gaussian COA model, which had an equilibrium value of $\tilde{\sigma}_a^2 = 0$. However, adding a term, σ_m^2 , for new mutation to Equation 24.2a, ignoring the effects of linkage disequilibrium (i.e., assuming $d = 0$, and hence the genic variance, σ_a^2 , equals the additive-genetic variance σ_A^2), and setting $N_e = \infty$, yields

$$\Delta \tilde{\sigma}_a^2 = 0 = -\frac{\kappa \tilde{h}^2 \tilde{\sigma}_A^2}{2n} + \sigma_m^2, \quad \text{implying} \quad 2n\sigma_m^2 = \kappa \tilde{h}^2 \tilde{\sigma}_A^2 \quad (28.14d)$$

Recall that κ is a measure of the strength of stabilizing selection, namely, the fraction by which the phenotypic variance is reduced following selection (Equation 16.10a). Because $\tilde{h}^2 = \tilde{\sigma}_A^2 / \tilde{\sigma}_z^2$, Equation 28.14d can be expressed as

$$\tilde{\sigma}_A^4 = 2n\sigma_m^2(\tilde{\sigma}_z^2 / \kappa), \quad \text{yielding} \quad \tilde{\sigma}_A^2 = \sqrt{2n\sigma_m^2(\tilde{\sigma}_z^2 / \kappa)} \quad (28.14e)$$

Because $\kappa \simeq \tilde{\sigma}_z^2 / V_s$ (Equation 16.18a), then $\tilde{\sigma}_z^2 / \kappa = V_s$, which recovers Equation 28.14a.

Fleming (1979) presented an improved (but still approximate) analysis of Kimura's model. He did so by scaling both the strengths of selection and mutation by a small parameter, ϵ , and then expressing the strength of selection as $(2V_s)^{-1} = \gamma\epsilon$ and the mutational-effects variance as $\sigma_\alpha^2 = \delta\epsilon$. This scaling (which Turelli notes implies a per-locus mutation rate $\mu \gg \sigma_\alpha^2/V_s$) assumes both selection and mutation are weak. By letting $\epsilon \rightarrow 0$, Fleming was able to express the equilibrium distribution of allelic effects in terms of zero and first-order expressions of ϵ , namely, $\phi(x) = \phi_0(x) + \epsilon\phi_1(x) + O(\epsilon^2)$. His zero-order term (i.e., the function $\phi_0[x]$) is a normal with a variance given by Equation 28.14a, and it is independent of the linkage map. The first-order expression (ϕ_1) has significant kurtosis, which shows that the distribution of segregating allelic effects departs from a Gaussian. When the mutational increment, α , is drawn from a normal distribution, Fleming's approximation yields

$$\tilde{\sigma}_A^2 \simeq \sqrt{2nV_s\sigma_m^2} \left[1 + \left(1 - \frac{3}{16n\mu} \right) \sqrt{\frac{n\sigma_m^2}{2V_s}} \right] \quad (28.15)$$

Fleming (1979) and Bürger (1998a) present more general expressions, which allow for non-Gaussian kurtosis in the distribution of mutational effects. Simulation studies by Turelli (1984) found that Equation 28.15 is accurate over a much wider range of parameter values ($1 < \sigma_{\alpha_i}^2/(V_s\mu_i) < 10$) than might be expected given the nature of the approximation. Applied mathematics aficionados are referred to Fleming's paper, and less technical discussions were provided by Nagylaki (1984) and Turelli (1984). By using methods from applied physics, Bürger (1986, 1988a, 1988c) obtained a number of conclusions regarding the solution to the general Kimura model, but as we now detail, most results are based on one of two different approximations of the equilibrium solution.

Gaussian Versus House-of-Cards Approximations for Continuum-of-alleles Models

Equations 28.12a and 28.14a offer very different predictions for the expected genetic variance under mutation-selection balance. Under Kimura's result (and Lande's extension), the effect of the number of loci and strength of phenotypic selection on the trait scale as \sqrt{n} and $\sqrt{V_s}$, respectively, while under Latter's model, these scale as n and V_s . The Latter-Bulmer model (Equation 28.12a) simply requires the total mutation rate, $n\bar{\mu}$ (independent of the variance, σ_α^2 , of mutational effects), while the Kimura-Lande-Fleming results (Equations 28.14a, 28.14c, and 28.15) are more pleasingly stated in terms of the mutational variance, σ_m^2 , which is a more easily measured parameter than its components (μ , n , and σ_α^2). Further, the Latter-Bulmer model does not appear to maintain sufficient variation to account for observed h^2 values, while the Kimura-Lande-Fleming model does. Why is there this vast disparity, and which approach, if either, is correct?

Turelli (1984) showed that these rather different outcomes arise from different approximations of the complex integro-differential equation for the distribution of allelic effects for the general Kimura model (Equation 28.21c in Example 28.4). Kimura and Fleming obtained their approximate solutions by assuming that the variance of mutational effects at a locus (the allelic effects *given* that a mutation has occurred) to be much less than the current variance of allelic effects at that locus, $\sigma_{\alpha_i}^2 \ll \sigma_{A(i)}^2$, a point first stressed by Lande (1975). From Equation 28.14a, this condition implies that

$$\sigma_{\alpha_i}^2 \ll \sqrt{\mu_i \sigma_{\alpha_i}^2 V_s} \quad (28.16a)$$

which can be rearranged as

$$\mu_i \gg \frac{\sigma_{\alpha_i}^2}{V_s} \quad (28.16b)$$

If we recall Equation 28.4c, this condition is equivalent to $\mu_i \gg E[s_i]$, which shows that mutation is much stronger than selection at a given locus. Turelli (1984) referred to this as the **Gaussian approximation**, as the resulting equilibrium solution approaches a normal

distribution of allelic effects at a locus (Example 28.5). Note that Lande (1975) *assumed* a Gaussian distribution of allelic effects in his multiple-locus treatment that accounted for linkage, whereas Kimura and Fleming *obtained* it following their assumption that $\sigma_{\alpha_i}^2 \ll V_s \mu_i$. Kimura obtained exact normality with his solution, while normality was the zero-order term in Fleming's more careful analysis.

Turelli (1984) argued that the inequality given by Equation 28.16b is typically reversed, namely, $\mu_i \ll \sigma_{\alpha_i}^2/V_s$ (implying $\sigma_{\alpha_i}^2 \gg \sigma_{A(i)}^2$), so that the Gaussian approximation is often inappropriate. His logic follows from the standard value of $\sigma_m^2 = \sigma_E^2/10^3$, which implies $\sigma_m^2 \simeq \sigma_A^2/10^3$ for a typical heritability ($0.3 \leq h^2 \leq 0.7$). Because both σ_m^2 and σ_A^2 are the sums of single-locus effects, with equivalent loci we can replace $\sigma_m^2 \simeq \sigma_A^2/10^3$ by the single-locus contributions to each component to give $\mu_i \sigma_{\alpha_i}^2 \simeq \sigma_{A(i)}^2/10^3$. Hence, the Gaussian approximation that $\sigma_{\alpha_i}^2 \ll \sigma_{A(i)}^2$ (the variance of new mutations is much smaller than the standing variance) requires that $\mu_i \cdot 10^3 \gg 1$ or that $\mu_i \gg 10^{-3}$. This value is orders of magnitudes above traditional estimates of per-locus mutation rates.

Based on these concerns, Turelli considered Kimura's model when the inequality in Equation 28.16b is reversed

$$\mu_i \ll \frac{\sigma_{\alpha_i}^2}{V_s} \quad (28.17)$$

where now mutation is weak relative to selection ($\mu_i \ll E[s_i]$). Turelli's **house-of-cards approximation (HCA)** uses this assumption to obtain an equilibrium solution of the general Kimura equation (Example 28.5). The basis for Turelli's approximation follows from the HOC (house-of-cards) mutation model (Table 28.1), which assumes, at each locus, that the new mutational variance is likely to swamp any existing variance. (As a notational aside, we use HOC to refer to the mutational *model*, and HCA to refer to Turelli's *approximation* motivated by this model, to stress that these are *different*.) Under HOC mutation, the new allelic value, x' , following mutation is independent of its current value, x (i.e., $x' = \alpha$; as opposed to the situation with the incremental model, where $x' = x + \alpha$). As shown in Example 28.5, the HCA gives

$$\tilde{\sigma}_A^2 \simeq 4V_s n \mu \quad (28.18a)$$

which is simply the Latter-Bulmer result (Equation 28.12a). The connection between the HCA and the Latter-Bulmer model follows because the latter requires $a_i^2 > 8\mu_i V_s$ (Equation 28.11e) in order to obtain Equation 28.12a, while the HCA requires that $\sigma_{\alpha_i}^2 \gg \mu_i V_s$. The a_i^2 (mutational effects in a two-allele model) essentially equate to the mutational-effects variance $\sigma_{\alpha_i}^2$ under a continuum-of-alleles model. Under HCA conditions, selection is strong and the dominant (close to fixation) allele at a locus is expected to have a value close to the optimum. New mutations are thus deleterious, and tend to disappear quickly, resulting in most of the genetic variation being due to rare alleles with relatively large effects.

As with many of the results in this section, Equation 28.18a is simply the sum of single-locus results. Turelli and Barton (1990) examined the impact of linkage, finding that with n identical loci

$$\tilde{\sigma}_A^2 \simeq 4V_s n \mu \left[1 + \frac{2(n-1)\mu}{c_H} \right] \quad (28.18b)$$

where c_H is the harmonic mean of all pairwise recombination frequencies between all combinations of the underlying loci, or roughly 1/2 for loose linkage. As with the Gaussian approximation, the impact from linkage is small unless it is very tight.

As was discussed in Chapter 24, the kurtosis (given by $E[x^4]$ when $\mu_x = 0$; LW Chapter 2) provides one measure of departure from normality. The kurtosis for a normal equals $3\sigma_x^4$, suggesting two scaled measures of departure from normality. In Chapter 24, we used $\kappa_4 = (E[x^4] - 3\sigma_x^4)/\sigma_x^4$, which has a value of zero for a normal. Alternatively, we here use $k_4 = E[x^4]/(3\sigma_x^4)$, which equals one for a normal. Under the HCA, the resulting kurtosis for the distribution of allelic effects at locus i , where $E[\alpha_i] = 0$, is

$$k_{4,i} = \frac{E[\alpha_i^4]}{3E[\alpha_i^2]^2} \simeq \frac{2V_s \mu_i \sigma_{\alpha_i}^2}{3(2V_s \mu_i)^2} = \frac{\sigma_{\alpha_i}^2}{6V_s \mu_i} \quad (28.18c)$$

which is $\gg 1$ (highly leptokurtic, i.e., a heavier tail, and hence more outliers, than a Gaussian distribution) under the HCA (which follows from Equation 28.17, as $\sigma_{\alpha_i}^2 \gg \mu_i V_s$). The resulting distribution of allelic effects thus departs significantly from a normal, with its leptokurtosis indicating the presence of rare alleles of large effect. Further, note that the (unscaled) kurtosis in the distribution of genotypic values (twice the haploid value) can be expressed as

$$2E[\alpha_i^4] = 4V_s \mu_i \sigma_{\alpha_i}^2 = \tilde{\sigma}_{A(i)}^2 \sigma_{\alpha_i}^2 \quad (28.18d)$$

with the last step following from Equation 28.11c. Recall from Example 24.11 that this expression for kurtosis has the same form as seen in the rare-alleles model (a constant times the second moment; Equation 24.32a), which is reasonable, as under HCA, most alleles are rare.

Kurtosis also influences the accuracy of Equation 28.18a, which is an upper bound. When the distribution of mutational effects is normal, the accuracy is quite good. As the distribution of mutational effects becomes increasing leptokurtic, the true variance (even under HCA conditions) can be significantly less than suggested by Equation 28.18a (Bürger and Hofbauer 1994; Bürger and Lande 1994).

Thus, we have Kimura-Lande-Fleming when $\mu_i \gg \sigma_{\alpha_i}^2/V_s$ (which fulfills the Gaussian assumption of that mutation is stronger than selection) and Latter-Bulmer when $\mu_i \ll \sigma_{\alpha_i}^2/V_s$ (the HCA assumption that selection is stronger than mutation). Extensive simulations by Turelli (1984) refined these domains. The Gaussian approximation overestimates the additive variance by less than 10% when $\mu_i \geq 5\sigma_{\alpha_i}^2/V_s$, while the HCA model gives a good fit when $\mu_i \leq 0.05\sigma_{\alpha_i}^2/V_s$. Bürger (1988a, 1988b) was able to obtain an upper bound for the equilibrium additive variance under a fairly general Kimura model (assuming symmetric mutations and quadratic fitnesses near the optimum). He found that the first-order bound is simply the HCA value, $\tilde{\sigma}_A^2 \leq 4\mu_i V_s$ (we remind the reader that $\sigma_{\alpha_i}^2$ is the variance of mutational effects, while $\tilde{\sigma}_A^2$ refers to the additive variance). When Kimura's single-locus expression, $\sqrt{2V_s \sigma_m^2}$, exceeds this value, the Gaussian approximation has clearly failed, giving the restriction

$$\sqrt{2V_s \sigma_m^2} = \sqrt{2V_s (2\mu_i \sigma_{\alpha_i}^2)} = \sqrt{(4\mu_i V_s) \sigma_{\alpha_i}^2} \leq 4\mu_i V_s, \quad \text{or} \quad \sigma_{\alpha_i}^2 \leq 4\mu_i V_s \quad (28.18e)$$

with the Gaussian approximation always failing when $\sigma_{\alpha_i}^2 > 4\mu_i V_s$.

While the reader may perceive this difference between the Gaussian and HCA approximations as being a function of the assumed mutation *model*, it is rather a function of the *relative strengths* of selection to mutation at a locus. When mutation is strong, one expects a number of alleles at a locus, while when mutation is weak relative to selection, one expects very few segregating alleles (the rare-alleles model from Example 24.11). While both the Gaussian and HCA approximations follow from a continuum-of-alleles model, the transition from Gaussian to HCA behavior can be seen in models with a modest to small number of assumed alleles per locus. Equation 28.13c shows how the HCA variance follows from a triallelic model when Equation 28.17 holds.

An extension of Turelli's triallelic model provides further insight. Slatkin (1987a) assumed an unlimited number of alleles with a stepwise mutation model, with an allele mutating to a new effect with increment of α or $-\alpha$ (relative to its current value), with a mutation rate of $\mu/2$ for each step (a scheme also used by Narain and Chakraborty 1987), namely,

$$\dots -2\alpha \xrightarrow{\mu/2} -\alpha \xrightarrow{\mu/2} 0 \xleftarrow{\mu/2} \alpha \xleftarrow{\mu/2} 2\alpha \dots$$

As shown in Example 28.6, if selection is weak relative to mutation (such that many allelic states are present), this model reduces to Kimura's Gaussian result, while if selection is strong relative to mutation (meaning that a single major allele, whose value equals the

phenotypic optimum, and two very minor alleles, each one step away, are present), this reduces to the HCA result (Turelli's triallelic model). Analyses of models assuming five alleles per locus further make this point (Turelli 1984; Slatkin 1987a). Example 28.8 presents Waxman's (2004) exact solution for the continuum-of-alleles model under a specific distribution of mutational effects, which recovers the HCA results for low mutation rates and the Gaussian for high rates, and shows the structure of the transition between these two domains.

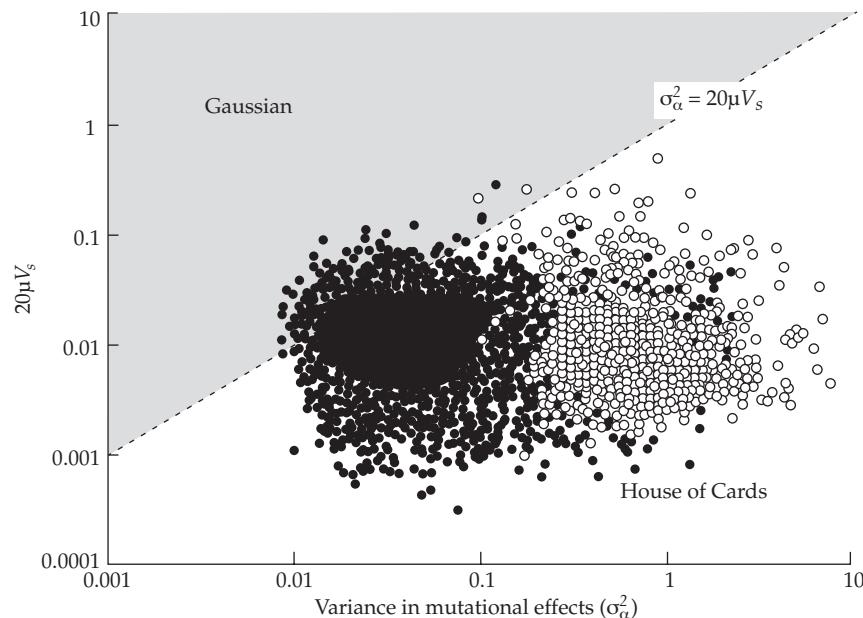

Example 28.3. An interesting biological application of the house-of-cards versus Gaussian models is the work of Hodgins-Davis et al. (2015). These authors examined variation in gene expression in roughly 3500 yeast (*S. cerevisiae*) genes, 930 *C. elegans* genes, and 563 genes from *D. melanogaster*.

As discussed in Chapter 11, gene expression is thought to be under weak stabilizing selection. Hodgins-Davis et al. obtained estimates of σ_m^2 for expression data ($\simeq [10^{-5}$ to $10^{-4}] \sigma_E^2$, which tend to be much smaller than estimates for other traits), along with estimates of the number of genes (using both eQTL studies and extrapolation from single-gene knockout experiments). Coupling these values with estimates of μ , they estimated the variance of mutational effects, $\sigma_\alpha^2 = \sigma_m^2/(2n\mu)$. Next, given an estimate of σ_A^2 , they estimated the potential strength of stabilizing selection from the standing variation in expression at each gene as either

$$V_s^G = \frac{\sigma_A^4}{2n\sigma_m^2} \quad \text{or} \quad V_s^{HC} = \frac{\sigma_A^2}{4n\mu}$$

which are obtained by rearranging either the Gaussian (Equation 28.14a) or HCA (Equation 28.18a) expressions.

With estimates of σ_α^2 and V_s (the latter is based on the Bayesian model-averaged values of V_s^G and V_s^{HC}) for each expression trait in hand, Hodgins-Davis et al. examined what fraction of traits fell within the HCA versus Gaussian domains. Recalling that $\sigma_\alpha^2 > 20\mu V_s$ is Turelli's bound for the HCA to hold, the authors plotted $20\mu V_s$ versus σ_α^2 for each expression trait. As shown in the following figure (after Hodgins-Davis et al. 2015), their finding was that the house-of-cards domain is satisfied by nearly all of the genes examined, with only a very few exhibiting any likelihood of being in the Gaussian domain.

For example, the above figure plots values for expression levels for *D. melanogaster* (filled circles) and *C. elegans* (open circles). Expression levels for most of the 563 measured

melanogaster genes appear to evolve under the HCA framework (falling below the line $\sigma_\alpha^2 = 20\mu V_s$), as do expression levels at essentially all of the 930 measured *C. elegans* genes.

Epistasis

Epistasis in models of stabilizing selection can act on several levels. **Fitness epistasis** naturally arises even for a completely additive trait under stabilizing selection, because the mapping from trait value to fitness is nonlinear (Examples 5.10 and 6.6). Likewise, the values for trait under stabilizing selection could themselves show epistasis (**trait epistasis**). Hermisson et al. (2003) showed that trait epistasis reduces the amount of trait additive variation at equilibrium relative to purely additive models. While Gavrilets and de Jong (1993) found that certain models of fitness epistasis can both maintain a high amount of trait additive variation *and* show strong apparent stabilizing selection for that trait, this outcome results from assuming a neutral trait influenced by pleiotropic loci under balancing selection, a rather different setting from an epistatic trait itself being under stabilizing selection (see Lawson et al. 2011 for a potential example).

Tachida and Cockerham (1988) examined the expected amount of additive versus additive-by-additive variance in *fitness* for a trait under stabilizing selection. They found that additive-by-additive variance in fitness is larger than additive variance under conditions for the Gaussian approximation, but that the converse is true (additive variance is larger than nonadditive variance) under HCA conditions. In part, this likely arises because the rare-allele conditions under HCA implies that most of any genetic variation loads onto the additive component; see Example 24.11). Important caveats for this HCA result are that the number of loci per trait not be too large and that the number of traits that are influenced per locus (their amount of pleiotropy) be small. A review of the *Drosophila* fitness-components literature suggested more additive than additive-by-additive variance in fitness components, which led Tachida and Cockerham to suggest that the HCA domain might be more applicable in these cases. However, they also noted that this distinction between the two classes of approximation breaks down when the trait means depart from their optimal values.

Effects of Linkage and Mating Systems

The more diligent reader may recall situations in two-locus models wherein the effects of linkage disequilibrium were quite considerable (Chapter 5). This occurs in cases where selection is much stronger than recombination. In contrast, the analysis of polygenic models typically assumes that recombination is much stronger than selection at a given locus, resulting in linkage effects being much smaller, often to the point (depending on the problem) that they can be ignored as a good first approximation.

Most of the above analysis, under either the HCA or Gaussian approximations, extrapolates the additive variance by summing single-locus variances. Recalling Equation 16.2, the additive variance, σ_A^2 , is the sum of the genic variance, σ_a^2 (the additive variance in the absence of linkage disequilibrium), plus the disequilibrium contribution, d , with $\sigma_A^2 = \sigma_a^2 + d$. σ_A^2 is often called the **expressed variation**, and $\sigma_a^2 - \sigma_A^2 = -d$ the **hidden variation** (the amount recovered upon decay of LD). Simply summing single-locus results (as we have done multiple times above) recovers the genic variance, σ_a^2 , not the additive variance, σ_A^2 , and we expect the genic variance to overestimate the additive variance (as $d < 0$ under stabilizing selection; Chapter 16). While the actual value of d can be considerable, simulations (Turelli 1984; Hastings 1989) and analytic results (Lande 1975; Fleming 1979; Nagylaki 1984; Bürger 1989) show that the relative error by ignoring d is generally small, negative, and increases (slowly) with n . Fleming found that the zero-order approximation of the distribution of allelic effects was independent of the recombination map, which entered as first-order terms. Assuming n equivalent loci ($\mu_i = \mu$, $\sigma_{\alpha_i}^2 = \sigma_\alpha^2$), Turelli (1984) used the Lande and Fleming results to find that the relative error in using the linkage equilibrium

(LE) value in place of the true additive variance under the Gaussian approximation was

$$\frac{\tilde{\sigma}_A^2(LE) - \tilde{\sigma}_A^2}{\tilde{\sigma}_A^2} \simeq \left(1 - \frac{1}{n}\right) \sqrt{\frac{n\sigma_m^2}{2V_s}} \quad (28.19)$$

A simulation study by Hastings (1989), essentially using the HCA approximation, found that the impact of LD is again small and scales with $n\mu$, the total (haploid) mutation rate. If $n\mu < 0.025$, the contribution from LD was small, less than 10% of the total variance. However, for $n\mu > 0.05$, the contribution can be considerable. Turelli and Barton (1990) also found that the impact of linkage under HCA scales with $n\mu$, see Equation 28.18b.

In an exact analysis of a two-locus model, Bürger (1989) found that the impact of linkage depends on the relative strengths of mutation and selection, namely, the HCA versus Gaussian assumptions. Under the Gaussian assumption, the genic variance, σ_a^2 , remains constant, while the additive variation decreases as linkage becomes tighter (d becomes more negative). Under the HCA assumption, the genetic variance remains constant under linkage (as long as it is not too tight), while the genic variance increases with decreasing recombination (as seen in Equation 28.18b). If recombination is below a critical value, then the behavior is as for the Gaussian approximation.

A second issue of potential concern is the mating system. Thus far, we have been assuming random mating. However, previous chapters showed that inbreeding (Chapter 11) and assortative mating (Chapter 16) can both impact the additive-genetic variance. Given these observations, Lande (1977a) obtained the counterintuitive result that these departures from random mating have essentially no impact on the equilibrium additive variance for a Gaussian model with only additive effects. Inbreeding and assortative mating change the rate of approach to the equilibrium, but not its final value. Conversely, Turelli (1986) and Frank and Slatkin (1990b) found that inbreeding *does* change the equilibrium additive variance under HCA assumptions. Turelli suggested that the robustness of the Gaussian model to the mating system may be an artifact of the high mutation rate per locus required for this model to be accurate.

Spatial and Temporal Variation in the Optimum

As shown previously in this chapter, spatial and temporal variation in the optimum can maintain some variance under stabilizing selection in the absence of mutation, but the conditions necessary for a large effect are fairly restrictive. Does incorporating a variable optimum, θ , increase the additive variance when mutation is present? It does, and the increase can be substantial.

A number of authors have examined the impact of temporal variation in θ (Kirzhner et al. 1996a, 1996b; Kondrashov and Yampolsky 1996a, 1996b; Korol et al. 1996; Bürger 1999; Zhang 2012), with the most detailed treatment by Bürger and Gimelfarb (2002). When there is a periodic change in θ with a sufficiently long cycle time (>10 generations) and a sufficient amplitude ($>\sqrt{V_s}$), the amount of additive-genetic variation significantly will exceed the constant- θ value, often by at least an order of magnitude. When there are persistent directional shifts in the optimum, alleles that were initially rare and deleterious can become favorable and will be under directional selection to track the new optimum (Chapter 27). If the directional change persists for a sufficiently long period of time and the change in the trait mean while tracking θ is sufficiently large, significant allele-frequency change will occur, increasing the additive variance. The change in the optimum, however, must be ongoing, in that if θ stops at a new value, we return to a constant- θ model. The open question is not whether the optimum changes, as most ecologists would suspect that it does, but rather whether these changes are periodic and persistent enough to dramatically impact the additive variance. Changes in θ that are entirely random (i.e., with no short-term directional trend or positive autocorrelation) have little impact on the additive variance.

Table 28.2 Comparison of the Gaussian and house-of-cards (HCA) approximations for a trait under stabilizing selection. Here, V_s is the strength of selection on a genotypic value (Equation 28.3f), $\sigma_{A(i)}^2$ is the additive variation at locus i , n is the number of loci, $\sigma_{\alpha_i}^2$ and μ_i (respectively) are the variance of the effects of new mutations and the mutation rate at locus i , and $\sigma_m^2 = \sum 2\mu_i\sigma_{\alpha_i}^2$ denotes the mutational variance. When mutational effects are constant over loci, we use σ_α^2 and μ rather than retain the subscript i , with $\sigma_m^2 = 2n\mu\sigma_\alpha^2$. See text for further details.

	Gaussian	HCA
Mutational input vs. standing variation	$\sigma_{\alpha_i}^2 \ll \sigma_{A(i)}^2$ Smaller	$\sigma_{\alpha_i}^2 \gg \sigma_{A(i)}^2$ Larger
Strength of mutation relative to selection	$\mu_i \gg \sigma_{\alpha_i}^2/V_s$ Stronger	$\mu_i \ll \sigma_{\alpha_i}^2/V_s$ Weaker
Domain of applicability (single trait, $N_e = \infty$)	$\sigma_{\alpha_i}^2 \leq \mu_i V_s/5$	$\sigma_{\alpha_i}^2 \geq 20\mu_i V_s$
Impact of drift on domain of applicability	Decreases domain	Little to no effect
Impact of pleiotropy on domain of applicability	Decreases domain	Increases domain
Equilibrium additive variance, $\tilde{\sigma}_A^2$	$\sqrt{2nV_s\sigma_m^2}$	$4V_s n \mu$
Finite population $\tilde{\sigma}_A^2$	$\sqrt{\left(\frac{nV_s}{2N_e}\right)^2 + 2n\sigma_m^2 V_s - \frac{nV_s}{2N_e}}$	$\frac{4n\mu V_s}{1 + V_s/(N_e\sigma_\alpha^2)}$
Sensitivity to linkage map	Little unless $c_{ij} \simeq 0$	Little unless $c_{ij} \simeq 0$
Impact of mating system on $\tilde{\sigma}_A^2$	Insensitive	Sensitive
Number of alleles/locus	Many	One major, few rare
Distribution of allelic effects	Normal. Many alleles at intermediate frequencies.	Leptokurtic. Rare alleles of large effect.
Impact of multiple-trait selection	None for uncorrelated traits.	Sensitive to uncorrelated traits.

The impact of spatial variation in the optimum under stabilizing selection has been examined by Felsenstein (1977), Slaktin (1978), and Barton (1999). We previously discussed Felsenstein's model, which assumed a linear gradient in the optimum, such that at location x on some linear cline (such as a river bank), $\theta(x) = \beta x$, with individuals randomly dispersing over some distance $d \sim N(0, \sigma_d^2)$. Felsenstein showed that this model can maintain at least some variation in the face of stabilizing selection without mutation, as migration effectively fills the role of generating variation. Slaktin (1978) and Barton (1999) extend Felsenstein's model to allow for mutation. Felsenstein and Slaktin both assumed a Gaussian distribution of mutational effects at a locus, which Barton showed was a good approximation even under HCA conditions. Slaktin found that the equilibrium additive variance becomes

$$\tilde{\sigma}_A^2 = 2Z\sqrt{V_s + Z^2} + 2Z^2 \quad (28.20a)$$

where

$$Z^2 = \sum_{i=1}^n \sqrt{\mu_i \sigma_{\alpha_i}^2 + \beta^2 \sigma_d^2} \quad (28.20b)$$

This is simply Lande's (1975) result (Equation 28.28f), with $\beta^2 \sigma_d^2$ (a measure of how quickly selection changes relative to migration) augmenting the mutational variance. If this change

is sufficiently large, namely, $\beta^2 \sigma_d^2 > \mu_i \sigma_{\alpha_i}^2 = \sigma_m^2 / (2n_e)$, then spatial differences in fitness (given by the variation in θ) dominate mutation, and $Z^2 \simeq n\beta\sigma_d$.

Summary: Implications of Gaussian Versus HCA Approximations

Table 28.2 summarizes the major features of the Gaussian and House-of-cards approximations and their differences in behavior (some of which are developed in later sections). While the reader might infer that the conditions for the Gaussian approximation to hold are unusual, Charlesworth (1993) and Bürger (2000) made the important point that this approximation might be highly relevant in asexual species or species with a large fraction of the genome in regions of low recombination or for species that undergo cyclical parthenogenesis (Lynch and Gabriel 1983). In these cases, the mutational size of what corresponds to a locus is much larger (equivalent to the entire genome), resulting in a higher mutation rate. We conclude this section with the derivations of many of the results given above, which can be skipped by the casual reader. A number of these results were also obtained by Zhang and Hill (2010), using the framework of the Price equation (Chapter 6), which offers the reader an independent set of derivations.

Example 28.4. Before proceeding with the derivation of Kimura's (1965a) result, recall the important distinction between an allele effect, a , and a mutational effect, α . Under the incremental model, the allelic effect following a new mutation is $a' = a + \alpha$. Our interest is in the variance of allelic effects, $\sigma^2(a)$, as this is half of the additive variance contributed by a locus (for a diploid and assuming additivity). As we will see, in many models, $\sigma^2(a)$ is a function of the variance in the *mutational effects*, σ_α^2 . In what follows, because a and α are very similar in appearance, we use x for the allelic effect in much of the deviation, before returning to express $\sigma^2(x)$ as $\sigma^2(a)$ in the discussion. Finally, while our focus is for a particular locus, we suppress the subscript throughout much of the derivation to keep the notation simpler.

Kimura (1965a) considered a haploid continuum-of-alleles model, following the distribution, $p(x)$, of allelic effects at a locus with no linkage disequilibrium. He assumed a continuous-time model in Hardy-Weinberg equilibrium and under quadratic stabilizing selection (Equation 28.3a). Our treatment follows Bulmer (1989), who obtained the same result under Gaussian stabilizing selection (with the population mean set at θ). In this setting, Bulmer showed that the expected infinitesimal change in the distribution of allelic effects from selection is

$$\frac{\partial p(x)}{\partial t}(\text{sel}) = \frac{-p(x)[x^2 - \sigma^2(x)]}{2V_s} \quad (28.21a)$$

where $\sigma^2(x) = \sigma^2(a)$ is the variance in allelic effects at the focal locus.

Under the incremental mutational model, $\mu f(\alpha)$ is the probability that an allele mutates from value x to value $x + \alpha$, where $E(\alpha) = 0$ and $E(\alpha^2) = \sigma_\alpha^2$. The resulting rate of change from mutation becomes

$$\frac{\partial p(x)}{\partial t}(\text{mut}) = -\mu p(x) + \mu \int p(x - \alpha) f(\alpha) d\alpha \quad (28.21b)$$

The first term is the loss of alleles with an effect size of x due to mutation, and the second is the gain of such alleles from new mutation. The latter is expressed as the cumulative probability that alleles with some other effect mutate to an effect size of x .

Formally, if the life cycle is selection followed by mutation, then $p(x)$ in the Equation 28.21b is replaced by $p'(x)$, the postselection value. However, for weak selection and mutation, we can simply sum Equations 28.21a and 28.21b to yield the integro-differential equation for the distribution of allelic effects at time t . The equilibrium distribution is reached when

$$\frac{\partial p(x)}{\partial t} = \frac{\partial p(x)}{\partial t}(\text{sel}) + \frac{\partial p(x)}{\partial t}(\text{mut}) = 0$$

or

$$\frac{-p(x)[x^2 - \sigma^2(x)]}{2V_s} - \mu p(x) + \mu \int p(x - \alpha) f(\alpha) d\alpha = 0 \quad (28.21c)$$

which Bulmer (1989) called the **fundamental equation of the continuum-of-alleles model**. Most early workers assumed that such an equilibrium distribution exists and that it is unique, but this was not formally shown until the publications of Bürger (1986, 1988a, 1988b, 1988c, 1991b; Bürger and Bomze 1996). Notice that the solution to Equation 28.21c depends strongly on the choice of $f(\alpha)$, the assumed probability density function for new mutational effects.

The assumption of a Gaussian distribution of allelic effects breaks down in Equation 28.21b. Even assuming that a Gaussian allelic-effects distribution exists following selection *and* also that there is a Gaussian distribution of mutational effects, Equation 28.21b is a *weighted* sum of two Gaussians, with different variances, and hence is clearly *not* Gaussian. However, under certain conditions it can be close to normally distributed.

Different approximations have been used to proceed from Equation 28.21c to an explicit solution. Kimura assumed that mutational effects, α , are sufficiently small to approximate $p(x - \alpha)$ by a second-order Taylor series

$$p(x - \alpha) \simeq p(x) - \alpha \frac{\partial p(x)}{\partial x} + \frac{\alpha^2}{2} \frac{\partial^2 p(x)}{\partial^2 x} \quad (28.22a)$$

This approximation requires that $\sigma_\alpha^2 \ll \sigma^2(x) = \sigma^2(a)$, namely, that the effect of a new mutation is much smaller than the current variance in allelic effects. Substituting this approximation into the integral in Equation 28.21c yields

$$\begin{aligned} & \mu \int \left(p(x) - \alpha \frac{\partial p(x)}{\partial x} + \frac{\alpha^2}{2} \frac{\partial^2 p(x)}{\partial^2 x} \right) f(\alpha) d\alpha \\ &= \mu \left(p(x) \int f(\alpha) d\alpha - \frac{\partial p(x)}{\partial x} \int \alpha f(\alpha) d\alpha + \frac{1}{2} \frac{\partial^2 p(x)}{\partial^2 x} \int \alpha^2 f(\alpha) d\alpha \right) \\ &= \mu \left(p(x) + 0 + \frac{1}{2} \frac{\partial^2 p(x)}{\partial^2 x} \sigma_\alpha^2 \right) \end{aligned} \quad (28.22b)$$

where we have used $\int \alpha f(\alpha) d\alpha = E[\alpha] = 0$. Using the approximation given by Equation 28.22a, the equilibrium solution of $p(x)$ satisfies the differential equation

$$\frac{-p(x)[x^2 - \sigma^2(x)]}{2V_s} + \frac{\mu\sigma_\alpha^2}{2} \frac{\partial^2 p(x)}{\partial^2 x} = 0 \quad (28.22c)$$

Kimura (1965a) showed that this equation is satisfied when $p(x)$ follows a normal distribution, with the parameters

$$p(x) \sim N \left(0, \sqrt{\mu\sigma_\alpha^2 V_s} \right) \quad (28.22d)$$

In particular, the variance in allelic effects at locus i is given by

$$\sigma^2(a_i) = \sqrt{\mu_i \sigma_{\alpha_i}^2 V_s} \quad (28.22e)$$

with the additive-genetic variance contributed by locus i being $\sigma^2(A_i) = 2\sigma^2(a_i)$.

This result of allelic effects at individual loci being normally distributed motivated the continuum-of-alleles models introduced in Chapter 24. Equation 28.22a is referred to as the **Gaussian approximation** because this weak selection assumption leads to a Gaussian distribution of effects at equilibrium (Equation 28.22d).

Ignoring LD, the additive variance is just twice (for the two alleles in a diploid) the sum of the locus-specific allelic variances

$$\tilde{\sigma}_A^2 = 2 \sum_{i=1}^n \sigma^2(a_i) = 2\sqrt{V_s} \sum_{i=1}^n \sqrt{\mu_i \sigma_{\alpha_i}^2} \quad (28.22f)$$

With loci of equal effects, $\sigma_m^2 = 2n\mu\sigma_\alpha^2$, implying $\mu\sigma_\alpha^2 = \sigma_m^2/(2n)$. Substituting into Equation 28.22f recovers Equation 28.14a, as

$$\tilde{\sigma}_A^2 = 2\sqrt{V_s n \sqrt{\sigma_m^2/(2n)}} = \sqrt{2nV_s \sigma_m^2} \quad (28.22g)$$

Example 28.5. We now turn to the to the expected equilibrium additive variance under the house-of-cards model. As in Example 28.5, we use x (instead of a) to denote a random allelic effect to avoid confusion with α , the effect of a new mutation, and $p(x)$ and $f(\alpha)$, respectively, denote the probability density functions for allelic effects (x) and mutational increments (α). Under the house-of-cards mutational model, the allelic effect of a new mutation is independent of its current value, x (unlike the incremental model), and is drawn from a common distribution, so that the new allelic effect following a mutation is $x' = \alpha$. Under this model, the mutational input term in Equation 28.21c, $\mu \int p(x - \alpha) f(\alpha) d\alpha$, is replaced by $\mu f(x)$, yielding a much simpler equation for the equilibrium value of $p(x)$,

$$\frac{-p(x)[x^2 - \sigma^2(x)]}{2V_s} - \mu p(x) + \mu f(x) = 0 \quad (28.23a)$$

which has an immediate solution of

$$p(x) = \frac{2V_s \mu f(x)}{x^2 - \sigma^2(x) + 2V_s \mu} \quad (28.23b)$$

As noted by Bulmer (1989), the $\sigma^2(x)$ term—the variance in allelic effects, $\sigma^2(a)$ —is a constant that can be found by noting that $\int p(x) dx = 1$, as $p(x)$ is a probability density function. Hence, for a given choice of $f(x)$, one integrates Equation 27.23b, and then solves for the value of $\sigma^2(x)$ that returns an integral of one.

If $x^2 \gg \sigma^2(x) + 2V_s \mu$, then

$$p(x) \simeq \frac{2V_s \mu f(x)}{x^2} \quad (28.23c)$$

Under this approximation, the expected value of x^k is

$$E[x^k] = \int x^k p(x) dx = \int x^k \frac{2V_s \mu f(x)}{x^2} dx = 2V_s \mu E[\alpha^{k-2}] \quad (28.23d)$$

namely, a function of the expected $k - 2$ power of the mutational effects (α). Hence, setting k equal to 2 and 4, respectively, yields the equilibrium variance and kurtosis of allelic effects for locus i as

$$\sigma^2(a_i) \simeq 2V_s \mu_i E[\alpha_i^0] = 2V_s \mu_i \cdot 1 \quad \text{and} \quad E[x_i^4] \simeq 2V_s \mu_i E[\alpha_i^2] = 2V_s \mu_i \sigma_{\alpha_i}^2$$

Upon recalling that $\sigma_{A(i)}^2 = 2\sigma^2(a_i)$, this first expression recovers Equation 28.18a, while the second expression yields Equation 28.18c.

Example 28.6. An intermediate model between Kimura's Gaussian and Turelli's HCA approximations was offered by Slatkin (1987), and our derivation here is based on his work, as well as that of Bulmer (1989). As with many of the above analyses, we start with a single-locus haploid model, which is extended to a diploid multilocus result by assuming additivity and no significant linkage effects. While our initial focus is on a single locus, the model now has multiple alleles, which we index by the subscript j . Further, our focus shifts from the distribution of allelic effects, $p(x)$ (from the previous example), to the frequency, p_j , of allele j . Again, the trait is scaled so that the optimum $\theta = 0$, and we assume that the current phenotypic mean resides at the optimum. Slatkin assumed a stepwise (as opposed to a continuum) series of alleles, where A_j mutates to either A_{j-1} or A_{j+1} , each with rate $\mu/2$ (independent of allelic state, j). Further, let us assume that allele A_j has effect $a \cdot j$. In that case Slatkin showed that the expected allele-frequency change from selection becomes

$$\frac{\partial p_j}{\partial t}(\text{sel}) = -\frac{p_j [a^2 j^2 - \sigma^2(x)]}{2V_s} \quad (28.24a)$$

where $\sigma^2(x)$ is the variance of allelic effects (which changes through time as the value of p_j change). The change from mutation is

$$\frac{\partial p_j}{\partial t}(\text{mut}) = -\mu p_j + \frac{\mu}{2} (p_{j-1} + p_{j+1}) \quad (28.24b)$$

Hence, at equilibrium,

$$-\frac{p_j[a^2 j^2 - \sigma^2(x)]}{2V_s} + \frac{\mu}{2} (p_{j-1} - 2p_j + p_{j+1}) = 0 \quad (28.24c)$$

The mutation term in Equation 28.24c is a second-degree difference equation, which, in the limit, approaches a second derivative, as

$$\begin{aligned} & \lim_{\delta \rightarrow 0} \left(\frac{f(x - \delta) - 2f(x) + f(x + \delta)}{\delta} \right) \\ &= \lim_{\delta \rightarrow 0} \left(\frac{[f(x - \delta) - f(x)] - [f(x) - f(x + \delta)]}{\delta} \right) \rightarrow \frac{d^2 f(x)}{dx^2} \end{aligned}$$

Thus, if many alleles are segregating, the differences between the frequencies of adjacent allele are small, we can approximate the rightmost term in Equation 28.24c by the second derivative of p_j with respect to t , and Equation 28.24c becomes Kimura's Gaussian approximation (28.22c). Conversely, if selection is strong relative to mutation, there are typically only three alleles (one that is favored and the two single-step mutations), where p_0 is large and $p_{-1} = p_1$ are small. This is Turelli's triallelic model (Equation 28.13a), yielding $p_{-1} = p_1 = V_s \mu / a^2$ (Equation 28.13b), for a variance of $\sigma^2(x) = 2V_s \mu$, thus recovering the HCA results.

Example 28.7. A potential deficiency in Kimura's (1965a) mutation-selection balance model is that it is a one-locus haploid analysis extrapolated to n diploid loci by assuming no linkage effects. Lande (1975) attempted to remedy this by considering a model for a single trait with n underlying, potentially linked, loci under Gaussian stabilizing selection. (This paper is often cited as Lande 1976, as although his paper appeared in late 1975, the listed journal publication date was 1976.) In order to fully account for linkage effects, Lande followed the change over time in the covariances between the allelic effects at loci i and j in the maternal gamete and between those at i' and j' in the paternal gamete. We use the notation from Equation 16.1b, with $C_{ij} = \sigma(x^{(i)}, x^{(j)})$ denoting the covariance between the effects of alleles at loci i and j . Random mating ensures that in each generation zygotes start with zero covariances between alleles residing on different gametes (i.e., $C_{ij'} = C_{i'j} = 0$). However, because of linkage disequilibrium, the corresponding covariances C_{ij} and $C_{i'j'}$ for loci on the same gamete are nonzero. Further, we expect selection to generate covariances between loci from different gametes, so

$$B_{ij}(t) = C_{ij}(t)_s = C_{i'j}(t)_s \neq 0 \quad (28.25a)$$

where C_s denotes a covariance following selection. Assuming the incremental model, the change from mutation is

$$\Delta_m C_{ij} = \delta_{ij} \mu_i \sigma_{\alpha_i}^2, \quad \text{where } \delta_{ij} = \begin{cases} 1 & i = j \\ 0 & i \neq j \end{cases} \quad (28.25b)$$

meaning that mutation changes the variances but not the covariances. Finally, let r_{ij} denote the recombination fraction between loci. Combining the joint actions of selection, recombination, and mutation (operating in that order) yields

$$C_{ij}(t+1) = (1 - r_{ij})C_{ij}(t)_s + r_{ij}B_{ij}(t) + \delta_{ij} \mu_i \sigma_{\alpha_i}^2 \quad (28.25c)$$

The last term accounts for mutation, while the first two account for recombination as follows. With probability $1 - r_{ij}$, loci i and j do not recombine, passing their covariance after selection, $C_{ij}(t)_s$, to their gametes, while with probability r_{ij} recombination does occur, with the

covariance between i and j in a gamete equaling the between-gamete covariance following selection, $B_{ij}(t)$. (A notational aside is that, as in Chapter 24, we depart from using c_{ij} and instead use r_{ij} for recombination rates to avoid confusion with the C_{ij} terms.)

Because the $C_{ij}(t)$ determine the additive variance at generation t , let

$$2C_i(t) = 2 \sum_{j=1}^n C_{ij}(t) \quad (28.25d)$$

denote the genetic variation that is due to locus i (the factor of two arises because C_{ij} is a covariance of single allelic effects, with both alleles contributing to the genetic variance; see Equation 16.1a). Recalling Equation 16.1a, the total additive variance at time t is

$$\sigma_A^2(t) = 2 \sum_{i=1}^n \sum_{j=1}^n C_{ij}(t) = 2 \sum_{i=1}^n C_i(t) \quad (28.25e)$$

In order to proceed, we need to compute the covariance, C_s , among alleles on the same gamete, and the covariance, B , among alleles on different gametes, after selection. Following Lande, we do so by considering the $n \times n$ matrices $\mathbf{C}_s(t)$, $\mathbf{B}(t)$, and $\mathbf{C}(t)$ for the $C_{ij}(t)_s$, $B_{ij}(t)$ and $C_{ij}(t)$ elements. Lande's key assumption is that the joint distribution of allelic effects for the n loci in a gamete is multivariate normal (MVN) before selection. Under Gaussian stabilizing selection, it remains normal after selection. However, Equation 28.25c shows that the distribution of allelic effects following recombination is the weighted sum of two normals (with differing variances), which is *not* normal (Felsenstein 1977; Fleming 1979; Nagylaki 1984; Turelli 1984; Bürger 1986). Hence, the assumption of multivariate normality is an approximation, a point that Lande himself stressed. The same issue holds with mutation, where even if the mutational increments are Gaussian, Equation 28.25c again becomes a weighted sum of Gaussians, and hence is not strictly normal.

Under a MVN, the joint distribution of the vectors \mathbf{x} and \mathbf{x}' of maternal and paternal allelic effects in a newly formed zygote are also MVN, with covariance matrix

$$\mathbf{V}(t) = \begin{pmatrix} \mathbf{C}(t) & \mathbf{0} \\ \mathbf{0} & \mathbf{C}(t) \end{pmatrix} \quad (28.26a)$$

The matrix $\mathbf{0}$ of zeros on the off-diagonals corresponds to independent union of gametes (random mating), with the nonzero diagonal matrices, $\mathbf{C}(t)$, corresponding to the variances and LD structure (covariances) within each gamete. After Gaussian stabilizing selection, this covariance matrix becomes

$$\mathbf{K}(t) = \begin{pmatrix} \mathbf{C}_s(t) & \mathbf{B}(t) \\ \mathbf{B}(t) & \mathbf{C}_s(t) \end{pmatrix} \quad (28.26b)$$

and the task is to compute the elements of $\mathbf{K}(t)$. Under Gaussian stabilizing selection (with an optimal value of zero), the fitness of individuals with genotypic value $g = \sum(x_i + x'_i)$ is

$$W(g) = \exp \left(- \left[\sum_{i=1}^n (x_i + x'_i) \right]^2 / (2V_s) \right) = \exp \left(- \frac{\mathbf{x}\mathbf{1}\mathbf{x}^T + 2\mathbf{x}'\mathbf{1}\mathbf{x}^T + \mathbf{x}'\mathbf{1}(\mathbf{x}')^T}{2V_s} \right) \quad (28.26c)$$

where $\mathbf{1}$ is an $n \times n$ matrix of ones (i.e., $\mathbf{1}_{ij} = 1$).

The distribution of allelic effects after selection is proportional to the product of the maternal and paternal allelic-effect density functions (the independence of these follows because we assumed random mating) times their resulting fitness, yielding

$$p(\mathbf{x})p(\mathbf{x}')W \left[\sum(x_i + x'_i) \right] \quad (28.26d)$$

Because all three terms contain exponentials of quadratic products, the resulting exponential term is the sum of the quadratic products. The quadratic product in W is given by Equation 28.26c, while the two quadratic products associated with the MVN density functions are of

the form $[\mathbf{x} - \boldsymbol{\mu}] \mathbf{C}^{-1} [\mathbf{x} - \boldsymbol{\mu}]^T$ (LW Equation 8.24). Because the remaining terms are constants with respect to \mathbf{x} and \mathbf{x}' , the product given by Equation 28.26d is proportional to $\exp(-F/2)$, where F equals the sum of the quadratic products

$$[\mathbf{x} - \boldsymbol{\mu}(t)] \mathbf{C}^{-1}(t) [\mathbf{x} - \boldsymbol{\mu}(t)]^T + [\mathbf{x}' - \boldsymbol{\mu}(t)] \mathbf{C}^{-1}(t) [\mathbf{x}' - \boldsymbol{\mu}(t)]^T + \frac{\mathbf{x} \mathbf{1} \mathbf{x}^T + 2\mathbf{x}' \mathbf{1} \mathbf{x}^T + \mathbf{x}' \mathbf{1} (\mathbf{x}')^T}{V_s} \quad (28.26e)$$

Because the resulting distribution of allelic effects after selection is also MVN with covariance matrix \mathbf{K} , it has an associated quadratic product of

$$\begin{pmatrix} \mathbf{x} - \boldsymbol{\mu}(t) \\ \mathbf{x}' - \boldsymbol{\mu}(t) \end{pmatrix} \mathbf{K}^{-1} \begin{pmatrix} \mathbf{x} - \boldsymbol{\mu}(t) \\ \mathbf{x}' - \boldsymbol{\mu}(t) \end{pmatrix}^T \quad (28.26f)$$

Our task is to find the value of \mathbf{K} such that Equation 28.26f recovers Equation 27.26e. Matching terms yields

$$\mathbf{K}^{-1}(t) = \begin{pmatrix} \mathbf{C}^{-1}(t) + \mathbf{1}/V_s & \mathbf{1}/V_s \\ \mathbf{1}/V_s & \mathbf{C}^{-1}(t) + \mathbf{1}/V_s \end{pmatrix} \quad (28.26g)$$

Lande noted that because $\mathbf{K}\mathbf{K}^{-1} = \mathbf{I}$, Equations 28.26b and 28.26e imply

$$\begin{pmatrix} \mathbf{C}_s(t) & \mathbf{B}(t) \\ \mathbf{B}(t) & \mathbf{C}_s(t) \end{pmatrix} \begin{pmatrix} \mathbf{C}^{-1}(t) + \mathbf{1}/V_s & \mathbf{1}/V_s \\ \mathbf{1}/V_s & \mathbf{C}^{-1}(t) + \mathbf{1}/V_s \end{pmatrix} = \begin{pmatrix} \mathbf{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{I} \end{pmatrix} \quad (28.26h)$$

Solving this system of equations gives

$$\mathbf{C}_s(t) = \frac{1}{2} \left(\mathbf{C}^{-1}(t) + 2 \cdot \mathbf{1}/V_s \right)^{-1} + \frac{1}{2} \mathbf{C}(t) \quad (28.27a)$$

$$\mathbf{B}(t) = \mathbf{C}_s(t) - \mathbf{C}(t) \quad (28.27b)$$

Taking the inverse in 28.27a yields

$$\mathbf{C}_s(t) = \mathbf{C}(t) - \frac{\mathbf{C}(t) \mathbf{1} \mathbf{C}(t)}{V_s + \sigma_A^2(t)} \quad (28.27c)$$

The ij th term in the matrix product $\mathbf{C}(t) \mathbf{1} \mathbf{C}(t)$ is $C_i(t) \cdot C_j(t)$, and Equation 28.27c becomes

$$C_{ij}(t)_s = C_{ij}(t) - \frac{C_i(t) C_j(t)}{V_s + \sigma_A^2(t)} \quad (28.27d)$$

Recalling Equation 28.27b, this implies

$$B_{ij}(t) = C_{ij}(t)_s - C_{ij}(t) = -\frac{C_i(t) C_j(t)}{V_s + \sigma_A^2(t)} \quad (28.27e)$$

Substituting Equations 28.27d and 28.27e into Equation 28.25c yields the following set of recurrence equations

$$\Delta C_{ij}(t+1) = -\frac{C_i(t) C_j(t)}{V_s + \sigma_A^2(t)} - r_{ij} C_{ij}(t) + \delta_{ij} \mu_i \sigma_{\alpha_i}^2 \quad (28.28a)$$

where δ_{ij} is given by Equation 28.25b. At equilibrium, $\Delta C_{ij}(t) = 0$ or

$$\frac{\tilde{C}_i \tilde{C}_j}{V_s + \tilde{\sigma}_A^2} + r_{ij} \tilde{C}_{ij} = \delta_{ij} \mu_i \sigma_{\alpha_i}^2 \quad (28.28b)$$

For $i = j$, $r_{ij} = 0$ and Equation 28.28b reduces to

$$\tilde{C}_i^2 = \mu_i \sigma_{\alpha_i}^2 (V_s + \tilde{\sigma}_A^2), \quad \text{hence} \quad \tilde{C}_i = \sqrt{\mu_i \sigma_{\alpha_i}^2 (V_s + \tilde{\sigma}_A^2)} \quad (28.28c)$$

Likewise, the off-diagonal elements can be shown to have the solution

$$\tilde{C}_{ij} = -\frac{\sqrt{\mu_i \sigma_{\alpha_i}^2 \mu_j \sigma_{m_j}^2}}{r_{ij}} \quad \text{for } i \neq j \quad (28.28d)$$

showing the presence of negative LD at equilibrium, as expected from Chapter 16. Note, however, that the \tilde{C}_{ij} values are independent of the strength of selection, V_s . Recalling Equation 28.25d, $\tilde{C}_{ii} = \tilde{C}_i - \sum_{j \neq i} \tilde{C}_{ij}$, which yeilds

$$\tilde{C}_{ii} = \sqrt{\mu_i \sigma_{\alpha_i}^2 (V_s + \tilde{\sigma}_A^2)} + \sqrt{\mu_i \sigma_{\alpha_i}^2} \sum_{j \neq i}^n \frac{\sqrt{\mu_j \sigma_{m_j}^2}}{r_{ij}} \quad (28.28e)$$

Finally, because the equilibrium additive variance can be expressed in terms of the \tilde{C}_i , as $\tilde{\sigma}_A^2 = 2 \sum \tilde{C}_i$, a little algebra yields

$$\tilde{\sigma}_A^2 = 2Z \sqrt{V_s + Z^2} + 2Z^2, \quad \text{where } Z = \sum_{i=1}^n \sqrt{\mu_i \sigma_{\alpha_i}^2} \quad (28.28f)$$

For n equivalent loci, $\sigma_m^2 = 2n\mu\sigma_\alpha^2$, reducing Z to $n\sqrt{\mu\sigma_\alpha^2}$, so $2Z^2 = 2n^2\mu\sigma_\alpha^2 = n\sigma_m^2$, and we recover Equation 28.14c.

Example 28.8. Additional insight into the HCA versus Gaussian approximations was provided by the work of Waxman (2003) and Hermisson and Wagner (2004), who provided a solution (the former) and an approximation (the latter) ranging from the HCA result for low mutation rates to the Gaussian approximation for high mutation rates. As in Examples 28.4–28.6 we (mostly) denote allelic effects by x (instead of a) to avoid confusion with the mutational increment (α).

We again remind the reader that two different distributions appear in the fundamental equation of the continuum-of-alleles model (Equation 28.21c): the equilibrium distribution of allelic effects, $p(x)$, that we are trying to obtain, and the distribution of the assumed effects of new mutations, $f(\alpha)$, where the solution to $p(x)$ depends on the choice of $f(\alpha)$. Waxman (2003) made the clever observation that a closed-form solution of $p(x)$ can be obtained with a judicious choice of $f(\alpha)$. In particular, he assumed that the distribution of mutational effects is given by

$$f(\alpha) = \frac{\alpha}{\sigma_\alpha^2 \sinh\left(\frac{\pi\alpha}{\sigma_\alpha\sqrt{2}}\right)} \quad (28.29a)$$

where $\sinh(y) = (1 - e^{-2y})/(2e^{-y})$ denotes the hyperbolic sine function, and σ_α^2 is the mutational-effects variance. As Figure 28.4A shows, this distribution (solid curve) is a symmetric, unimodal function around its mean of zero and very close in appearance to a Gaussian (dashed curve). More important, when substituted into Equation 28.21c, it provides an *exact* solution to the equilibrium distribution of allelic effects, $p(x)$, with

$$p(x) = \frac{2^{\beta-3/2}}{\pi\sigma_\alpha} \cdot \frac{\left| \Gamma\left(\frac{\beta}{2} + i \frac{x}{\sigma_\alpha\sqrt{2}}\right) \right|^2}{\Gamma(\beta)} \quad (28.29b)$$

where Γ denotes the gamma function (Equation A2.26a) extended into the complex plane (with $i = \sqrt{-1}$). The parameter $\beta = 2\tilde{\sigma}^2(a)/\sigma_\alpha^2$ is the ratio of the equilibrium variance in allelic effects, $\tilde{\sigma}^2(a)$, to the variance of mutational increments, σ_α^2 . Waxman found that

$$\tilde{\sigma}^2(a) = \frac{\sigma_\alpha^2}{4} \left(\sqrt{1 + \frac{16\mu V_s}{\sigma_\alpha^2}} - 1 \right) \quad (28.29c)$$

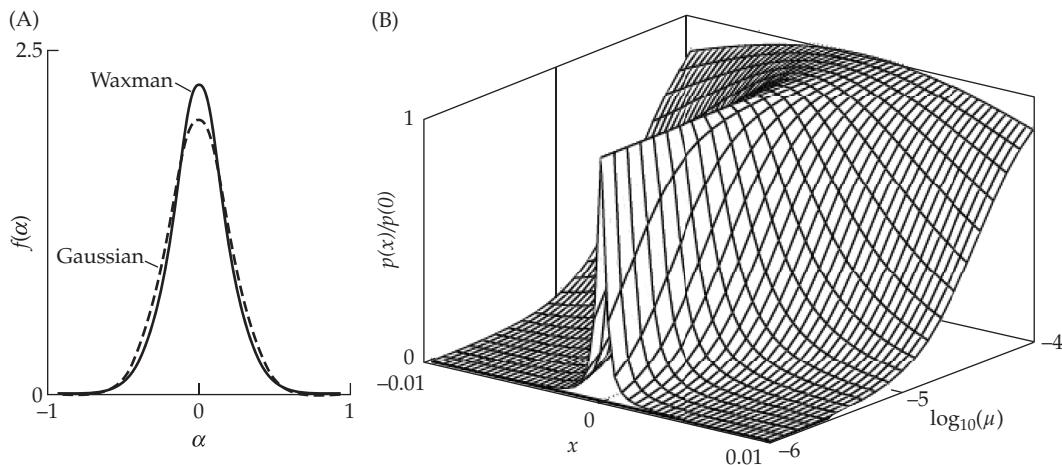

Figure 28.4 **A:** Comparison of Waxman's assumed distribution of the *mutational effects*, α (Equation 28.29a), and a Gaussian distribution. **B:** Use of the Waxman distribution for mutational effects leads to an exact solution of Equation 28.21c, showing the impact of varying mutation rates on the equilibrium distribution, $p(x)$, of *allelic effects*, x . The solution distribution is plotted as $p(x)/p(0)$, namely, the value of $p(x)$ scaled by its value at 0. In the front slice, the mutation rate is low and we recover the HCA result. As the mutation rate increases (moving toward the rear slices), the distribution becomes much more spread out, recovering the Gaussian approximation for the distribution of allelic effects. (After Waxman 2003.)

is the selection-mutation equilibrium variance in allele effects at a haploid locus (half the additive variance from that locus in a diploid, assuming additive effects). Equation 28.29a defines the **Waxman model** of mutational effects, with Equation 28.29b denoted as the **Waxman distribution** distribution of allelic effects at equilibrium, plotted in Figure 28.4B as a function of the mutation rate, μ .

For low mutation rates, Equation 28.29c recovers the HCA variance, while the Gaussian variance is recovered when mutation rates are high. To see this, let $y = 16\mu V_s/\sigma_\alpha^2$. For $y \ll 1$ (low mutation rates), $\sqrt{1+y}-1 \simeq (1+y/2)-1 = y/2$, yielding $\tilde{\sigma}^2(a) = \sigma_\alpha^2 y/8 = 2\mu V_s$, recovering the (haploid) HCA variance (Equation 28.12a). For sufficiently high mutation rates ($y \gg 1$), $\sqrt{1+y}-1 \simeq \sqrt{y}$, giving $\tilde{\sigma}^2(a) = \sigma_\alpha^2 \sqrt{y}/4 = \sqrt{u \sigma_\alpha^2 V_s}$, the single-locus haploid version of Kimura's Gaussian result (Equation 28.14a). Figure 28.4B shows more fully the impact of tuning the mutation rate in the Waxman solution. Under weak mutation (front slices of the graph), a sharply peaked distribution of allelic effects around zero occurs, while for stronger mutation (back slices of the graph) a much broader distribution occurs.

A complementary extension of Waxman's result is provided by the **House-of-Gauss (HG) model** of Hermisson and Wagner (2004). They assumed weak stabilizing selection around an optimum of $\theta = 0$, so that we can write the fitness as $W(z) = 1 - z^2/(2V_s)$. Under these assumptions, the equilibrium additive-genetic variance can be expressed in terms of cumulants (Chapter 24) of the distribution of allelic effects, with

$$\frac{2\tilde{\sigma}^4(a) + \tilde{K}_4}{2V_s} = \mu\sigma_\alpha^2 \quad (28.29d)$$

at equilibrium, representing the balance between the removal of variation by selection (left-hand side) and its introduction by new mutations (right-hand side). The Gaussian assumption is that the equilibrium fourth-order cumulant $\tilde{K}_4 = \tilde{\mu}_4(a) - 3\tilde{\sigma}^4(a)$ (Equation 24.20) is small relative to $\tilde{\sigma}^4(a)$, in which case solving Equation 28.29d recovers Kimura's haploid variance (Equation 28.14a). Under the HCA, Equation 28.18d shows that \tilde{K}_4 is replaced by $\sigma_\alpha^2 \tilde{\sigma}^2(a)$ and the $\tilde{\sigma}^4(a)$ term is ignored (the rare-alleles approximation discussed in Example 24.11), in which case Equation 28.29d recovers the haploid HCA variance (Equation 28.12a). The **House-of-Gauss approximation (HGA)** retains $\tilde{\sigma}^4(a)$ in Equation 28.29d (the Gaussian approximation) while replacing \tilde{K}_4 by its HCA, $\sigma_\alpha^2 \tilde{\sigma}^2(a)$, which changes Equation 28.29d to

$$2\tilde{\sigma}^4(a) + \sigma_\alpha^2 \tilde{\sigma}^2(a) = 2V_s \mu \sigma_\alpha^2 \quad (28.29e)$$

where $\tilde{\sigma}^2(a)$ denotes the equilibrium variance of allelic effects and σ_α^2 denotes the variance of mutational effects. It is remarkable that the solution using this approximation recovers Equation 28.29c, the equilibrium variance for the Waxman distribution.

MUTATION-STABILIZING SELECTION BALANCE: DRIFT

Impact on Equilibrium Variances

Because mutation-drift models yield too large a genetic variance, and mutation-selection models yield too small a variance, perhaps a mutation-selection model with drift might be just right. Alas, this is not the case. The incorporation of drift into mutation-selection balance models starts with Latter (1970) and Bulmer (1972). As might be expected, if the strength of selection is sufficiently weak (V_s is sufficiently large), the equilibrium variance approaches the pure-drift result (Equation 11.20c), while if the effects of drift are small (N_e sufficiently large), it approaches its deterministic value (e.g., Equation 28.18a under HCA).

Ignoring linkage disequilibrium (as above, by simply summing the single-locus results) and assuming Gaussian selection and the incremental mutational model with $\alpha \sim N(0, \sigma_\alpha^2)$, Bürger et al. (1989) obtained their **stochastic house-of-cards (SHC)** approximation

$$\tilde{\sigma}_A^2(SHC) \simeq \frac{4n\mu V_s}{1 + V_s/(N_e \sigma_\alpha^2)} \quad (28.30a)$$

Bürger (1988a), Keightley and Hill (1988), Barton (1989), and Houle (1989) all obtained similar expressions using different approaches. As with the deterministic HCA model, linkage has little effect on this result, leading to only a slight overestimate (Bürger 1988a; Bürger et al. 1989; Bürger and Lande 1994). Equation 28.30a interpolates between the pure-selection HCA result (Equation 28.18a), denoted $\tilde{\sigma}_A^2(HC)$, and the pure-drift (neutral) result (Equation 11.20), denoted $\tilde{\sigma}_A^2(N)$. Following Bürger et al. (1989), a little algebra shows that

$$\tilde{\sigma}_A^2(SHC) = \frac{\tilde{\sigma}_A^2(HC) \cdot \tilde{\sigma}_A^2(N)}{\tilde{\sigma}_A^2(HC) + \tilde{\sigma}_A^2(N)} \quad (28.30b)$$

which is simply half the harmonic mean of the pure selection and pure drift results. Analysis of Equation 28.30a gives the selection- and drift-dominated domains as

$$\tilde{\sigma}_A^2(SHC) \simeq \begin{cases} \tilde{\sigma}_A^2(N) & \text{when } N_e \sigma_\alpha^2 \ll V_s \\ \tilde{\sigma}_A^2(HC) & \text{when } N_e \sigma_\alpha^2 \gg V_s \end{cases} \quad (28.30c)$$

An alternative way to recover these domains is to recall that selection overpowers drift at a single locus when $|4N_e s| \gg 1$, while drift dominates when $|4N_e s| \ll 1$ (Chapter 7). Using Equation 28.4c, the expected selection coefficient for a new mutation (effect α_i under HOC) is

$$E(s_i) = \frac{E(\alpha_i^2)}{2V_s} = \frac{\sigma_{\alpha_i}^2}{2V_s} \quad (28.30d)$$

Hence, $|4N_e s| \gg 1$ implies $2N_e \sigma_{\alpha_i}^2 \gg V_s$, while $|4N_e s| \ll 1$ implies $2N_e \sigma_{\alpha_i}^2 \ll V_s$, thus recovering the selection- and drift-dominated domains given in Equation 28.30c.

An important caveat is that finite-population expressions for $\tilde{\sigma}_A^2$ are *expected values*. Simulations show considerable spread around this expected value (Keightley and Hill 1988; Bürger 1989; Bürger et al. 1989; Bürger and Lande 1994). Barton (1989) found that the variation in the realizations is approximately

$$\sigma^2 \left[\tilde{\sigma}_A^2(SHC) \right] \simeq \left(\frac{\sigma_\alpha^2}{1 + \sigma_\alpha^2 N_e / V_s} \right) \tilde{\sigma}_A^2(SHC) \quad (28.31)$$

This reduces (to leading order) to Equation 11.25 as $V_s \rightarrow \infty$ (i.e., as the strength of selection approaches zero).

The Gaussian counterpart to the stochastic HCA can be obtained using the same logic leading to Equations 28.14d and 28.14e. Again, we start with Equation 24.2a, which assumes a Gaussian distribution of allelic effects. Adding a term σ_m^2 for new mutation and ignoring disequilibrium ($d = 0, \sigma_a^2 = \sigma_A^2$), then at equilibrium

$$\sigma_m^2 = \frac{\tilde{\sigma}_A^2}{2N_e} + \left(1 - \frac{1}{N_e}\right) \frac{\tilde{\sigma}_A^4}{2nV_s} \simeq \frac{\tilde{\sigma}_A^2}{2N_e} + \frac{\tilde{\sigma}_A^4}{2nV_s} \quad (28.32a)$$

where again we used the result that $\kappa h^2 = \sigma_A^2/V_s$ (note that our use of κ here and in Equations 28.14d and 28.14e follows from its use in Equation 16.10a to measure the reduction in variance following selection, and is distinct from κ_4 , which is used above to denote a scaled measure of kurtosis; Equation 28.18c). This yields the quadratic equation

$$\tilde{\sigma}_A^4 + \left(\frac{nV_s}{N_e}\right) \tilde{\sigma}_A^2 - 2n\sigma_m^2 V_s = 0 \quad (28.32b)$$

whose solution is the **stochastic Gaussian result**

$$\tilde{\sigma}_A^2 \simeq \sqrt{\left(\frac{nV_s}{2N_e}\right)^2 + 2n\sigma_m^2 V_s} - \left(\frac{nV_s}{2N_e}\right) \quad (28.32c)$$

Latter (1970), Keightley and Hill (1988), Houle (1989), Lynch and Lande (1993), and Santiago (1998) all independently obtained slightly different versions of this expression. For sufficiently weak drift (large N_e), Equation 28.32c approaches Kimura's Gaussian result (Equation 28.14a). For sufficiently weak selection (large V_s), the $\tilde{\sigma}_A^4$ term in Equation 28.32b can be ignored, which recovers the pure drift result (Equation 11.20c). Bürger (2000) found that the stochastic version of Fleming's Gaussian approximation (Equation 28.15) is also of the form of Equation 28.32c, with the $2n\sigma_m^2 V_s$ term (the square of Kimura's result; Equation 28.14a) replaced by the square of Fleming's result (Equation 28.15).

Using the stochastic version of the House-of-Gauss (HG) approximation (Example 28.8) of Hermisson and Wagner (2004) provides a unified treatment of the above results. Recall that the HG approximation recovers the HCA when the mutation rate is sufficiently low and the Gaussian when the mutation rate is sufficiently high. Adding a drift term, $-\tilde{\sigma}^2(a)/N_e$, to the right-hand side of the deterministic version (Equation 28.29d) of the HG approximation yields

$$\frac{2\tilde{\sigma}^4(a) + \sigma_\alpha^2 \tilde{\sigma}^2(a)}{2V_s} = \mu\sigma_\alpha^2 - \frac{\tilde{\sigma}^2(a)}{N_e} \quad (28.33a)$$

where $\tilde{\sigma}^2(a)$ is the haploid, single-locus variance. Under linkage equilibrium, for n equivalent loci, $\tilde{\sigma}^2(A) = 2n\tilde{\sigma}^2(a)$. Using this result and solving Equation 28.33a, results in Hermisson and Wagner's **stochastic House-of-Gauss** expression

$$\tilde{\sigma}^2(a) = 2n\sigma_\alpha^2 \frac{\gamma N_e + 1}{4\gamma N_e} \left(\sqrt{1 + 2\frac{\gamma N_e \cdot 4\mu N_e}{(\gamma N_e + 1)^2}} - 1 \right), \quad \text{where } \gamma = \frac{\sigma_\alpha^2}{2V_s} \quad (28.33b)$$

Finally, a more subtle effect of drift is that it can impact the domain of applicability of the Gaussian approximation. Houle (1989) noted that higher mutation rates than those necessary for the deterministic Gaussian approximation are required to compensate for the loss of alleles from drift, further restricting its domain of applicability.

Near Neutrality at the Underlying Loci?

Lande (1975) noted that with n loci, selection to move the mean to the optimum uses only a single degree of freedom (the sum of the allelic effects over all loci). He argued that the

remaining $n - 1$ degrees of freedom leaves ample opportunity for drift at the underlying loci, and an important role for historical events, as well as considerable genetic differentiation between populations, while still preserving the same mean and variance. The possibility of extensive neutral evolution at such loci was first examined by Kimura (1981), and later by Foley (1987, 1992), Hastings (1987b), Barton (1989) and Bürger et al. (1989). As we will see, Lande's initial suggestion of extensive neutrality is only partly correct.

A point in favor of Lande's suggestion is that the loci underlying a trait under stabilizing selection experience underdominant selection (heterozygote disadvantage; see Example 5.6), and such underdominant mutations are far more likely to become fixed than an unconditionally deleterious mutation with the same (initial) selection coefficient (Kimura 1981). Equation 28.4b shows that s_i varies with allele frequency, moving from negative values for $p < 1/2$ to positive values for $p > 1/2$. From Equation 28.4c, the initial selection against a new mutation (assuming that $\bar{z} \simeq \theta$) is $s_i = a_i^2/(2V_s)$, which decreases to zero (neutrality) as p_i approaches 1/2 (Equation 28.4b). Once the frequency drifts above 1/2, the allele is now favored, and increasingly so, as p_i approaches one. Kimura (1981) found that as a result of these frequency-dependent changes in s_i , extensive neutral evolution at the underlying loci is possible when $N_e s_i \ll 2$, a larger region than for a deleterious mutation with constant selection coefficient of the same value. Foley (1987) refined Kimura's result, showing that the expected substitution rate, λ , at loci underlying a trait under stabilizing selection is

$$\lambda \simeq \frac{\mu}{\sqrt{1 + \sigma_m^2 N_e / V_s}} \quad (28.34a)$$

$$\simeq \begin{cases} \mu & \text{when } \sigma_m^2 N_e \ll V_s \quad (\text{effective neutrality}) \\ \mu \sqrt{\frac{V_s}{\sigma_m^2 N_e}} & \text{when } \sigma_m^2 N_e \gg V_s \quad (\text{strong constraint}) \end{cases} \quad (28.34b)$$

Kimura also suggested that underdominance results in a more U-shaped allele-frequency distribution (which has a larger probability mass near both zero and one) relative to a neutral diallelic locus with the same mutation rates. Foley (1992) obtained weak-selection approximations for the number of alleles and the frequency spectrum under the infinite-alleles model. These results showed that the Lande-Kimura notion of nearly neutral behavior at the loci of a trait undergoing stabilizing selection does not hold. Rather, their behavior is more akin to loci subjected to weak purifying selection (e.g., background selection; Chapters 3 and 8), and Barton (1989) noted that it was not possible to use the allele-frequency distribution to distinguish between stabilizing and weak purifying selection.

Finally, Bürger et al. (1989) examined the heterozygosity at the underlying loci through simulation studies. Generally, there was a reasonable fit between the fully neutral expectation of $\tilde{H}_n = \theta/(1 + \theta)$, where $\theta = 4N_e\mu$, and the observed value, \tilde{H}_o , except under strong selection or a high variance of mutational effects. Foley (1992) found that a slightly better fit was obtained by replacing θ by

$$\theta_s = \frac{\theta}{\sqrt{1 + \sigma_m^2 N_e / (2V_s)}} \quad (28.34c)$$

Both Foley and Bürger et al. noticed that heterozygosity is not necessarily highly correlated with the additive variance. In particular, Bürger et al. noted that the relationship often used for a diallelic locus to relate the equilibrium additive variance to the observed heterozygosity, namely $\tilde{\sigma}_A^2 = n\sigma_\alpha^2 \tilde{H}_o$ (e.g., Bulmer 1972), generally *does not hold* under the infinite-alleles assumption.

MUTATION-STABILIZING SELECTION BALANCE: PLEIOTROPY

Finally, we conclude our discussion of models assuming direct stabilizing selection on a focal trait balanced by mutation by considering the impact when mutations have pleiotropic

effects (namely, influencing additional traits, beyond the focal one, that are under selection). The presence of pleiotropy introduces considerable complications. Many of the previous models depend on difficult-to-estimate quantities (n , μ , and σ_α^2). Pleiotropy adds additional, usually hidden, players that are even more difficult to detect and whose effects are essentially impossible to estimate with any precision. This is especially problematic, as seemingly very small differences in pleiotropy models can lead to qualitatively different outcomes. Johnson and Barton (2005) stressed that the lack of understanding of both the nature of pleiotropy, and how to robustly model it, are the main impediments to a deeper understanding of the maintenance of variation. This section considers the impact of adding pleiotropic effects to direct-selection models (wherein the trait itself is under selection), while pure pleiotropy models (wherein the focal trait is neutral) are examined in the final selection.

Gaussian Results

To model multiple-trait selection with pleiotropic mutations, we follow the standard approach of working with a single-locus haploid model, whose results are then extended to a diploid multilocus model by summing over loci (i.e., assuming additivity and ignoring linkage disequilibrium). In order to proceed, several conceptual extensions are required to move from a single- to a k -trait model. While our discussion is for a particular locus, i , we will often suppress the subscript for ease of presentation.

First, the single effect, a , of an allele on the focal trait is replaced by the vector of k allelic effects, \mathbf{a} , whose j th element is the allelic effect for trait j . As a result, the variance of allelic effects at a given locus is replaced by a variance-covariance matrix, \mathbf{V}_a , of effects on all pairs of traits influenced by pleiotropic mutations (that involve the focal trait), where

$$(\mathbf{V}_a)_{j,\ell} = \sigma(a_j, a_\ell) \quad 1 \leq j, \ell \leq k \quad (28.35a)$$

namely, the covariance between the effects of an allele at the focal locus on traits i and j .

Second, under the incremental model, the vector of allelic effects following mutation becomes $\mathbf{a}' = \mathbf{a} + \boldsymbol{\alpha}$, whose j th element is $a'_j = a_j + \alpha_j$. As a result, the single-trait mutational effects variance, σ_α^2 , is replaced by a **pleiotropic mutation matrix**, \mathbf{V}_m , whose elements are given by

$$(\mathbf{V}_m)_{j,\ell} = \sigma(\alpha_j, \alpha_\ell) \quad 1 \leq j, \ell \leq k \quad (28.35b)$$

where α_j is the mutational increment to trait j . A critical point is that *extensive pleiotropy can occur without any mutational covariance between traits*, namely, with $\sigma(\alpha_j, \alpha_\ell) = 0$ for all values of j and ℓ , a condition referred to as **hidden pleiotropy**. For example, consider a locus that influences two traits, with all mutations having pleiotropic effects, but comprising a random collection of $++, --, +-$ and $-+$ effects on the two traits. The between-trait covariance for the mutational effects is zero, even though there is complete pleiotropy (all mutations impact both traits). Short of actually measuring the joint effects of individual mutations, the presence of hidden pleiotropy would be difficult, if not impossible, to detect, yet has dramatic consequences for mutation-selection balance, and for multivariate evolution in general (the latter discussed in detail in Volume 3).

Finally, modeling selection requires a multivariate extension of Equation 28.3b. If \mathbf{z} is the vector of k trait values, and $\boldsymbol{\theta}$ a vector of optimum values, then

$$W(\mathbf{z}) = \exp\left(-\frac{(\mathbf{z} - \boldsymbol{\theta})\mathbf{V}_\omega^{-1}(\mathbf{z} - \boldsymbol{\theta})^T}{2}\right) \quad (28.36a)$$

where \mathbf{V}_ω is a symmetric, positive-definite matrix (a matrix with all positive eigenvalues; see Chapter 30 and Appendix 5 for further details). For weak selection, expanding the quadratic product in the exponential gives

$$W(\mathbf{z}) \simeq 1 - \frac{1}{2} \sum_{j=1}^k \sum_{\ell=1}^k (z_j - \theta_j)(z_\ell - \theta_\ell) V_{j\ell} \quad (28.36b)$$

where $V_{j\ell}$ is the $j\ell$ th element of \mathbf{V}_ω^{-1} . From the assumed positive-definiteness of \mathbf{V}_ω , outside of $\mathbf{z} = \boldsymbol{\theta}$, this double summation is always positive (Equation A5.17a), resulting in fitness being maximized at $\mathbf{z} = \boldsymbol{\theta}$ and declining quadratically in any direction around $\boldsymbol{\theta}$ (Chapter 30). Assuming environmental effects are multivariate normal, $\mathbf{z}|\mathbf{a} \sim \text{MVN}(\mathbf{a}, \mathbf{V}_E)$, the multivariate version of Equation 28.3e gives the fitness associated with \mathbf{a} as $w(\mathbf{a}) \propto \exp[-(\mathbf{a} - \boldsymbol{\theta})\mathbf{V}_s^{-1}(\mathbf{a} - \boldsymbol{\theta})^T/2]$, where

$$\mathbf{V}_s = \mathbf{V}_\omega + \mathbf{V}_E \quad (28.36c)$$

is the multivariate extension of Equation 28.3f. Below, we will use the weak-selection approximation that $\mathbf{V}_\omega + \mathbf{V}_z \simeq \mathbf{V}_s$ and $\mathbf{V}_\omega + \mathbf{V}_a \simeq \mathbf{V}_a$.

Assuming that the vector of phenotypes is multivariate normal, $\mathbf{z} \sim \text{MVN}(\mathbf{0}, \mathbf{V}_z)$, the multivariate analog for the change by selection in the (univariate) phenotypic variance (Equation 28.3g) is given by the change in the phenotypic covariance matrix, \mathbf{V}_z , where

$$\Delta \mathbf{V}_z = -\mathbf{V}_z (\mathbf{V}_\omega + \mathbf{V}_z)^{-1} \mathbf{V}_z \simeq -\mathbf{V}_z \mathbf{V}_s^{-1} \mathbf{V}_z \quad (28.36d)$$

Similarly, when \mathbf{a} is multivariate normal, the change in the covariances for the vector of allelic effects following selection becomes

$$(\Delta \mathbf{V}_a)_s = -\mathbf{V}_a (\mathbf{V}_s + \mathbf{V}_a)^{-1} \mathbf{V}_a \simeq -\mathbf{V}_a \mathbf{V}_s^{-1} \mathbf{V}_a \quad (28.36e)$$

Following Lande (1980), the change in \mathbf{V}_a from the joint action of selection and mutation is

$$\Delta \mathbf{V}_a = (\Delta \mathbf{V}_a)_s + \mu_i \mathbf{V}_m \quad (28.37a)$$

which is zero at equilibrium. Note that \mathbf{V}_m is the multivariate extension of σ_α^2 , and hence is multiplied by the mutation rate at the i th locus, μ_i .

Recalling Equation 28.36e, the removal of genetic variances and covariances by selection balances the input from new mutation when

$$\tilde{\mathbf{V}}_a \mathbf{V}_s^{-1} \tilde{\mathbf{V}}_a = \mu_i \mathbf{V}_m \quad (28.37b)$$

which has the solution

$$\tilde{\mathbf{V}}_a \simeq \mathbf{V}_s^{1/2} \left(\mu_i \mathbf{V}_s^{-1/2} \mathbf{V}_m \mathbf{V}_s^{-1/2} \right)^{1/2} \mathbf{V}_s^{1/2} \quad (28.37c)$$

where $\mathbf{V}^{1/2}$ denotes the square root of \mathbf{V} (where $\mathbf{V}^{1/2} \mathbf{V}^{1/2} = \mathbf{V}$; see Equation A5.11b). If \mathbf{V}_s and \mathbf{V}_m are diagonal matrices (corresponding to no correlations in the fitness function and no pleiotropic covariance between mutational effects, respectively), Equation 28.37c gives the equilibrium variance for trait j at locus i as

$$\tilde{\sigma}^2(a_{j,i}) \simeq \sqrt{\mu_i \sigma_{\alpha_{j,i}}^2 V_{s,j}} \quad (28.38a)$$

where $\sigma_{\alpha_{j,i}}^2$ is the variance in the effects on trait j from new mutations at locus i . This is simply Kimura's result for a single trait (Equation 28.22d), and Lande's key finding: *under the Gaussian assumption, the equilibrium additive variance of a trait is unaffected by selection on uncorrelated (both selectively and mutationally) traits.*

As noted by Turelli (1985), the condition for the multivariate Gaussian approximation to be reasonable is that

$$\mu_i \gg \frac{\sigma_{\alpha_{k,i}}^2}{V_{s,k}} \quad (28.38b)$$

for all loci and all traits. The presence of *any* locus-trait combination that violates this condition invalidates the Gaussian approximation. A second restriction on the plausibility of

the Gaussian approximation is the realistic number of functionally distinct alleles that can be maintained at a locus. Turelli (1984) found that a locus with roughly 20 alleles can fairly closely match the continuum-of-alleles model for a single trait. However, with two traits, allowing over 100 alleles still did not provide sufficient granularity to capture the bivariate continuum-of-alleles structure. This problem becomes increasingly more acute as the number of traits that a pleiotropic mutant impacts grows.

Example 28.9. To be a bit more formal on the conditions required for selection to be uncorrelated over a set of traits, consider the two-trait versions of the matrices \mathbf{V}_ω , \mathbf{V}_E , and \mathbf{V}_s . When the off-diagonal element of this last matrix is zero, the two traits are selectively uncorrelated. Because \mathbf{V}_ω is a symmetric, positive definite matrix, it is also a covariance matrix (Appendix 5), and hence we can write it as

$$\mathbf{V}_\omega = \begin{pmatrix} \omega_1^2 & \rho_\omega \omega_1 \omega_2 \\ \rho_\omega \omega_1 \omega_2 & \omega_2^2 \end{pmatrix}$$

A nonzero value of ρ_ω implies selection favoring a covariance between z_1 and z_2 (Chapter 30). Similarly expressing the covariance matrix of environmental effects as

$$\mathbf{V}_E = \begin{pmatrix} \sigma_{E_1}^2 & \rho_e \sigma_{E_1} \sigma_{E_2} \\ \rho_e \sigma_{E_1} \sigma_{E_2} & \sigma_{E_2}^2 \end{pmatrix} \quad \text{yields} \quad \mathbf{V}_s = \mathbf{V}_\omega + \mathbf{V}_E = \begin{pmatrix} V_{s,1} & C_s \\ C_s & V_{s,2} \end{pmatrix}$$

where

$$V_{s,i} = \omega_i^2 + \sigma_{E_i}^2 \quad \text{and} \quad C_s = \rho_e \sigma_{E_1} \sigma_{E_2} + \rho_\omega \omega_1 \omega_2 \quad (28.39a)$$

The two traits are selectively uncorrelated when $C_s = 0$, which requires that the phenotypic selection (ρ_ω) and environmental (ρ_e) correlations are zero, or the unlikely event that $\rho_e = -\rho_\omega \omega_1 \omega_2 / (\sigma_{E_1} \sigma_{E_2})$. We can also write \mathbf{V}_s as

$$\mathbf{V}_s = \begin{pmatrix} V_{s,1} & \rho_s \sqrt{V_{s,1} V_{s,2}} \\ \rho_s \sqrt{V_{s,1} V_{s,2}} & V_{s,2} \end{pmatrix}$$

where

$$\rho_s = \frac{C_s}{\sqrt{V_{s,1} V_{s,2}}} = \frac{\rho_e \sigma_{E_1} \sigma_{E_2} + \rho_\omega \omega_1 \omega_2}{\sqrt{V_{s,1} V_{s,2}}} \quad (28.39b)$$

HCA Results

An encouraging feature of the single-trait house-of-cards analysis was its relative robustness to the underlying genetic model. Provided that Equation 28.17 (or its diallelic counterpart; Equation 28.11e) hold, the equilibrium additive-genetic variance (Equation 28.18a) is independent of many of the underlying genetic details, such as the number of alleles per locus. Unfortunately, this robustness vanishes when pleiotropy is introduced (Turelli 1985, 1986). Even more troubling, and unlike the Gaussian result just obtained (Equation 28.38a), selection acting on pleiotropically connected but *uncorrelated* traits influences the additive variance of a focal trait under the HCA (Turelli 1985, 1986, 1988; Wagner 1989; Slaktin and Frank 1990).

Turelli (1985) examined the simplest case of the HCA for a pleiotropic continuum-of-alleles model: two traits that are mutationally and selectively uncorrelated, $(\mathbf{V}_m)_{12} = 0$ and $\rho_s = 0$ (defined by Equation 28.39b). He found that the bivariate condition for the HCA approximation to be reasonable was more lenient than in the univariate condition. For two (uncorrelated) traits, the condition for locus i becomes

$$\mu_i \ll \sqrt{\frac{\sigma_{\alpha_{1,i}}^2 \sigma_{\alpha_{2,i}}^2}{V_{s,1} V_{s,2}}} \quad (28.40)$$

which (unlike the Gaussian approximation) can be satisfied even when one of the loci does not itself satisfy the univariate HCA condition (Equation 28.17). Under the bivariate HCA, the equilibrium additive variance in trait 1 becomes

$$\tilde{\sigma}_{A(i)}^2 \simeq \frac{4\mu_i V_{s,1}}{1 + \beta_i}, \quad \text{where } \beta_i = \sqrt{\frac{\sigma_{\alpha_{2,i}}^2 V_{s,1}}{\sigma_{\alpha_{1,i}}^2 V_{s,2}}} \quad (28.41a)$$

Even if trait 1 is mutationally and selectively uncorrelated to trait 2, it is still impacted by selection on the latter when $\sigma_{\alpha_{2,i}}^2 > 0$, namely, locus i experiences pleiotropic mutations influencing trait 2. Recalling Equation 28.30d, we see that β_i^2 is the ratio of the average selection coefficients for the two traits associated with a mutation at locus i (Turelli 1985), as

$$\beta_i^2 = \frac{\sigma_{\alpha_{2,i}}^2 / (2V_{s,2})}{\sigma_{\alpha_{1,i}}^2 / (2V_{s,1})} = \frac{E[s_{2,i}]}{E[s_{1,i}]} \quad (28.41b)$$

Under the HCA setting (wherein selection dominates mutation), both traits are near their optimum ($\bar{z} \simeq \theta$), meaning that a change in any direction is likely deleterious. Thus, any new mutations influencing trait 1 will also change trait 2, further lowering fitness. The stronger selection is on trait 2, the greater the additional reduction in fitness for a mutation that also affects trait 1. When most of the selection on new mutations at locus i is on trait 1 ($\beta_i \ll 1$), Equation 28.41a is close to the single-trait HCA value (Equation 28.18a). Conversely, when there is much stronger selection on trait 2 ($\beta_i \gg 1$), the amount of variation maintained for trait 1 is considerably below its single-trait HCA prediction. If a large number of traits are under multivariate Gaussian selection, one can easily construct a single synthetic trait (a linear combination of the remaining traits) to reduce this to a two-trait (focal plus synthetic) model (Example 28.10). Hence, for most traits we expect selection on the “other” trait to be larger, and likely considerably so, resulting in an overprediction of trait 1’s genetic variance using the univariate HCA result (Equation 28.18a).

Finally, because the HCA assumes that selection at a locus is much stronger than mutation, a consequence of this additional selection on the nonfocal trait is to make the HCA approximation more plausible. Thus, pleiotropy expands the domain of applicability of the HCA while shrinking that of the Gaussian approximation (Equation 28.38b).

In addition to generating a dependency on hidden traits, pleiotropy has another, equally insidious, feature. Under single-trait HCA conditions, the equilibrium variance does not depend on the genetic details beyond the total mutation rate (with diallelic, triallelic, and continuum-of-alleles models all giving the same results). However, Turelli (1985) found that a five-allele model (the bivariate extension of his univariate triallelic model, now following five alleles, $A_{0,0}$ and $A_{i,j}$ for $i, j = \pm 1$, where allele A_{ij} has effects of $i \cdot a_1$ and $j \cdot a_2$ on traits 1 and 2, respectively) yielded

$$\tilde{\sigma}_{A(i)}^2 \simeq \frac{4\mu_i V_{s,1}}{1 + \beta_i^2} \quad (28.42)$$

which is a different result from the continuum-of-alleles model (Equation 28.41a). Thus, additional genetic details (such as the number of alleles) seem to matter under pleiotropy.

In the univariate case, the qualitative difference in the additive variance under continuum-of-alleles (Kimura-Lande-Fleming) versus diallelic (Latter-Bulmer) models was due to the relative strengths of mutation and selection, *not* the number of alleles. Wagner (1989) suggested that something similar is behind the difference between Equations 28.41a and 28.42, with the amount of pleiotropic constraints among the effects of new mutations, rather than the number of alleles, accounting for the difference in equilibrium values. Turelli’s five-allele model is highly constrained due to the limited number of alleles, while this is not the case for the continuum-of-alleles result. Wagner considered a model of constraints wherein the effect on trait j from a mutation of effect α_i at an underlying generator locus i is $b_{ij}\alpha_i$ (where the b_{ij} are constants). This structure implies that all of the mutational effects from a given locus are completely correlated, with the two-trait version recovering Turelli’s

five-allele result. Wagner suggested that differences in the amount of constraint on the pleiotropic nature of new mutations accounts for the difference between Equations 28.41a (little constraint) and 28.42 (significant constraint). Zhang and Hill (2003) showed this to be the case, recovering the Turelli five-allele result from a two-trait, continuum-of-alleles model when the correlation between the pleiotropic effects of new mutations is high.

Finally, as in the univariate case, the radical differences in behavior between the Gaussian and HCA approximations in the presence of pleiotropy are the result of differences in the strength of selection relative to mutation, *not* the underlying mutational model. Slatkin and Frank (1990) verified this by considering a nine-allele model, whose mutational structure is given by the following lattice of trait values. The center allele (0,0) is at the bivariate optimum, and this allele is allowed to have a nonpleiotropic mutation for either trait, e.g., $(-a, 0)$, $(a, 0)$, $(0, -a)$, or $(0, a)$; or to jointly mutate for both traits in four possible directions, $(-a, -a)$, $(-a, a)$, $(a, -a)$, (a, a) . This model offers a bit more granularity than Turelli's five-allele model. Slatkin and Frank found that, depending on the relative strengths of selection and mutation, this model can generate either the Gaussian behavior (weak to no impact from selection on uncorrelated traits) or the HCA behavior (strong impact from uncorrelated selection).

Example 28.10. Under the fitness function given by Equation 28.36a, Turelli (1985) and Zhang and Hill (2003) showed that if the population is at (or very close to) its optimal value ($\theta = \mathbf{0}$), then the initial selection coefficient against a new mutation at locus i with effects vector $\alpha^T = (\alpha_{1,i}, \alpha_{2,i}, \dots, \alpha_{k,i})$ is approximately given by the quadratic product

$$s_i \simeq \frac{\alpha^T \mathbf{V}_s^{-1} \alpha}{2} \quad (28.43a)$$

This is the multivariate equivalent of Equation 28.4c. When \mathbf{V}_s is diagonal (uncorrelated selection; Example 28.9), this reduces to

$$s_i \simeq \sum_{j=1}^k \frac{\alpha_{j,i}^2}{2V_{s,j}}, \quad \text{implying} \quad E[s_i] \simeq \sum_{j=1}^k \frac{\sigma_{\alpha_{j,i}}^2}{2V_{s,j}} = \sum_{j=1}^k E[s_{j,i}] \quad (28.43b)$$

namely, the sum of the average selection coefficients of a new mutation associated with each of the k traits. More generally, expanding the quadratic product given by Equation 28.43a yields

$$s_i \simeq \sum_{j=1}^k \sum_{\ell=1}^k \alpha_{j,i} \cdot V_{j,\ell} \cdot \alpha_{\ell,i}$$

where $V_{j,\ell}$ is the $j\ell$ th element of \mathbf{V}_s^{-1} . Taking expectations yields

$$E[s_i] \simeq \sum_{j=1}^k \sum_{\ell=1}^k \left[V_{j,\ell} \cdot \sigma(\alpha_{k,i}, \alpha_{\ell,i}) \right] \quad (28.43c)$$

showing that the average selection coefficient for a new mutation depends on the mutational covariances, $\sigma(\alpha_{k,i}, \alpha_{\ell,i})$, in addition to the pattern and strength of stabilizing selection, \mathbf{V}_s .

Zhang and Hill (2003) noted that if all n traits impact locus i with roughly similar selection coefficients ($E[s_{j,i}] \simeq s_i$), then from the central limit theorem, the distribution of the s_i approaches a normal. Further, the coefficient of variation of this distribution goes to zero at an approximate rate of $\sqrt{(3\kappa_{4,s} - 1)/n}$, where $\kappa_{4,s} = E[(s_i - \bar{s}_i)^4]/\{3[\sigma^2(s_i)]^2\}$ is the scaled kurtosis of s_i . Thus, for a sufficiently large number of independent traits under selection, s_i is approximately a constant plus a small amount of normally distributed error.

MAINTENANCE OF VARIATION BY PLEIOTROPIC DELETERIOUS ALLELES

We conclude our discussion of theory with **deleterious-pleiotropy models**, in which the loci underlying a trait have pleiotropic effects on fitness, independent of their trait effects. This is the extension of the previous models, wherein the pleiotropic effects were on traits that were themselves under stabilizing selection. We start this section by assuming that the focal trait is *neutral*—its phenotypic value has no direct fitness consequences—but that its underlying loci are under selection (i.e., they have pleiotropic effects on both the trait and fitness), relaxing this neutral trait assumption later. We previously considered Robertson's model, wherein the underlying loci display fitness overdominance, which had a number of problems as a general explanation for the maintenance of trait variation (Example 28.2). We now turn to models in which the underlying loci are deleterious, and variation is maintained through selection-mutation balance. The logic behind such models is twofold. First, many new mutations are expected to be deleterious. Second, while purely neutral models (wherein all underlying loci have no fitness consequences) maintain too much variation in even modestly sized populations, perhaps introducing slightly deleterious underlying alleles allows the population to achieve the observed levels of variation.

This is the idea behind the Hill-Keightley (1988) (HK) model of **pleiotropic side-effects**, wherein the amount of additive-genetic variation for the neutral trait is determined by pleiotropic effects from deleterious alleles in mutation-selection balance. One observation motivating this model is that mutations that have major effects on a trait also tend to be deleterious (Chapters 25 and 26). Coupling this with the belief (and some observations; Chapter 27) that single mutations often influence multiple traits, and that many mutations are at least slightly deleterious, suggests that at least *some* of the variation for any trait is due to such deleterious alleles. As with much of the above analysis, the issue is whether such a model, by itself, can generate *both* sufficient variation *and* sufficiently strong apparent stabilizing selection to account for the observed values of these two features.

The Hill-Keightley Pleiotropic Side-effects Model

Organisms, and their underlying genetic systems, are expected to be highly integrated, with single genes and single traits unlikely to be isolated from others. Hence, pleiotropy and correlated selection are expected to be the norm, not the exception. We have previously considered one special case of this, namely a locus influencing a number of traits that are all under stabilizing selection. Is there a more general way to model this complex situation?

Hill and Keightley (1988) and Keightley and Hill (1990) suggested that one approach is to sweep all pleiotropic selective effects into a single fitness term, s , generally expected to be deleterious (e.g., Example 28.10). Their model assumes that each new mutation has *two effects*: (i) α , on the focal trait; and (ii) s , on fitness (measured as the fitness reduction in heterozygotes, as homozygotes are expected to be rare and hence make little contribution). From Chapter 7, the (infinite-population) equilibrium frequency of such an allele arising under recurrent mutation is $\tilde{p} = \mu/s \ll 1$. Assuming additive trait effects, the contribution to the additive-genetic variance of the trait from this locus is

$$2\alpha^2 \tilde{p}(1 - \tilde{p}) \simeq 2\alpha^2 \tilde{p} \simeq \frac{2\alpha^2 \mu}{s} \quad (28.44a)$$

Because new mutations show a distribution of both α and s values, the expected contribution from this locus becomes $2\mu E[\alpha^2/s]$. Some insight into this expectation is offered by using a Taylor-series approximation for the expected value of a ratio (LW Equation A1.19a). Recalling that $E[\alpha^2] = \sigma_\alpha^2$ (as we assumed that $E[\alpha] = 0$) and denoting $E[s]$ by \bar{s} , LW Equation A1.19a yields

$$E\left[\frac{\alpha^2}{s}\right] \simeq \frac{\sigma_\alpha^2}{\bar{s}} \left(1 + \frac{\sigma^2(\alpha^2)}{\sigma^2(s)} - \frac{\sigma(\alpha^2, s)}{\sigma_\alpha^2 \cdot \bar{s}}\right) \quad (28.44b)$$

Hence, in addition to σ_α^2 and \bar{s} , the equilibrium additive variance also depends on at least three other quantities. The first is the kurtosis of mutational trait effects, which enters

through the $\sigma^2(\alpha^2) = E[\alpha^4] - \sigma^4(\alpha)$ term in Equation 28.44b. The second is $\sigma(\alpha^2, s)$, the covariance between the selective effect, s , of a new mutation and the squared effect, α^2 , of that mutation on the focal trait. The third is $\sigma^2(s)$, the variance in pleiotropic selection coefficients. All three of these quantities influence the expected equilibrium variance. It is important to stress that knowledge of these quantities may not be sufficient, however, as the approximation given by Equation 28.44b can easily break down, making $E[\alpha^2/s]$ dependent on additional moments of the bivariate mutational distribution of (α^2, s) .

Barton (1990) and Kondrashov and Turelli (1992) examined a simplified version of this model with n identical loci, in which all mutations have the same deleterious effect, s (Example 28.10 provides some justification for this assumption), while α can vary. This base model sidesteps delicate issues on the bivariate (α, s) distribution, such as the nature of the covariance $\sigma(\alpha^2, s)$, and the behavior of the distribution for values of s near zero. While these **constant-s models** offer some important insights, as we detail below they can also be misleading.

Barton (1990) assumed multiplicative fitnesses, with an individual heterozygous at k deleterious loci having a fitness of $(1 - s)^k \simeq \exp(-sk)$, while Kondrashov and Turelli (1992) allowed for much more general fitness functions (including synergistic epistasis, and hence less of a selective load; Chapter 7). Both approaches yielded essentially the same conclusions. Let $\bar{k} = 2n\mu/s = 2n\tilde{p}$ denote the average number of deleterious alleles per diploid individual (an average of $2\tilde{p}$ deleterious alleles per locus). Assuming no linkage disequilibrium, summing Equation 28.44a over the contributions from the n loci yields

$$\tilde{\sigma}_A^2 \simeq 2n E[\alpha^2] \tilde{p} = \frac{2n\mu\sigma_\alpha^2}{s} = \bar{k} \sigma_\alpha^2 \quad (28.45a)$$

Because $\sigma_m^2 = 2n\mu\sigma_\alpha^2$, Equation 28.45a can also be expressed as the ratio of the amount of variation introduced by mutation each generation to the rate of its removal by selection

$$\tilde{\sigma}_A^2 = \frac{\sigma_m^2}{s} \quad (28.45b)$$

Recall that this is an alternative expression for the equilibrium additive variance under the Latter-Bulmer (and hence HCA) model (Equation 28.12b), showing that these very different models (pure pleiotropy versus stabilizing selection) have some similar features. This should not be surprising, as under the HCA, wild-type alleles are near the optimum and thus nearly all new mutations are deleterious (Chapter 27). The conceptual distinction between these two models is that the reason that a mutation is deleterious is specified under the HCA (it impacts a trait under stabilizing selection), but unspecified under the deleterious-pleiotropy model.

Using the standard value of $\sigma_m^2 \simeq 10^{-3}\sigma_E^2$ (LW Table 12.1) with $s \simeq 0.001$, Equation 28.45b yields $\tilde{\sigma}_A^2 \simeq \sigma_E^2$, and hence $\tilde{h}^2 \simeq 0.5$. This result looks promising in that weakly deleterious alleles can maintain levels of additive variance similar to those seen in natural populations. This is perhaps not surprising, in that a strictly neutral model maintains extensive variation in a large population, so that a model where the underlying loci are somewhat close to neutral should also accommodate significant variation.

Because there is no assumed selection on the focal trait, can this model also generate sufficiently strong apparent stabilizing selection? Individuals carrying more deleterious alleles also tend to have more extreme (positive and negative) trait values, generating a quadratic relationship between trait value and fitness, and thus a spurious signature of stabilizing selection. For example, an individual with k deleterious alleles has an approximate fitness of $1 - sk$ (under Barton's model) and a squared trait value of $z^2 = \sum_i^k \alpha_i^2$, where $E[z^2 | k] = k\sigma_\alpha^2$ (as $E[\alpha_i] = 0$ and $E[\alpha_i^2] = \sigma_\alpha^2$). The apparent strength of stabilizing selection, \hat{V}_s , follows from the quadratic term in Equation 28.3i, γ_{w,z^2} , the regression of relative fitness on the squared deviation from the mean (set here to zero for convenience),

$$\hat{V}_s \simeq -\frac{1}{\gamma_{w,z^2}} = \frac{\sigma^2(z^2)}{2\sigma(w, z^2)} \quad (28.46a)$$

as obtained by Barton (1990), Kondrashov and Turelli (1992), Gavrilets and de Jong (1993), Bürger (2000), and Zhang et al (2002). By evaluating the variance and covariance term in Equation 28.46a, Barton (1990) showed that the resulting apparent strength of stabilizing selection becomes

$$\hat{V}_s = \frac{\sigma_\alpha^2(3\kappa_4 + 2\bar{k})}{2s} = 3\frac{\sigma_\alpha^2\kappa_4}{2s} + 2\frac{\sigma_\alpha^2 n\mu}{s^2} = 3\frac{\sigma_\alpha^2\kappa_4}{2s} + \frac{\sigma_m^2}{s^2} \quad (28.46b)$$

with the middle step following from $\bar{k} = 2n\mu/s$. Here $\kappa_4 = E[\alpha^4]/(3\sigma_\alpha^4)$, the scaled kurtosis of trait mutational effects (Equation 28.18c), is greater than 1/3 if there is any variation in the values of trait mutations (as $E[\alpha^4] \geq \sigma_\alpha^4$). For $\bar{k} \gg \kappa_4$, Equation 28.46b implies that

$$\hat{V}_s \simeq \frac{\sigma_\alpha^2\bar{k}}{s} = \frac{\sigma_m^2}{s^2} = \frac{\tilde{\sigma}_A^2}{s} \quad (28.46c)$$

For arbitrary values of \bar{k} , combining Equations 28.45b and 28.46b yields the relationship

$$\frac{\tilde{\sigma}_A^2}{\hat{V}_s} = \left(\frac{2n\mu\sigma_\alpha^2}{s} \right) \left(\frac{2s}{\sigma_\alpha^2[3\kappa_4 + 2\bar{k}]} \right) = \frac{4n\mu}{3\kappa_4 + 2\bar{k}} = \frac{4n\mu}{3\kappa_4 + 4n\mu/s} \quad (28.46d)$$

which can be rearranged to

$$\tilde{\sigma}_A^2 = \frac{4\hat{V}_s n\mu}{3\kappa_4 + 2\bar{k}} < 4\hat{V}_s n\mu \quad (28.46e)$$

where the last step follows because $3\kappa_4 \geq 1$. Hence, for the same apparent strength of stabilizing selection, less additive variation is maintained under the constant- s pleiotropy model than with the same amount of real stabilizing selection under HCA conditions ($4V_s n\mu$; Equation 28.18a).

In contrast to the emergence of $\tilde{\sigma}_A^2 = \sigma_m^2/s$ for both the HCA and pleiotropy models (Equations 28.12b and 28.45b), the ratio of the equilibrium additive-genetic variance to the apparent strength of stabilizing selection is rather different between models, as

$$\tilde{\sigma}_A^2/\hat{V}_s = \begin{cases} \frac{4n\mu}{s} & \text{HCA} \\ \frac{4n\mu/(3\kappa_4)}{s} & \text{Deleterious pleiotropy (with } \bar{k} \ll 1) \\ s & \text{Deleterious pleiotropy (with } \bar{k} \gg 1) \end{cases} \quad (28.47a)$$

Under direct selection, V_s determines s (Equation 28.12c), while under pleiotropy, s determines \hat{V}_s (Equation 28.46b).

Can the constant- s model account for *both* the observed levels of variation *and* the strengths of stabilizing selection? It can not. With $s = 0.001$ and $\sigma_m^2 = \sigma_E^2/10^3$, Equation 28.45b yields $\tilde{\sigma}_A^2 = \sigma_E^2$. From Equation 28.47a, the induced apparent strength of stabilizing selection is $1000\sigma_E^2$ ($\hat{V}_s = \tilde{\sigma}_A^2/s = \sigma_E^2/0.001$), far too weak relative to estimates from natural populations of $\sim 20\sigma_E^2$. Conversely, taking observed values of V_s to be around $20\sigma_E^2$ and using a value of $\sigma_m^2 = \sigma_E^2/10^3$ in Equation 28.46c yields $s = \tilde{\sigma}_A^2/\hat{V}_s = \sigma_E^2/(20\sigma_E^2) = 0.05$. With this value of s , Equation 28.45a yields $\tilde{\sigma}_A^2 = 10^{-3}\sigma_E^2/0.05 = 0.02\sigma_E^2$, for an equilibrium heritability of $\tilde{h}^2 = 0.02/(1 + 0.02) \simeq 0.02$. Hence, using the typical estimate of the strength of stabilizing selection to estimate s yields too small a heritability.

The problem with the constant- s model is that it either does not produce enough additive variance (s is too large) or it gives apparent stabilizing selection that is too weak (s is too small, and the corresponding \hat{V}_s is too big). This failure follows because s influences both $\tilde{\sigma}_A^2$ and \hat{V}_s , imposing a constraint on their relationship (Barton 1990; Kondrashov and Turelli 1992; Gavrilets and de Jong 1993; Zhang et al 2002). From Equation 28.46d

$$\frac{\hat{V}_s}{\tilde{\sigma}_A^2} = \frac{3\kappa_4 + 4n\mu/s}{4n\mu} = \frac{3\kappa_4}{4n\mu} + \frac{1}{s} \geq \frac{1}{s} = \frac{\tilde{\sigma}_A^2}{\sigma_m^2} \quad (28.47b)$$

Noting that $\sigma_A^2 = [h^2/(1-h^2)]\sigma_E^2$, Equation 28.47b can be expressed as

$$\frac{\hat{V}_s}{\sigma_E^2} \geq \left[\frac{\tilde{h}^2}{1 - \tilde{h}^2} \right]^2 \frac{\sigma_E^2}{\sigma_m^2} \quad (28.47c)$$

Using this expression, typical values for selection ($\hat{V}_s/\sigma_E^2 = 20$) and mutational variance ($\sigma_E^2/\sigma_m^2 = 10^3$) imply an equilibrium heritability of less than 0.17. Thus, as with previous models, no constant value of s in the pure-pleiotropy model can produce both sufficiently strong apparent stabilizing selection and a moderate heritability.

While the constant- s model is mathematically tractable, it is also biologically unrealistic, as we expect s to vary and to be at least somewhat correlated with α , because mutations with large absolute effects are expected to be more deleterious. Does incorporation of these features resolve the inconsistencies between the equilibrium additive variance and strength of apparent stabilizing selection? The short answer is no, while the longer answer is that variation in s introduces additional complications.

When s (and α) vary over mutations, Equation 28.44a shows that the expected additive variation from a locus is $2\mu E[\alpha^2/s]$, and Equation 28.44b shows that in order to approximate $E[\alpha^2/s]$, one must (at least) specify both the correlation, ρ , between s and α^2 , as well as the kurtosis of the distribution of trait mutational effects, $\sigma^2(\alpha^2)$. Further, different families of bivariate distributions that otherwise have the same values for ρ and $\sigma^2(\alpha^2)$ can give very different results, making the outcome extremely model-dependent (Hill and Keightley 1988; Caballero and Keightley 1990; Keightley and Hill 1990; Johnson and Barton 2005), see Example 28.12.

One immediate problem arises from ρ . If $\rho = 1$, the HK model simply recovers mutation-stabilizing selection balance with its inherent limitations (because mutational effects are completely correlated, the value of α^2 determines the value of s). Conversely, for variable s when $\rho < 1$, the additive variance can continue to increase without limit with N_e . This occurs because some small fraction of new mutations are effectively neutral, with the additive variance approaching the neutral result (Equation 11.20c), but with a lower mutation rate. Because the effectively neutral mutation rate decreases as N_e increases (for any value of s , a sufficiently large value of N_e satisfies $4N_e|s| \gg 1$), the result is a less than linear increase in additive variation with N_e , but the resulting variance is still unbounded under many joint distributions of s and α . As Johnson and Barton (2005) note, the conditional distribution of α for those values of s very near zero (near neutrality) determines whether the additive variance is unbounded in N_e , and very slight differences in the assumed joint distribution of α and s can result in dramatic differences in behavior.

Despite this impact of ρ on the model behavior for large values of N_e , a few general features of the HK model emerge from extensive simulations by Caballero and Keightley (1990) and Keightley and Hill (1990), as well as from analytic results assuming a general bivariate gamma distribution for α and s (Zhang et al. 2002):

1. Allowing s to vary increases both $\tilde{\sigma}_A^2$ and V_s relative to a constant- s model (using $E[s]$ as the constant value), so that the strength of apparent stabilizing selection is generally too weak relative to observed values in nature, although abundant variation can potentially be maintained.
2. Dominance in trait mutations has little effect on the amount of trait variance maintained (this is not the case for fitness mutations, as we discuss shortly).
3. Increasing the correlation, ρ , between α^2 and s , decreases $\tilde{\sigma}_A^2$, as does increasing the average strength of deleterious selection, $E[s]$.
4. The volume of mutations in the effectively neutral region ($0 \leq N_e|s| \leq 1$) significantly impacts the resulting genetic architecture.
5. Increasing the kurtosis (generating a thicker tail, and therefore more outliers relative to a normal) has opposite effects for trait and fitness mutations. The equilibrium

additive variance for the focal trait increases with the kurtosis of the fitness effects, s , (and can be much larger than that for a constant- s model), but decreases with the kurtosis of trait mutational effects, α . Increased kurtosis in the distribution of fitness effects of mutations implies more nearly neutral mutations (and hence higher equilibrium frequencies), while increased trait kurtosis implies a larger fraction of small trait-effect mutations (with a smaller variance contribution per mutation). Recall that Example 28.10 showed that if the pleiotropic effects are the result of stabilizing selection on a number of independent traits, the distribution of s values approaches a normal, so that the resulting fitness distribution is *not* leptokurtic and does not generate extra variation.

Example 28.11. While the correlation between the fitness and trait effects of new mutations is extremely difficult to directly measure, McGuigan and Blows (2012) used a clever mutation-accumulation (MA) design (LW Chapter 12) in *Drosophila serrata* to examine the genetic covariances between fitness and two traits (wing size and shape) due to new mutations. Their experiment consisted of 100 completely inbred MA lines, where a female was allowed to choose among five brothers, allowing for sexual selection based on mate choice (S lines) versus another MA experiment in which random brothers were used for mating (N lines). Both mating designs have the same effective population size (females were allowed to only mate once), so that any significant changes in trait values (relative to the control, which accounts for the effects of drift on both traits) are the consequences of selection for mate choice. Previous work demonstrated that these wing features were not involved in mate choice, so that any significant change in these traits is due to pleiotropic effects from loci under selection for mate choice.

In addition to contrasting the evolution of these wing features in S versus N lines, McGuigan and Blows also scored fitness from the extinction rate of the MA lines and from the productivity (the number of offspring) of the extant lines. In the N lines, both wing traits decreased in extant lines, with lines with larger trait values also showing greater productivity. However, these associations were not seen in the sexually selected S lines. Both observations suggest deleterious mutations (for either total fitness or sexual selection) also had pleiotropic effects on the wing traits scored.

Example 28.12. As mentioned, the HK model for the maintenance of variation critically depends on the fine details of the joint distribution of fitness and trait effects in new mutations. While parameters of the joint distribution of α and s for spontaneous mutations are extremely difficult to obtain, Mackay et al. (1992) were able to estimate these for bristle number using a set of spontaneous P-factor insertion-induced mutations in *Drosophila melanogaster*. The mean effect of an insertion on bristle number was around 0.4 phenotypic standard deviations (σ_z), the mean s effect was 0.2, and the haploid genome mutation rate was about 0.1. The distributions of both s and α were leptokurtic, with many mutations having little to no effect, and a few mutations having major effects. The correlation, ρ , between the selection coefficient and absolute mutational effect was around 0.4.

Caballero and Keightley (1994) used these P-factor mutational values to parameterize an (α -reflected) bivariate gamma distribution ($s \leq 0; -\infty < \alpha < \infty$), which was then used to generate an α and s value for a new mutation. These authors used $N_e = 10^4$, and hence an average number of $2N_e\mu = 2000$ new mutations per generation, with the bivariate effects of each new mutation drawn from the aforementioned distribution. These simulations returned an equilibrium heritability of 0.4. A closer look at the architecture of the mutations generated in the simulations showed that the vast majority (87%) of these were highly deleterious ($N_e s < -30$). The table below gives the expected number of mutations (each generation) in various (s, α) classes, and the percentage of total additive-genetic trait variance attributable to each class. For example, in their simulations, on average 7 slightly deleterious mutations ($-1 \leq N_e s \leq 0$) arose in each generation, with an effect of 0.125–0.25 standard deviations on the trait. Such mutations account for roughly 13% of the equilibrium

additive-genetic variance.

α/σ_z	$-1 \leq N_e s \leq 0$		$-5 \leq N_e s < -1$	
	Num.	% σ_A^2	Num.	% σ_A^2
0–0.125	33	4	47	2
0.125–0.25	7	13	7	6
0.25–0.5	3	23	6	14
0.5–1	< 1	7	< 1	3
> 1	< 1	7		

The classes presented in this table accounted for 79% of the total additive variance, with the remaining 21% associated with highly deleterious mutations ($N_e s < -5$). The bulk, 56%, of additive-genetic trait variance is due to mildly to weakly deleterious alleles ($-5 \leq N_e s \leq 0$) of modest effect ($0.125 < \alpha/\sigma_z < 0.5$). On average, this contribution was due to only 1% (23/2000) of the new mutations that arose in the population each generation.

Caballero and Keightley (1994) also used a second, more crude, set of estimates of α and s from mutation-accumulation (MA) lines (and hence likely more reflective of the full spectrum of spontaneous mutations than the P -element values). The kurtosis and correlation of α and s were unknown for these MA data, but the haploid mutation rate was much higher (~ 1), while the average effects on fitness (s in the range of 0.01–0.02) and bristle number ($\sim 0.07\sigma_z$) were much lower than those estimated from the P -insertion data. The estimates of σ_m^2 differed by roughly a factor of two between the P and MA datasets, yet both datasets gave roughly similar expected heritabilities in simulations. Thus, when judged by the two easiest-to-measure macroscopic parameters, σ_m^2 and h^2 , the simulated outcomes using the MA and P -based joint distributions of α and s appear rather similar. Their resulting genetic architectures, however, are radically different. The bulk of additive variation in simulations using the MA-line values is due to alleles with small α values (58% with α less than $0.125\sigma_z$), most of which are highly deleterious ($N_e s < -30$). These disparate results arose from assumed differences in the bivariate distribution of effects, and thus depend on microscopic parameters that are extremely challenging to measure, much less with any precision.

Example 28.13. Much of the analytic results for the pleiotropic side-effects model follow from the results of Wright (1938b), and especially Kimura (1969), on the expected time, $\phi(x)$, that a selected (additive) mutation under irreversible mutation spends at frequency x . From Equation 7.13b, this is given by

$$\phi(x|N, N_e, s) = \frac{2N_e(1 - \exp[-4N_e s(1 - x)])}{Nx(1 - x)[1 - \exp(-4N_e s)]} \quad \text{for } \frac{1}{2N} \leq x \leq 1 - \frac{1}{2N}$$

Given that the additive variance contributed by an additive allele with effect α at frequency x is $2\alpha^2 x(1 - x)$, the variance contributed by the flux of new alleles ($2N\mu$ per generation) becomes

$$\begin{aligned} & 2N\mu \int_{1/(2N)}^{1-1/(2N)} \int_{s,\alpha} 2\alpha^2 x(1 - x) \cdot \phi(x|N, N_e, s) \cdot \varphi(s, \alpha) ds d\alpha dx \\ &= 4N_e \mu \int_{1/(2N)}^{1-1/(2N)} \int_{s,\alpha} \frac{\alpha^2(1 - \exp[-4N_e s(1 - x)])}{1 - \exp(-4N_e s)} \varphi(s, \alpha) ds d\alpha dx \end{aligned}$$

where $\varphi(s, \alpha)$ is the joint distribution of s and α in new mutations (Keightley and Hill 1990; Zhang and Hill 2002; Eyre-Walker 2010). Caballero and Keightley (1994) and Zhang et al. (2004) present a more general version allowing for dominance in both the trait and fitness.

An interesting analysis using this approach was provided by Eyre-Walker (2010). For analytic tractability, he assumed that the trait effect, α , of a mutation was related to its (deleterious) selection coefficient, s , by

$$\alpha = \delta(4N_e s)^\tau(1 + \epsilon)$$

where δ and ϵ are random variables, with δ either +1 or -1 with equal probability and $\epsilon \sim N(0, \sigma_\epsilon^2)$. Note that as $\sigma_\epsilon \rightarrow 0$, $|\alpha|$ and s are perfectly associated, while they become uncorrelated as $\sigma_\epsilon \rightarrow \infty$. The parameter τ measures how $|\alpha|$ increases with the strength of selection, for example, linearly when $\tau = 1$.

By assuming that the distribution of s was gamma, Eyre-Walker was able to obtain an analytic expression for the additive variance (in terms of the Hurwitz Zeta function, see his paper for details). Of particular interest was the fraction of the equilibrium additive-genetic variance contributed by alleles at frequency x , which turned out to be independent of σ_ϵ^2 . Figure 28.5 plots this fraction for various assumed values of τ for strong ($4N_e\bar{s} = 3000$) and weak ($4N_e\bar{s} = 30$) average selection against new mutations. When $\tau = 0$, trait alleles are neutral, and the majority of the genetic variance is due to intermediate to high frequency (derived) alleles. Conversely, as τ increases, the majority of variation is due to alleles of large effect at very low frequency. For example, for $4N_e\bar{s} = 3000$ and $\tau = 1$, 96% of the variance is contributed by alleles with frequency < 0.1%. As selection becomes weaker ($4N_e\bar{s}$ becomes smaller), the vast majority of the variation is due to alleles that are at low, rather than very low, frequencies.

The variance to allele-frequency relationship for purely neutral alleles is in sharp contrast to this observation that rare alleles account for most of the variation under the pleiotropic selection model. Because alleles are assumed neutral, there is no correlation between the effect of a new mutation, α , on a trait and its allele frequency. When expressed in terms of the minor-allele frequency (MAF), x , the folded Watterson distribution (Equation 2.34b) for neutral alleles at equilibrium is

$$\phi(x) = \frac{\theta}{x(1-x)} \quad \text{for } \frac{1}{2N} \leq x \leq \frac{1}{2} \quad \text{where } \theta = 4N_e\mu$$

Because the additive variance is given by $\sigma_A^2(x) = 2\alpha^2x(1-x)$, we have $\phi(x) \cdot \sigma_A^2(x) = 2\alpha^2/\theta$ for all values of x . As shown in Figure 28.6, this implies a uniform distribution, over $[0, 1/2]$, for the fraction of equilibrium variation contributed by a given allele-frequency class, with a fraction $2x$ of the total additive variance due to alleles with $\text{MAF} \leq x$ (Visscher et al. 2012b; Robinson et al. 2014). For example, in this neutral setting, 80% of all variation is due to alleles with a minor-allele frequency between 0.1 and 0.5.

Example 28.14. An interesting example of apparent stabilizing selection was given by McGuigan and Blows (2009). Recall from Chapter 13 (e.g., Equation 13.26a) that the genetic variance-covariance matrix, \mathbf{G} , associated with a vector, \mathbf{z} , of trait values is critical to understanding multivariate evolution (discussed in great detail in Volume 3). The first principal component (the leading eigenvector) of this matrix, \mathbf{g}_1 , represents the linear combination that accounts for the most genetic variation in this set of traits. In particular, the index $\mathbf{g}_1^T \mathbf{z} = \sum g_{1,i} z_i$ (where $g_{1,i}$ is the i th element of the leading eigenvector) has the largest genetic variance of any index of \mathbf{z} (Appendix 5).

McGuigan and Blows classified male *Drosophila bunnanda* into those that were successful in a mate-choice experiment (high fitness) and those that were not (low fitness). Previous work from the Blows lab demonstrated that females favor males with a particular combination of cuticular hydrocarbons (CHC), which we can write as an index score, $I = \mathbf{b}^T \mathbf{z}$, where \mathbf{b} is the vector of weights and \mathbf{z} is the vector of CHC scores. This score has been under strong directional selection, and hence it is not surprising that there is very little genetic variation in this index (i.e., little variation along the direction of the CHC multivariate-trait space given by the vector \mathbf{b} of weights). McGuigan and Blows compared the mating success of individuals based on a different CHC index, $H = \mathbf{g}_1^T \mathbf{z}$, namely, the index with the maximum genetic variance for CHC traits. Low-fitness males (poor mating success) tended to have extreme (high or low) H scores, while high-fitness males tended to have intermediate H values. Hence, a plot of mating success versus H shows an intermediate optimum, namely apparent stabilizing selection on H . However, there is no direct selection on H (indeed, it is almost orthogonal to the index, I , under selection by female choice), so the appearance of stabilizing selection likely arises from pleiotropic stabilizing selection on other fitness components that also influence CHC scores.

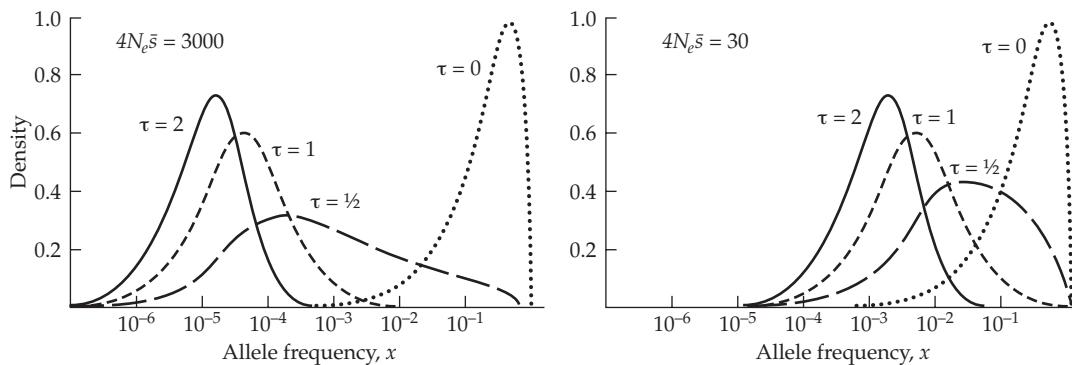

Figure 28.5 Results of the Eyre-Walker (2010) model for the maintenance of genetic variation for a neutral trait by deleterious mutations having pleiotropic effects. Here, \bar{s} is the average strength of selection against a new allele, and τ is a measure connecting the trait effect, α , to s , with $\tau = 0$ indicating neutrality (see Example 28.13 for details). The figure plots the probability density of the amount of equilibrium additive-genetic variance accounted for by alleles at a specific allele frequency, x , for two different values of $4N_e \bar{s}$. Hence, the amount of variation attributable to alleles in a certain frequency range is simply the area under the curve for that range.

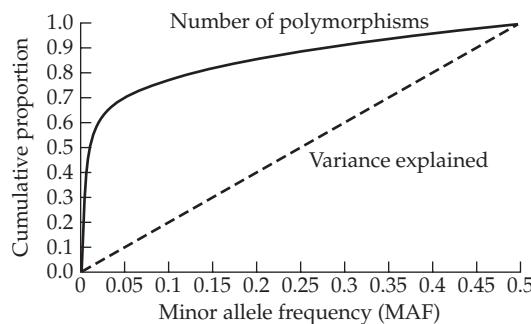

Figure 28.6 Expected number of polymorphisms, and the fraction of the trait variance explained, as a function of the minor allele frequency (MAF) under an equilibrium neutral model (i.e., the Watterson distribution). See Example 28.13 for details.

Sztepanacz and Rundle (2012) also observed this pattern in mate-choice experiments in the sister species *D. serrata*. Because \mathbf{g}_1 represents the direction of the most genetic variation, McGuigan et al. (2011) stated that it “is expected to capture a greater portion of the accumulated pleiotropic mutation in a set of traits, including mutations with pleiotropic effects on fitness. Consequently, strong stabilizing selection should be generated on \mathbf{g}_1 , providing the opportunity to investigate the genetic basis of fitness using this simple summary statistic.”

Deleterious Pleiotropy-stabilizing Selection (Joint-effects) Models

The final class of models relaxes the Hill-Keightley assumption that the focal trait is neutral, and instead allows it to be under stabilizing selection. This unified model is the most realistic, allowing for direct stabilizing selection, deleterious pleiotropic effects, and drift, but as such is also the most highly parameterized. It has all of the inherent complexity just seen for the HK model plus the additional complication of real stabilizing selection. While the most detailed analyses are by Zhang and Hill (Zhang and Hill 2002, 2003, 2005b; Zhang et al. 2004a), and indeed the term **joint-effects model** was coined by Zhang and Hill (2002), its

roots trace back to brief comments by Kondrashov and Turelli (1992). These were expanded on by Tanaka (1996b, 1998), who considered a model with a constant pleiotropic selection coefficient and (what amounts to) a constant effect, α , on the trait from new mutations. First, we present these early results, the conclusions of which are substantially altered when either α or s varies (Zhang and Hill 2002).

For weak selection, Kondrashov and Turelli noted that the total selection coefficient, s_T , on a new mutation is approximately the sum of its (assumed constant) pleiotropic deleterious effect, s_p , and the deleterious effect, s_d , from direct stabilizing selection (Equation 28.4c), yielding

$$s_T \simeq s_p + s_d = s_p + \frac{\alpha^2}{2V_s} \quad (28.48a)$$

Kondrashov and Turelli suggested that even when fairly strong stabilizing selection occurs on a trait, most of the selection on its underlying loci is from pleiotropic effects. One way to see their point is to consider the average value of s_d , which (from Equation 28.30d) is $\sigma_\alpha^2/(2V_s)$. Note that this increases with the mutational effects variance, σ_α^2 , and decreases with V_s (i.e., increases with the strength of stabilizing selection). To illustrate Kondrashov and Turelli's conjecture, we bias our assumptions in favor of larger values of s_d by assuming a high value, $0.1\sigma_E^2$, for σ_α^2 . By taking the standard value of $V_s \simeq 20\sigma_E^2$, Equation 28.30d yields $s_d \simeq 0.1/40 = 0.0025$. Using the Crow and Simmons (1983; also see Charlesworth 2015) estimate of $s_p = 0.02$ for deleterious mutations in *Drosophila* gives an eight-fold higher selection coefficient from pleiotropy, even under our assumption that was biased towards higher s_d values. Assuming an even larger mutational-effects variance ($\sigma_\alpha^2 = \sigma_E^2$, and hence $s_d = 0.025$) still leaves almost half of the selection from pleiotropic effects.

Given the value of s_T , Equation 28.45b suggests the equilibrium variance as

$$\tilde{\sigma}_A^2 \simeq \frac{\sigma_m^2}{s_T} = \frac{\sigma_m^2}{s_p + \alpha^2/(2V_s)} \quad (28.48b)$$

Further, as an approximation for α^2 , we can replace s_d by its average value (Equation 28.30d) to yield

$$\tilde{\sigma}_A^2 \simeq \frac{\sigma_m^2}{s_p + \sigma_\alpha^2/(2V_s)} = \frac{2V_s\sigma_m^2}{2V_ss_p + \sigma_\alpha^2} \quad (28.48c)$$

This expression recovers the pure pleiotropy value of σ_m^2/s_p (Equation 28.45b) for sufficiently large V_s (very weak stabilizing selection), and the HCA value of $2V_s\sigma_m^2/\sigma_\alpha^2 = 4V_sn\mu$ (Equation 28.18a) for sufficiently small s_p (very weak pleiotropic effects).

Comparison of Equations 28.48b and 28.45b shows that adding any amount of real stabilizing selection on the focal trait results in a reduction of the equilibrium variance relative to the pure pleiotropy model value of σ_m^2/s_p , as

$$\tilde{\sigma}_A^2 \simeq \frac{\sigma_m^2}{s_p + \alpha^2/(2V_s)} < \frac{\sigma_m^2}{s_p} \quad (28.48d)$$

This immediately resolves the delicate issue of additive variance increasing without limit as N_e increases under the HK model (when $\rho < 1$). Under the joint-effects model, as the effective population size increases, eventually $|N_e s_d| \gg 1$, and none of the trait mutations are effectively neutral, limiting the increase in additive variance as N_e increases.

Tanaka (1996b) and Zhang et al. (2004a) noted that the strength of *apparent* stabilizing selection, \hat{V}_s , under the joint action of *real* stabilizing selection, V_s , and deleterious pleiotropic effects, s_p , is

$$\hat{V}_s^{-1} = \hat{V}_{s,p}^{-1} + V_s^{-1} \quad (28.49)$$

where $\hat{V}_{s,p}$ is the induced strength of stabilizing selection from the pleiotropic effects alone (Equation 28.46b). Equation 28.49 implies $\hat{V}_s \leq V_s$, giving the apparent strength as greater

(as \widehat{V}_s is smaller) that the true amount of actual stabilizing selection, V_s . As noted by Zhang and Hill (2002), incorporating real stabilizing selection partly breaks the constraint given by Equation 28.46d between \widehat{V}_s and $\tilde{\sigma}_A^2$ that prevents a pure pleiotropy model from generating both significant variance and strong apparent stabilizing selection. However, even here there is a tradeoff. Relative to a pure pleiotropy model, adding direct stabilizing selection ($s_d > 0$) increases the apparent strength of selection (Equation 28.49), but does so at the expense of decreasing the equilibrium variance (Equation 28.48d).

Zhang and Hill (2002) showed that the connection between the observed strength of apparent stabilizing selection, \widehat{V}_s , and any real stabilizing selection on the trait, V_s , is given by

$$\widehat{V}_s = V_s \left(\frac{\tilde{\sigma}_A^4/V_s + \sigma_m^2 - \sigma_p(w, z^2)}{\tilde{\sigma}_A^4/V_s + \sigma_m^2} \right) \quad (28.50a)$$

where $\sigma_p(w, z^2)$ is the covariance between the relative fitness from pleiotropic effects and squared trait deviations from the mean (the latter is assumed to be at the optimum of zero). The bounds for this expression are

$$\widehat{V}_s^* \leq \widehat{V}_s \leq V_s \quad (28.50b)$$

The upper bound V_s (weakest apparent selection) occurs when the effects of pleiotropy are very small (Equation 28.50a converges to V_s as $\sigma_p[w, z^2] \rightarrow 0$). Conversely, the lower bound

$$\widehat{V}_s^* = \frac{\tilde{\sigma}_A^4}{\tilde{\sigma}_A^4/V_s + \sigma_m^2} \quad (28.50c)$$

corresponds to the strongest possible apparent selection under the joint-effects model. This lower bound is approached when the effects from pleiotropic selection dominate, so that $\sigma_p(w, z^2) \rightarrow \sigma_m^2$ (Zhang and Hill 2002; Zhang et al. 2002). When the lower bound holds, pleiotropy dominates, so $s_T \simeq s_p$, with Equation 20.45b yielding $\tilde{\sigma}_A^2 \simeq \sigma_m^2/s_p$, and Equation 28.50c rearranges to

$$\widehat{V}_s^* = \frac{(\sigma_m^2/s_p)^2/\sigma_m^2}{(\sigma_m^2/s_p)^2/(V_s \sigma_m^2) + 1} = \frac{(\sigma_m^2/s_p)/s_p}{(\sigma_m^2/s_p)/(V_s s_p) + 1} = \frac{\tilde{\sigma}_A^2/s_p}{\tilde{\sigma}_A^2/(V_s s_p) + 1} \quad (28.50d)$$

Recalling Equation 28.46c, $\tilde{\sigma}_A^2/s_p$ is the apparent stabilizing selection, $\widehat{V}_{s,p}$, under pure pleiotropy, implying that the smallest (strongest) value for apparent stabilizing selection under the joint-effects model is

$$\widehat{V}_s^* = \frac{\widehat{V}_{s,p}}{\widehat{V}_{s,p}/V_s + 1} \quad (28.50e)$$

Because $\widehat{V}_{s,p} = \tilde{\sigma}_A^2/s_p$ and $\tilde{\sigma}_A^2 = \sigma_m^2/s_p$ under the pure pleiotropy model (Equations 28.45b and 28.46c), when

$$\frac{\widehat{V}_{s,p}}{V_s} = \frac{(\tilde{\sigma}_A^2/s_p)}{V_s} \simeq \frac{\sigma_m^2}{V_s s_p^2} > 1 \quad (28.50f)$$

then \widehat{V}_s^* is less than half its constrained value under the pure pleiotropy model, $\widehat{V}_{s,p}$ (i.e., the apparent strength of stabilizing selection is twice as strong). Usually $\widehat{V}_{s,p}$ is fairly large when Equation 28.50f is satisfied, so reducing its value by half still leaves \widehat{V}_s too large to account for typically assumed values of $\sim 20\sigma_E^2$.

While joint-effects models with α and s constant give some insight as to how pure pleiotropy and real stabilizing selection interact, they also miss important consequences when either (or both) vary. A simple example makes the point. Suppose there are two equally frequent classes of pleiotropic mutants. The first has $s_p = 0.001$, while the second has $s_p = 0.1$. Further suppose that in both cases $s_d = 0.001$, generating half the mutations with $s_T = 0.002$ and the other half with $s_T = 0.101$. Substituting their average, $\bar{s}_T = 0.0515$,

into Equation 28.48b gives $\tilde{\sigma}_A^2 = \sigma_m^2/0.0515 \simeq 19\sigma_m^2$. However, the correct value is the average of the variation generated by each class

$$\frac{\sigma_m^2/0.002 + \sigma_m^2/0.101}{2} \simeq 255\sigma_m^2$$

resulting in substantially more genetic variance. More generally, suppose there are k classes of mutations, the i th of which has a total selection coefficient of $s_{T,i}$, and contributes a fraction, π_i , of the total mutational variance, then

$$\tilde{\sigma}_A^2 = \sigma_m^2 \sum_{i=1}^k \frac{\pi_i}{s_{T,i}} = \frac{\sigma_m^2}{(\bar{s}_T)_H} \quad \text{where} \quad (\bar{s}_T)_H = \left(\sum_{i=1}^k \frac{\pi_i}{s_{T,i}} \right)^{-1} \quad (28.51)$$

with s_T in Equation 28.48b replaced by its harmonic mean $(\bar{s}_T)_H$ (weighted by the fraction of σ_m^2 accounted for by a particular fitness class), rather than its arithmetic mean. This same argument applies to the pure pleiotropy model, and is the reason why variation in s generates a higher equilibrium variance than a constant- s model with the same mean selection value.

When s_p is constant but α varies, then for $s_p \gg \bar{s}_d$, the strength of apparent stabilizing selection approaches the lower bound, \hat{V}_s^* , given by Equation 28.50c. Zhang and Hill (2002) showed that the equilibrium additive variance is given by Equation 28.45b with

$$s_T \simeq s_p + 3\kappa_4 \bar{s}_d = s_p + 3\kappa_4 \frac{\sigma_\alpha^2}{2V_s} \quad (28.52a)$$

where κ_4 is the scaled kurtosis of trait mutational effects (Equation 28.18c). κ_4 is bounded below by 1/3, with $\kappa_4 = 1$ if mutational effects are drawn from a normal distribution and $\kappa_4 > 1$ for a leptokurtotic distribution. Equation 28.52a shows (as mentioned previously) that increasing the kurtosis of the trait mutational-effect values lowers the equilibrium additive variance. Alternatively, when $\bar{s}_d \gg s_p$, the apparent strength of stabilizing selection approaches V_s , and the equilibrium variance is given by the HCA (Equation 28.18a).

Finally, Zhang and Hill (2002) showed that when both α and s vary independently, these no longer need act in an additive fashion. By modeling α as normal and s as gamma, they found that

$$\bar{s}_T \simeq \bar{s}_d + \sqrt{\bar{s}_d \cdot \bar{s}_p} \quad (28.52b)$$

resulting in the average strength of direct selection, \bar{s}_d , being the primary driver for s_T , in contrast to the suggestion by Kondrashov and Turelli (1992), obtained by assuming constant values. Both types of selection (direct and pleiotropic) reduce the equilibrium additive variance, but the impact of pleiotropic selection now depends in part on the magnitude of direct selection. As Zhang and Hill noted, this unequal influence arises because a large value of s_d is always associated with large α^2 values, while the same is not true for s_p (as α , and hence s_d , and s are assumed to be uncorrelated in Equation 28.52b). For $\bar{s}_d \gg \bar{s}_p$, the equilibrium variance again reduces to the HCA result (Equation 28.18a), with $\hat{V}_s \simeq V_s$. When $\bar{s}_d \ll \bar{s}_p$, $\hat{V}_s \simeq \hat{V}_s^*$, and $s_T \simeq \sqrt{\bar{s}_d \cdot \bar{s}_p}$, and substituting into Equation 28.45b yields

$$\tilde{\sigma}_A^2 \simeq \frac{\sigma_m^2}{\sqrt{\bar{s}_d \cdot \bar{s}_p}} = \sqrt{\frac{\sigma_m^2}{\bar{s}_p}} \cdot \sqrt{\frac{\sigma_m^2}{\bar{s}_d}} \quad (28.52c)$$

Recalling (Equation 28.30d) that $\bar{s}_d = \sigma_\alpha^2/(2V_s)$ yields

$$\frac{\sigma_m^2}{\bar{s}_d} = \frac{2V_s \sigma_m^2}{\sigma_\alpha^2} = \frac{2V_s (2n\mu\sigma_\alpha^2)}{\sigma_\alpha^2} = 4n\mu V_s$$

resulting in

$$\tilde{\sigma}_A^2 \simeq \sqrt{4n\mu V_s \cdot \sigma_m^2 / \bar{s}_p} \quad (28.52d)$$

as found by Zhang and Hill (2002), who noted that this is the geometric mean of the HCA and pure pleiotropy models. Note that $\bar{s}_d \ll \bar{s}_p$ can occur under even strong direct stabilizing selection (V_s small) if the mutation rate is sufficiently high, as $\bar{s}_d = \sigma_\alpha^2 / (2V_s)$, and for fixed σ_m^2 , increasing the total mutation rate, $n\mu$, decreases $\sigma_\alpha^2 = \sigma_m^2 / (2n\mu)$, and hence decreases \bar{s}_d .

The above analysis for the joint-effects model assumes that mutations are additive for both the trait and for any pleiotropic effect on fitness. Zhang et al. (2004) noted that this assumption is not supported by the data, which suggest significant dominance, especially in fitness. Further, fitness mutations of large effect tend to be more recessive (otherwise they would simply not be segregating in the population). Under the assumption that mutations are more likely to be recessive for fitness than for a trait, Zhang et al. showed that the joint-effects model generates considerably more variation than under the above additive assumptions. Most of the resulting additive variance comes from alleles with nearly neutral effects on fitness as heterozygotes, while alleles of large effect contribute the most to the apparent stabilizing selection. Thus, there appear to be regions of the parameter space under which the joint-effects model could account for both significant additive variation and sufficiently strong stabilizing selection. The unresolved issue is whether these regions are biologically realistic. There is also the secondary concern (from our previous load arguments) that strong direct stabilizing selection can act on only a limited number of traits, which suggests that weak true stabilizing selection is the norm, not the exception, significantly narrowing the size of these successful regions of the parameter space.

Example 28.15. As an application of the joint-effects model, suppose that

$$V_s = 100\sigma_E^2, \quad \bar{s}_p = 0.005, \quad \sigma_m^2 = \sigma_E^2 / 10^3, \quad \text{and} \quad 2n\mu = 0.01$$

Thus, $\sigma_\alpha^2 = \sigma_m^2 / (2n\mu) = 0.1$ and $\bar{s}_d = \sigma_\alpha^2 / (2V_s) = 0.1 / (200) = 5 \cdot 10^{-5}$ (Equation 28.30d), so that $\bar{s}_d \ll \bar{s}_p$. Under HCA (Equation 28.18a), the equilibrium additive variance is $4n\mu V_s = 0.02 \cdot 100 \cdot \sigma_E^2 = 2\sigma_E^2$, while under pure pleiotropy (Equation 28.45b), it is $\sigma_m^2 / \bar{s}_p = 10^{-3}\sigma_E^2 / 0.005 = 0.2\sigma_E^2$. Applying Equation 28.52d, the equilibrium variance under the joint-effects model becomes $\sqrt{2 \cdot 0.2 \cdot \sigma_E^2} = 0.63\sigma_E^2$, for a heritability of $0.63 / (1 + 0.63) = 0.39$. Because $\bar{s}_d \ll \bar{s}_p$, the strength of apparent stabilizing selection is given by \hat{V}_s^* (Equation 28.50d)

$$\hat{V}_s^* / \sigma_E^2 = \frac{0.63 / 0.005}{0.63 / (100 \cdot 0.005) + 1} = 55.7$$

Thus, a reasonable amount of genetic variation is maintained at a moderate apparent strength of stabilizing selection.

HOW WELL DO THE MODELS FIT THE DATA?

To aid the reader who either skimmed or skipped the preceding rather technical theory sections, the major results from this analysis are summarized in Table 28.3. The central conclusion is that essentially all of the models have issues, generally being unable to simultaneously generate *both* a high value of $\tilde{\sigma}_A^2$ (heritability in the 0.2 to 0.6 range) *and* sufficiently strong apparent (or real) stabilizing selection ($\hat{V}_s \leq 20\sigma_E^2$). This led Johnson and Barton (2005) to lament that “it is puzzling that levels of heritability are so pervasive, so

Table 28.3 Inconsistencies between model predictions and the observed amounts of genetic variation, $\tilde{\sigma}_A^2$, and apparent strengths of natural selection, \hat{V}_s . Figure 28.1 summarized the various models.

Neutral focal trait, no selection	
Mutation-drift	Does not account for apparent stabilizing selection. Additive variance increases without limits as $N_e \rightarrow \infty$ under the incremental mutational model (Table 28.1).
Neutral focal trait, selection on pleiotropic underlying loci	
Fitness overdominance	Required strength of selection at overdominant loci generates a very large genetic load.
Mutation-selection balance	Prevents a small \hat{V}_s without a small $\tilde{\sigma}_A^2$.
Direct selection on focal trait	
Strict stabilizing selection	Fitness underdominance generated at underlying loci. Very little additive variance at equilibrium.
Stabilizing selection-mutation balance	Too much additive variance for the observed strengths of stabilizing selection.
Pleiotropic overdominance	Load and selection-response arguments (see Example 28.2).
Pleiotropic deleterious alleles (Joint-effects models)	Some parameter combinations allow for moderately strong apparent stabilizing selection with reasonable heritabilities.

high and roughly constant,” and that “we are in the somewhat embarrassing position of observing some remarkably robust patterns . . . and yet seeing no compelling explanation for them.” Before condemning the models, a more careful look at the data is in order.

Strength of Selection: Direct Selection on a Trait

Most of the above models can easily accommodate sufficient genetic variation. Indeed, a strictly neutral model generates *too much* variation. The more problematic issue is accounting for the observed strength of real (or apparent) stabilizing selection in nature, warranting a more careful look at the assumed literature values. If the strength of real or apparent stabilizing selection is weaker than is typically assumed, many of the apparent contradictions disappear, and a number of models can potentially account for the observations.

While Turelli’s (1984) benchmark of $V_s \simeq 20\sigma_E^2$ is typically assumed, the data today are both more extensive, and more problematic, than when he extracted this value from the literature. The classic paper by Lande and Arnold (1983), which launched an entire cottage industry on the estimation of these parameters, appeared at essentially the same time as Turelli’s analysis. We examine fitness estimation in detail in Chapters 29 and 30, noting here the basic conclusion that there is considerable uncertainty on the strength of natural selection on a typical trait. The relative constancy of many morphological phenotypes over evolutionary time is consistent with some form of stabilizing selection, as are the divergence data for gene-expression levels (Chapter 12). However, the *strength* of such selection is far less clear. The meta-analysis by Kingsolver et al. (2001) on the quadratic term, γ , of a Lande-Arnold fitness regression (Figure 30.5) shows that it is equally likely to be positive (disruptive selection) or negative (stabilizing selection). Conditioning on this value being negative, the mean strength is slightly stronger than Turelli’s value ($\sim 10\sigma_E^2$). If correct, these higher estimates of V_s are *more* problematic for the previous models.

Besides the standard concerns of measurement error and power (especially with an inherently noisy trait like fitness), there are three issues that significantly obscure the actual strength of selection on a trait (Chapters 29 and 30). First, almost all fitness-trait regressions in the literature use a *component* of fitness (such as mating success, fecundity, or viability), *not* total fitness itself. Such component-based estimates can be very misleading,

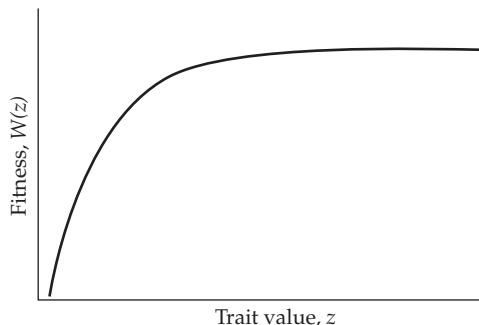

Figure 28.7 If the true fitness function has an asymptotic optimum, approximating it with a quadratic can be very misleading.

representing only a fraction of the total fitness (e.g., Johnston et al. 2013). Second, selection acting on phenotypically correlated characters obscures not just the actual strength of selection on a target trait, but more fundamentally can also disguise its true nature. For example, a neutral trait can show a strong signal of stabilizing selection if there is selection on phenotypically correlated traits (Example 28.1). The standard approach for dealing with this concern is a multivariate regression with a number of traits, in the hope that some of them are highly correlated with the actual targets of selection, so their inclusion acts as a covariate to reduce spurious associations. However, this approach is far from foolproof (Chapter 30). As Example 28.1 highlights, what matters for evolution is not the strength of selection on the phenotype, but rather the strength of selection on the *breeding value*. A highly heritable trait under strong apparent stabilizing selection can experience little to no selection on its breeding value if the target of selection is not the trait itself (Chapters 20, 29, and 30).

A more subtle issue is that most estimates of the strength of stabilizing selection are based on the quadratic term in a fitness regression (Equation 28.3i; Chapter 29). However, if Gaussian stabilizing selection or quadratic are poor models of the actual nature of nonadditive selection, these regression terms can be very misleading (see Figure 29.9). An alternative class of nonlinear candidate fitness functions are those that reach an asymptotic value (Figure 28.7). The quadratic approximations of such fitness functions are expected to be rather misleading, and (to our knowledge) little work has been done on the maintenance of quantitative-genetic variation under such a fitness function. The drift barrier (Chapter 7) arising from improved alleles eventually having too small a selective advantage to overpower drift could potentially result in considerable levels of variation at equilibrium.

Finally, there is also the issue of load discussed previously (e.g., Example 28.2), which suggests an upper bound on the number of independent traits under selection. Barton (1990) and Walsh and Blows (2009) suggested that strong selection is likely confined to a few dimensions in the multivariate trait space (i.e., a few indices of trait values), in which case selection impacts a very large number of traits, but each only weakly.

Example 28.16. Selection acts on multivariate phenotypes. When we examine the nature of selection on a trait-by-trait basis, we are examining the projection of this true multivariate selection surface onto a single dimension, which can be quite misleading. An excellent example of how to examine correlations between strength of stabilizing selection and genetic variation in a multivariate setting is found in Hunt et al. (2007b), which examined selection on mate calls in the cricket *Teleogryllus commodus*.

One advantage of this system is that the multivariate trait, call signal, can have any of its individual components artificially changed via computer software, and its impact on the measured fitness component (mate attraction) directly assessed through acoustic playback

trials in natural populations (Brooks et al. 2005). Five call components were examined, whose heritabilities ranged from 17% to 72%. These components were also strongly genetically correlated, with values ranging from -0.65 to 0.40 . Factor-analytic modeling (Hine and Blows 2006) gave strong support for three dimensions of the resulting genetic variance-covariance (\mathbf{G}) matrix for these five traits, with the first three eigenvalues (λ_1 to λ_3) accounting for 90% of the total additive-genetic variation. Here we denote their associated eigenvectors by \mathbf{g}_1 , \mathbf{g}_2 , and \mathbf{g}_3 . There was also close to significant support for the fourth eigenvalue, but no support for the final (fifth) dimension, as λ_5 was not significantly different from zero.

Using the methods of Chapter 30, the 5×5 matrix, $\boldsymbol{\gamma}$, of quadratic selection gradients of call components on mate attractiveness was estimated (Brooks et al. 2005). The diagonal elements (γ_{ii}) of $\boldsymbol{\gamma}$ correspond to the amount of quadratic selection on call component i , with a large negative value indicating strong stabilizing selection. This can be generalized to consider the amount of quadratic selection acting on some linear combination (i.e., an index) of trait values, $I = \sum a_i z_i = \mathbf{a}^T \mathbf{z}$, which is given by the quadratic product $\mathbf{a}^T \boldsymbol{\gamma} \mathbf{a}$ (Chapter 30 and Appendix 5). As expected, this generalization recovers the univariate result when the index $I = z_i$, as $\mathbf{a}^T \boldsymbol{\gamma} \mathbf{a} = \gamma_{ii}$ when $a_i = 1$ and all other elements of \mathbf{a} are 0.

Using these results, Hunt et al. examined the strength of stabilizing (negative values) or disruptive (positive values) selection on the index of trait values, $\mathbf{g}_i^T \mathbf{z}$, whose weights are given by the i th eigenvector. This corresponds to the nature of selection along the i th-largest axis of genetic variation, where the resulting strength of selection is given by $\mathbf{g}_i^T \boldsymbol{\gamma} \mathbf{g}_i$.

	\mathbf{g}_1	\mathbf{g}_2	\mathbf{g}_3	\mathbf{g}_4	\mathbf{g}_5
λ_i , eigenvalue of \mathbf{G}	0.930	0.468	0.235	0.125	0.065
% Genetic Variance	51.0	25.6	12.9	6.9	3.6
$\mathbf{g}_i^T \boldsymbol{\gamma} \mathbf{g}_i$	0.005	-0.012	-0.051	-0.097	-0.011

As the above table shows, there was very weak disruptive selection along the first eigenvector ($\mathbf{g}_1^T \boldsymbol{\gamma} \mathbf{g}_1 = 0.005$, which was not significantly different from zero), and increasingly strong stabilizing selection on eigenvectors 2 through 4. As the strength of stabilizing selection increased (-0.012 , -0.051 , -0.097), the amount of genetic variation in that direction decreased (25.6%, 12.9%, 6.9%). The eigenvector \mathbf{g}_5 breaks this pattern, but λ_5 was not significantly different from zero, and hence this direction of \mathbf{G} could simply be residual noise (Volume 3 examines the estimation of the true dimensionality of \mathbf{G} matrices in some detail). As summarized in the table, axes (combinations of trait values) with stronger stabilizing selection showed less genetic variation.

Another measure of the impact of selection is the expected within-generation change in \mathbf{G} from selection, which is given by $\Delta \mathbf{G} = \mathbf{G} \boldsymbol{\gamma} \mathbf{G}$ (in the absence of directional selection; Volume 3). The amount of change in the additive-genetic variance of a composite trait, $\mathbf{a}^T \mathbf{z}$, is

$$\Delta \sigma_A^2(\mathbf{a}^T \mathbf{z}) = \mathbf{a}^T \Delta \mathbf{G} \mathbf{a} = \mathbf{a}^T \mathbf{G} \boldsymbol{\gamma} \mathbf{G} \mathbf{a}$$

so that the amount of change in the genetic variance along the direction given by eigenvector i becomes $\Delta \sigma_A^2(\mathbf{g}_i) = \mathbf{g}_i^T \Delta \mathbf{G} \mathbf{g}_i = \mathbf{g}_i^T \mathbf{G} \boldsymbol{\gamma} \mathbf{G} \mathbf{g}_i$. The resulting absolute and percentage change in the genetic variance along each of the eigenvalues were as follows:

	\mathbf{g}_1	\mathbf{g}_2	\mathbf{g}_3	\mathbf{g}_4	\mathbf{g}_5
$\Delta \sigma_A^2(\mathbf{g}_i)$	0.00400	-0.00283	-0.00285	-0.00212	-0.00009
% change in σ_A^2	6.6	-7.8	-11.0	-13.0	-3.8

The expected change in the additive-genetic variance along the directions given by eigenvectors 2, 3, and 4 are -8% , -11% , and -13% , respectively. Axes (trait combinations) with the strongest amounts of stabilizing selection are expected to show the fastest erosion of additive variation, and this is the pattern seen in the above table.

For the five call components considered here, when considered one trait at a time (but still correcting for the fitness correlation among traits), the heritabilities and strengths of selection on the individual traits were

Trait	CPN	CIPD	TN	ICD	DF
h^2	0.719	0.388	0.257	0.167	0.293
γ_{ii}	0.006	-0.006	-0.040	-0.070	-0.047

While the previous pattern of lower heritabilities for traits under stronger selection still holds, note that stabilizing selection along the direction given by the eigenvectors of \mathbf{G} (i.e., on an index of trait values in this direction) is stronger than selection on any given trait (compare the magnitudes of γ_{ii} with those for $\mathbf{g}_i^T \boldsymbol{\gamma} \mathbf{g}_i$). If the strength of stabilizing selection was estimated in a truly univariate fashion (computing γ_{ii} ignoring the other four call components), estimates of the strength of quadratic selection would be even more untrustworthy given the strong correlations among these traits.

The message here is that a full multivariate analysis gives a much more accurate picture than a series of univariate analyses focusing on single traits, which can be very misleading (Blows and Walsh 2009; Walsh and Blows 2009; Volume 3). Assessment of the success of a model for the maintenance of variation has typically been applied to one trait at a time, by attempting to reconcile the observed values of V_s ($\simeq -1/\gamma_{ii}$; Equation 28.3i) with their corresponding h_i^2 values. As this example shows, a more accurate comparison is to examine the additive-genetic variance for the composite traits, $y_i = \mathbf{g}_i^T \mathbf{z}$, based on the eigenvalues of \mathbf{G} , and their corresponding multivariate measure of stabilizing selection, $\mathbf{g}_i^T \boldsymbol{\gamma} \mathbf{g}_i$.

Strength of Selection: Persistence Times of New Mutants

One measure of the strength of selection on the breeding value of a trait is offered by the ratio of the additive-genetic to mutational variances, $\tilde{\sigma}_A^2/\sigma_m^2$. As the equilibrium is reached when the variation introduced by mutation, σ_m^2 , is balanced by its removal, this ratio is a measure of the strength of selection against new mutations (whatever the cause, be it direct selection on the trait and/or pleiotropic fitness effects). This ratio also corresponds to the average number of individuals affected by a mutation before its removal (Li and Nei 1972), which Crow (1979, 1993) called the **persistence time** (as $1/s$ is the time scale for selective removal). The weaker selection, the slower the removal and the longer the persistence time of a new mutation.

More formally, we can use this ratio to assign approximate selection coefficients. Under the deleterious pleiotropy model, Equation 28.45b gives this ratio as $\tilde{\sigma}_A^2/\sigma_m^2 = 1/s$ when mutations have a fixed selective value. When s varies, it is replaced by their harmonic mean (Equation 28.51). Conversely, if the trait is under direct stabilizing selection, we can use the stochastic house of cards value for $\tilde{\sigma}_A^2$ (Equation 28.30a) to rewrite the persistence time in terms of s as

$$\begin{aligned}\tilde{\sigma}_A^2/\sigma_m^2 &= \frac{1}{\sigma_m^2} \left[\frac{4n\mu V_s}{1 + V_s/(N_e \sigma_\alpha^2)} \right] = \frac{N_e \sigma_\alpha^2}{2n\mu \sigma_\alpha^2} \left[\frac{4n\mu V_s}{N_e \sigma_\alpha^2 + V_s} \right] \\ &= \frac{2N_e V_s}{V_s + N_e \sigma_\alpha^2} = \frac{2N_e}{1 + N_e \sigma_\alpha^2/V_s} = \frac{2N_e}{1 + 2N_e s}\end{aligned}\quad (28.53a)$$

with the last step, $\sigma_\alpha^2/(2V_s) = s$, following from Equation 28.30d. Hence

$$\tilde{\sigma}_A^2/\sigma_m^2 = \frac{2N_e}{1 + 2N_e s} \simeq \begin{cases} 2N_e & \text{for } N_e s \ll 1 \\ s^{-1} & \text{for } N_e s \gg 1 \end{cases}\quad (28.53b)$$

Thus, under both pleiotropy and direct selection, it is often the case that $\tilde{\sigma}_A^2/\sigma_m^2 \simeq 1/s$. Akin to the use Robertson's secondary theorem of natural selection (Chapter 6 and 20) to examine the nature of selection acting directly on the breeding value of a trait, the persistence time measures the amount of selection (either directly or through pleiotropic effects) acting on the loci that underlie our focal trait.

Large values of this ratio (>1000) are more consistent with drift, smaller values with deleterious mutation-selection balance, be it pleiotropy or direct selection (Barton 1990). In a survey of 1 different organisms, Houle et al. (1996) found an average value of $\tilde{\sigma}_A^2/\sigma_m^2 \simeq 50$ for life history traits and $\simeq 100$ for morphological traits, supporting some version of deleterious mutation-selection balance, with stronger selection (shorter persistence times) on

life-history than on morphological traits. Houle et al. noted that these estimates raise a dilemma, in that if most of the genetic variation is associated with deleterious pleiotropic effects, it may have little bearing on adaptive evolution, which may largely be due to rare mutations with only weak pleiotropic side effects.

Number of Loci and Mutation Rates

One of the problematic issues with the maintenance of variation by stabilizing selection-mutation balance is that the haploid mutation rate, $n\mu$, must be sufficiently large to account for observed levels of variation. From Equation 28.12e, to achieve a heritability of h^2 when $V_s = K\sigma_E^2$ (i.e., a specific multiple, K) requires that

$$\frac{4V_s n\mu}{4V_s n\mu + \sigma_E^2} = \frac{4K\sigma_E^2 n\mu}{4K\sigma_E^2 n\mu + \sigma_E^2} = \frac{4Kn\mu}{4Kn\mu + 1} = h^2$$

or that $n\mu = h^2/[4K(1 - h^2)]$. For Turelli's value ($K = 20$), $h^2 = 1/3$ requires $n\mu = 0.0065$, while $h^2 = 1/2$ requires $n\mu = 0.0125$. For a standard assumed per-locus (per-generation) mutation rate of 10^{-5} , this value of $n\mu$ requires over a thousand loci ($n = 1250$). This argument led Latter (1960) to conclude that stabilizing selection-mutation balance could not account for standing levels of variation, a point echoed by Turelli (1984), provided standard assumptions ($n < 100$, $\mu < 10^{-5}$) are correct. Have more recent data shifted this view? Gametic mutation rates for fitness components have been estimated to be in the 0.01 to 0.1 range (LW Chapter 12; Shaw et al. 2002; Halligan and Keightley 2009). The few estimates for nonfitness traits are also in this range, although none of these estimates are without problems (LW Chapter 12). What do we know about the components n and μ ?

Consider the number of loci, n , first. Results from genome-wide association studies (GWASs) in humans typically find a large number of factors, each of very small effect (Chapter 24). The massive power loss in a typical GWAS due to conservative control over multiple comparisons ensures that the number of sites declared as significant is only a small fraction of the number of truly causative sites. This is one factor leading to the “problem” of “missing heritability” (Example 24.1). Thus, the notion that a typical trait may be influenced by hundreds of loci ($n > 500$) is less surprising than it once was. For example, Kemper et al. (2012) suggested that GWASs imply at least 1500 genes are involved in human height, while gene knock-out studies in mice suggested around 6000 loci for body size. At least several hundred loci are involved in maize plant height (Peiffer et al. 2014). Taken as a whole, the GWAS data have shifted the consensus to a much larger number of loci that can potentially influence a typical trait. Indeed, the method of genomic selection (Volume 3), which has rapidly been adopted by commercial breeders, rests on the assumption of a very large number of underlying loci, each of small effect (i.e., the infinitesimal genetics model; Chapter 24).

Turning to μ , as noted by Turelli (1984), the “typical” value of 10^{-6} to 10^{-5} for the mutation rate at a locus is based on alleles of large effect. One might easily imagine a higher mutation rate to alleles of smaller effect. Why is that the case? Under the view that much of quantitative-genetic variation is regulatory (as opposed to changes in amino-acid sequences), there is often a much larger, and far less granular, mutational target relative to a coding region, with many mutations likely resulting in very small regulatory changes. Other factors, such as the transposition of mobile elements (which often carry their own regulatory sequences) can potentially impact regulation at numerous sites far away from their point of insertion.

Assuming both a larger number of loci and a higher mutation rate per locus can account for the $n\mu$ values required for stabilizing selection-mutation balance to maintain sufficient variation, even in the face of fairly strong selection ($V_s = 20\sigma_E^2$). However, while one can certainly make a case for plausibility, it is also true that we are very uncertain about the estimates of key parameters (V_s , $n\mu$, σ_α^2). As a result, one can just as reasonably take values towards the lower end of their uncertainty distributions, retaining the claim that stabilizing selection-mutation balance cannot account for existing levels of variation. Further, as

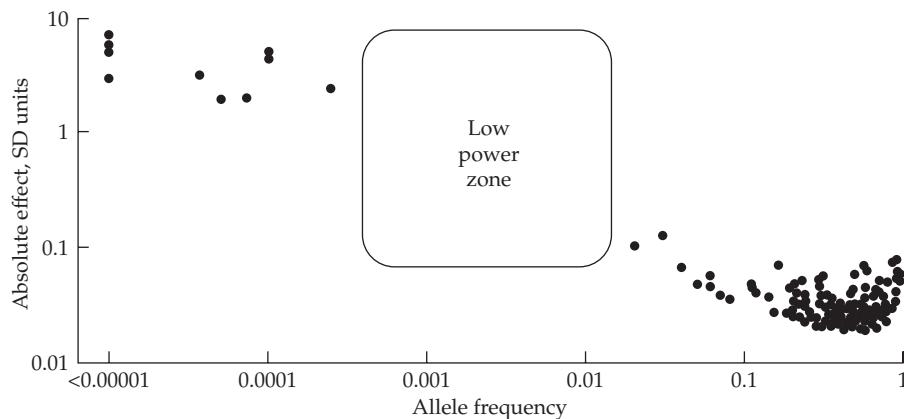

Figure 28.8 Plot of estimated allelic-effect size for known sites influencing human height versus allele frequency. The gap in the middle of the figure reflects a lack of power for either GWAS or linkage studies to detect genes in these regions. (After Kemper et al. 2012.)

we have noted above, load arguments imply that only a limited number of independent traits can be under stabilizing selection. Consequently, an observed V_s value for a focal trait is likely to be the projection (onto that trait) from some, likely very complicated, selection on a multivariate phenotype. Further, the strength of selection of interest is that on the *breeding value* of a trait, not that on its phenotype (Examples 28.1 and 28.16).

WHAT DOES GENETIC ARCHITECTURE TELL US?

A potential window into deciding which forces are predominantly responsible for quantitative variation is that the different models predict somewhat different genetic architectures. As noted by Kelly (2008), ideally such predictions are both **robust** and **exclusive**. Robust predictions imply that slight departures from model assumptions do not dramatically change the prediction, while exclusivity (predictions that are unique to a given model) is much more elusive.

One fairly robust prediction is that alleles in mutation-selection balance (MSB) should generally be at low frequencies. While this prediction is exclusive to MSB models, it does not distinguish between direct selection versus pleiotropic deleterious effects. In the case of direct stabilizing selection, alleles with larger trait effects have reduced fitness, generating a strong negative correlation between effect size and frequency. For trait alleles maintained by MSB due to pleiotropic deleterious fitness effects, the expected relationship between frequency and effect size is less clear. If there is a strong positive correlation between trait effect size and fitness, the same negative correlation is expected. Conversely, if there is a weak correlation, any such pattern would be greatly diminished.

These observations lead to the prediction of rare alleles of large effect under MSB scenarios (especially for direct stabilizing selection), while allele frequencies are expected to be more intermediate if balancing selection is involved. If trait alleles are largely neutral, (i.e., under selection, but only weakly so), then the distribution of allele frequencies is expected to be more L-shaped (approaching the Watterson distribution in an equilibrium population; Equation 2.34a), and (at best) show only a weak coupling between effect size and frequency. What do the data suggest? As we detail, the results from several independent lines of evidence are mixed.

As shown in Figure 28.8, the prediction under MSB of an inverse relationship between effect size and frequency clearly holds for human height. Alleles of large effect tend to be rare, although the poor resolution currently offered by mapping methods for genes of intermediate frequency and effect may temper this view somewhat. However, this observation

leaves unresolved the issue of whether this pattern is due to direct stabilizing selection on height, pleiotropic fitness effects (especially for mutations of large effects), or both. It is worth mentioning in passing that the assumption of the basic form of genomic selection (GBLUP, RR-BLUP) of a roughly constant variance over sites implies an assumption that alleles of large effect are rare, so that their variances, $\simeq 2\alpha^2 p$, are roughly constant.

Accelerated Responses in Artificial Selection Experiments

If rare alleles of large effect are the norm, this would imply an increase in the additive variance when such alleles are favored by artificial selection (Barton and Turelli 1987; Maynard Smith 1989). While such accelerated selection responses are typically not seen (Chapter 25), their absence may not be very damning for the rare-alleles model (Keightley and Hill 1989; Zhang et al. 2004b; Zhang and Hill 2005a). Most experiments start with a small sample from a natural population that is bred at modest size in the laboratory for several generations before being subjected to selection, which is problematic for detecting alleles whose frequencies are on the order of $\sim \mu/s \ll 0.001$ in the base population. Under such conditions, with significant drift and founder effects, rare alleles will be lost (the majority of the time) or (rarely) increase to modest frequencies, in both cases diminishing the likelihood of generating an accelerated response (Zhang et al. 2004b). Keightley and Hill (1989) and Zhang and Hill (2005a) showed that the effects of such sampling, coupled with the effects of negative linkage disequilibrium generated by directional selection reducing the additive variance (Chapter 16), make the predicted short-term response under rare-alleles models very close to that from the classic infinitesimal model. Thus, the lack of accelerated response is not a fatal observation against rare-alleles models under many experimental designs.

However, as noted by Curtsinger and Ming (1997), using an appropriate design can significantly improve the chances of rare alleles being detected (also see simulations by Kelly 2008). Curtsinger and Ming constructed three replicate base populations with favorable alleles at low frequency. They did so by repeatedly backcrossing three different inbred lines to a line that was selected for high ethanol tolerance for over 50 generations. Specifically, the F_1 s formed by crossing one of the inbred lines to the selected line was then backcrossed to the same inbred line, and then the resulting progeny again backcrossed to the same inbred line, and so on for five generations. Under this scheme, the frequencies of alleles from the increased tolerance line should be around 3% ($(0.5)^5$) in the base population for selection. They also constructed three control lines using the same general crossing scheme, but now backcrossing these same three inbred lines to an unselected population (the base population from which the tolerant line was selected). Thirty generations of selection for increased ethanol tolerance was performed using these six lines. All three lines constructed to contain favorable alleles (from the previously selected line) at low initial frequencies showed an acceleration in response around generation 15, while none of the control lines did. One key feature was large population size, with 1000 flies scored each generation and the top 20% used for the next generation.

Motivated by this “proof-of-concept” experiment, Kelly (2008) selected for both large and small flower size in *Mimulus guttatus*, using population sizes on the scale of the Curtsinger-Ming experiment. After accounting for potential scale effects (i.e., the variance increasing with the mean), Kelly found that the additive variance increased in the up-selected line, but decreased in the down-selected line. Such an asymmetric change in the variance is expected if rare alleles (presumably in MSB) disproportionately increase trait values. However, Kelly noted that such an asymmetric response could also occur with alleles at intermediate frequencies. He concluded that his results were, at best, only partly explained by the presence of rare alleles.

A related analysis by Nuzhdin et al. (1999) reached slightly different conclusions. They examined QTLs in high- and low-selected *Drosophila* lines for abdominal and sternopleural bristle number. While almost 30 QTLs were mapped, none was involved in the response in *both* the high- and low-selected lines. This suggests that none of the loci in the base population were segregating both positive and negative alleles at intermediate frequen-

cies, indicating a pre-selection architecture closer to a rare-alleles model. This is somewhat surprising, as Long et al. (2000) found two intermediate-frequency polymorphisms in the *achaete scute* gene complex in natural *Drosophila* populations that generated significant variation for both types of bristle number. However, both polymorphisms resulted in a reduction in both abdominal and sternopleural bristles, suggesting that directional mutation bias at underlying loci (generating either largely positive or largely negative alleles) could have also generated the results observed by both Kelly and Nuzhdin et al.

A final selection-based test for the majority of standing variation being due to rare alleles is to compare the selection response using a bottlenecked versus a larger initial population (Robertson 1960a; James 1970; Frankham 1980). As reviewed in Chapter 26, these results are more consistent with intermediate-frequency alleles, but Zhang and Hill (2005a) cautioned that when linkage is considered, the tests may not have much discriminating power.

Kelly's Test for Rare Recessives

A related prediction from MSB is that deleterious alleles will not only be rare, but will also tend to be recessive (because additive alleles would be removed much more quickly). Further, there should be directional dominance (with heterozygotes being closer in fitness to wildtype, as opposed to mutant, homozygotes), leading to inbreeding depression (LW Chapter 10). Kelly (1999c) used this observation to construct a creative test for the presence of rare, recessive alleles. He noted that if genetic variation is due to such alleles, the ratio of the covariance of additive and dominance effects, $\sigma(a, d)$, to the additive variance, σ_A^2 , should be greater than or equal to one (see the figure in Example 11.1). Recall that $\sigma(a, d) = \sigma_{ADI}/2$ (Table 11.1) appears in discussions of the covariance between inbred relatives (Chapter 11). Conversely, the ratio σ_{ADI}/σ_A^2 should be close to zero, or even negative, if most of standing variation is due to alleles at intermediate frequencies. Although Kelly assumed no epistasis, Charlesworth et al. (2007) discussed its impact on this test. Kelly (1999c, Kelly and Willis 2001) noted that while σ_{ADI} can be (rather imprecisely) estimated from covariances of inbred relatives (Chapter 11), a much cleaner estimate follows from a selection experiment. This is accomplished by contrasting the change in the mean, $\Delta\mu$, with the change in the coefficient, B , for inbreeding depression (Equation 23.1a). B (as well as μ) are measured over several generations of selection, and the ratio of their respective changes in computed (see Kelly 1999c for details). A value of $\Delta B/\Delta\mu$, which tracks σ_{ADI}/σ_A^2 , that is greater than or equal to one is consistent with rare, recessive alleles. Negative values, consistent with intermediate alleles, were seen in three independent selection experiments on flower size in *Mimulus guttatus* (Kelly and Willis 2001), leading the authors to suggest that some form of balancing selection maintains flower size. Charlesworth et al. (2007) used Kelly's method to also find evidence of intermediate-frequency alleles underlying female fecundity in *Drosophila melanogaster* (also see Charlesworth 2015).

SUMMARY: WHAT FORCES MAINTAIN QUANTITATIVE-GENETIC VARIATION?

Over thirty years after Turelli (1984) lamented that more data and theory are needed to resolve the maintenance of variation conundrum, we have a flood of estimates of the strength of selection, rich GWAS and other genomic data, and considerably more theoretical development. Despite this, Turelli's main point (echoed by Johnson and Barton 2005) remains: *There is still no clear resolution on the evolutionary forces responsible for the maintenance of variation.* Estimates of critical quantities, such as the strength of selection (\widehat{V}_S) and mutational parameters (n, μ, σ_α^2) are still sufficiently fuzzy to allow advocates of any particular model to proclaim that it largely fits the data, and opponents to insist that it does not. Further, despite a wealth of sophisticated analysis of new models, most fail to jointly account for high apparent levels of stabilizing selection while maintaining sufficient variation. Parameter values allowing for sufficient variation result in too little apparent stabilizing selection, and vice-versa. Adding to the confusion, genetic architecture data suggest an important role for mutation-selection balance (MSB), namely, the negative association

between trait effect and frequency, but also suggest intermediate frequency alleles are important for selection response, which is counter to predictions from MSB (at least in large populations).

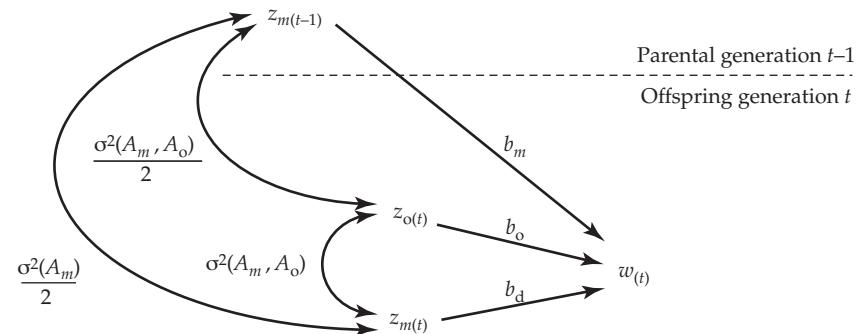

What is clear? Barton's (1990) insight that much of the variation associated with a trait is likely maintained for reasons independent of that trait's fitness continues to gain traction, both empirically and theoretically. Load arguments suggest that stabilizing selection can only act on a relatively small set of independent dimensions in character space. Pleiotropy is clearly the norm for many or even most genes, although the number of traits that a new mutation impacts remains unclear, as does the critical question of the pleiotropic connection between alleles influencing a given trait and general fitness. Chapter 27 examined some of the theory on the issues.

One factor that is likely clouding our view is that much of the discussion of the maintenance of variation has been set in a univariate framework: given the apparent strength of selection on a specific trait, how can we account for its heritability? As Example 28.16 illustrates, and as we stress at length in Volume 3, selection and evolution act on integrated and connected multivariate phenotypes, not a series of independent univariate traits. One can have considerable heritabilities over a series of traits, yet have one (or more) indices based on these traits with heritabilities very close to zero. Hence, one could have selection based on one or more indices of trait values, where selection drives the heritability of the index to rather small values, while still having moderate heritabilities in the component traits. As illustrated in this chapter, the theory for the maintenance of variation based on single traits gives a very poor fit to the data, but it might be in better accord with the underlying selection index if we were able to extract such information from a multivariate analysis.

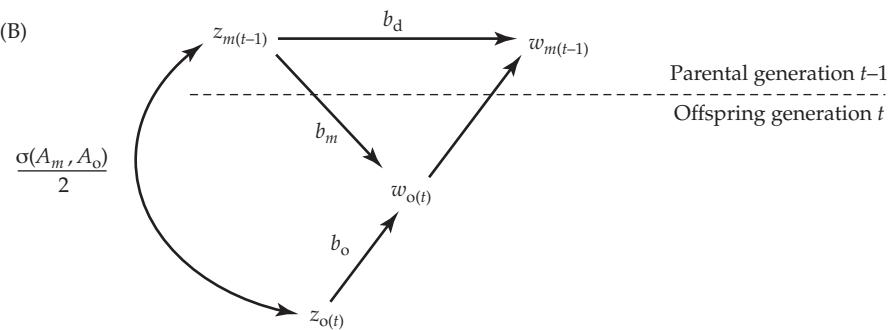

VII

Measuring Selection on Traits

(A)

(B)

Individual Fitness and the Measurement of Univariate Selection

Natural selection is not evolution. R. A. Fisher (1930)

Previous chapters have examined the response to artificial selection, wherein the nature of selection is known to the investigator. Here we are concerned with the complementary issue of measuring how selection acts on particular phenotypes (**phenotypic selection**). This involves two related issues: measuring **individual fitness**, W , and determining if the phenotype of a particular character influences fitness (and, if so, the nature of this relationship). The latter question is often phrased in terms of estimating the generalized regression $W(z) = E[W | z]$, the expected fitness of an individual with character value z .

The first half of this chapter deals with various aspects of individual fitness, focusing on fitness components and measuring fitness over multiple episodes of selection. We review the properties of an especially useful statistic, the population variance in relative fitness (the **opportunity for selection**, I), which bounds the maximum possible within-generation change in the mean and variance of any character. We also examine issues regarding the measurement of **sexual selection** (fitness variation generated by mate choice).

The second half of this chapter considers the complementary problem of predicting the expected fitness of an individual given its phenotypic value. Our discussion here is concerned with selection acting exclusively on a single character. This admittedly unrealistic situation offers the advantage of allowing basic methodological points to be addressed without the additional complications inherent in a multivariate analysis. Chapter 30 extends these univariate ideas to the situation where the individual phenotypic value is a vector, \mathbf{z} , of trait values. The major complication in assigning fitnesses to traits is selection on phenotypically correlated characters. A within-generation change in the distribution of a trait may be due to **direct** selection on that trait, **indirect** effects of selection on phenotypically correlated (and usually unmeasured) characters, or both (Chapters 13, 20, and 30).

Excellent discussions on the detection of selection in natural populations can be found in Manly (1985), Endler (1986), Primack and Kang (1989), Brodie et al. (1995), and Kingsolver and Pfenning (2007), while summaries of estimates of the nature and strength of selection can also be found in Endler (1986), Conner (2001), Hoekstra et al. (2001), Kingsolver et al. (2001, 2012), Geber and Griffen (2003), Hereford et al. (2004), Kingsolver and Pfenning (2007), Siepielski et al. (2009, 2011, 2013), Kingsolver and Diamond (2011), and Morrissey and Hadfield (2012). We emphasize that these approaches are not restricted to “wild” populations. They can be used to study natural selection in domesticated populations, even those undergoing artificial selection. As noted by Stearns et al. (2010), these methods can also be used to study selection in contemporary human populations (Example 20.7), especially given the rich datasets that exist for a number of very large clinical cohorts.

Much of the literature on estimating fitness, fitness components, and fitness-trait relationships is dominated by ideas initiated by Pearson (1903) and greatly expanded by Lande and Arnold (1983) and Arnold and Wade (1984a, 1984b), which we largely follow. Indeed, almost all of the current estimates of fitness gradients are based on the approach of Lande and Arnold. Despite the vast reach and importance of these papers, the last few decades have seen movement away from some of their approaches and toward more statistically robust methods. Thus, we conclude with a discussion of some of these more recent developments, which continues into Chapter 30.

EPISODES OF SELECTION AND THE ASSIGNMENT OF FITNESS

Selection can often be subdivided into discrete, nonoverlapping stages called **episodes of selection**. For example, a distinction is often made between **viability selection** (differences in survivorship) and **fertility selection** (differences in the number of offspring per mating). **Tradeoffs** may be found, wherein a trait that does well in one episode does poorly in another. For example, large body size is usually favored in adults of Darwin's medium ground finch (*Geospiza fortis*; Boag and Grant 1981; Price et al. 1984), while small body size is apparently favored in juveniles (Price and Grant 1984). The possibility of tradeoffs between **natural selection** and **sexual selection**, which was first suggested by Darwin (1859), has also received significant attention. It is interesting to note that Darwin's contemporary, and the co-propounder of evolution by natural selection, Alfred Wallace, did not believe that females would choose mates with lower viabilities, and hence discounted any such sexual selection versus natural selection tradeoffs (Moore and Pannell 2011). Sexual selection occurs when variance in the ability to acquire mates results in variance in the number of offspring, while natural selection results from variance in all other fitness components, such as viability and fertility differences, and variation in the quality in parental care.

Fitness Components

We start with two simplifying assumptions. The first is that generations are discrete and non-overlapping, where the actual *timing* of reproduction is unimportant. Second, we assume that the parental phenotypes (or more generally, the phenotypes of other individuals that interact with our focal individual) have no influence on that individual's fitness (Chapter 22). Some of the consequences when these assumptions fail will be considered shortly.

Under these simplifying assumptions, the **lifetime** (or **total**) **fitness** of an individual is the number of descendants that it leaves at the start of the next generation. When measuring the total fitness of an individual, care must be taken not to span generations or to overlook any stage of the life cycle in which selection acts. To accommodate these concerns, lifetime fitness is defined as the total number of zygotes (newly fertilized eggs) that an individual produces. Measuring total fitness from any other starting point in the life cycle (e.g., from adults in one generation to adults in the subsequent generation) can result in a very distorted picture of the true fitness of particular phenotypes (Prout 1965, 1969). In particular, if generations are spanned, measures of selection on a particular parental phenotype will be averages over both parental and offspring phenotypes, which can differ considerably. We revisit this strict view of not allowing fitness measures to cross generational boundaries later in this chapter (and also in Chapter 30 and in Volume 3), where we examine how fitnesses associated with parental care should be modeled.

Systems for measuring lifetime fitness have been especially well developed for laboratory populations of *Drosophila* (reviewed by Sved 1989). Measurement of *lifetime* fitness in nature is much more difficult and (not surprisingly) is rarely accomplished (although see Chapter 20). Attention instead is usually focused on particular *episodes* of selection or selection during particular phases of the life cycle. Fitness components for each episode of selection are usually defined to be **multiplicative**. For example, lifetime fitness (total number of offspring) can be partitioned as (probability of surviving to reproductive age)·(number of mates)·(number of zygotes per mating). Number of mates is a measure of sexual selection, while the viability and fertility components measure natural selection. A commonly measured fitness component is **reproductive success (RS)**, the number of offspring per adult, which confounds natural selection (fertility) and sexual selection (the number of successful matings). Clutton-Brock (1988a) reviewed estimates of reproductive success from natural populations.

Fitness components can themselves be further decomposed. For example, fertility in plants might be decomposed as (seeds per plant) = (number of stems per plant)·(number of inflorescences per stem)·(average number of seed capsules per inflorescence)·(average number of seeds per capsule). This decomposition allows an investigator to ask questions

of the form: do plants differ in the number of seeds mainly because some plants have more stems, or more flowers per stem, or are there tradeoffs between these? As this example suggests, the nature of fitness components chosen by an investigator is often set by ecological or behavioral, rather than evolutionary, concerns. Ideally, components should be *sequential*, with one episode finishing before the next begins, or (as with our plant example) they should represent nonoverlapping features. However, complications can occur. For example, the total number of mates (which is seemingly a measure of sexual selection) is equivalent to the product of the average number of mates per day and the number of days survived during the mating period. The former is a strict measure of sexual selection, whereas the latter (viability) is a measure of natural selection, resulting in the total number of mates being a compound measure of both natural and sexual selection.

Estimates of fitness can be obtained from either **longitudinal** studies or **cross-sectional** studies. A longitudinal study follows a cohort of individuals over time, while a cross-sectional study examines individuals at a single point (or a very narrow window) in time. Cross-sectional studies often generate only two fitness classes (e.g., dead versus living, mated versus unmated). Longitudinal studies are preferred, as the analysis of cross-sectional studies involves numerous assumptions (Lande and Arnold 1983; Arnold and Wade 1984b). Unfortunately, longitudinal studies usually require far more work and can be extremely challenging in many settings. As mentioned, age-structured populations pose further complications that will be considered in brief shortly, and in detail in Volume 3.

Finally, more complicated life cycles can be modeled as a path diagram (LW Appendix 2), generating a **life-history graph** (Figure 29.12). This more general structure allows for much more complex interactions among fitness components, which need not be sequential. One approach for the analysis of such graphs uses so-called **aster models** (Geyer et al. 2007; Shaw et al. 2008), a statistically rigorous framework that explicitly recovers the correct distribution of fitness effects after multiple episodes of selection. We examine this approach at the end of the chapter. Other approaches, such as those based on path analysis (e.g., latent variable analysis), are discussed in Chapter 30.

Assigning Fitness Components

We now turn to the task of partitioning measures of individual fitnesses in a longitudinal study into fitness components. A cohort of n individuals (indexed by $1 \leq r \leq n$) is followed through several discrete (nonoverlapping) episodes of selection. Let $W_j(r)$ be the fitness measure for the j th episode of selection for individual r . For example, if we are following viability, then W_j is either zero (dead) or one (alive) at the census period. **Relative fitness** components, $w_j(r) = W_j(r)/\bar{W}_j$ (mean-standardized fitnesses), will turn out to be especially useful (as $\bar{w}_j = 1$). At the start of a study, the frequency of each individual is $1/n$, yielding the mean fitness for the first (observed) episode of selection as

$$\bar{W}_1 = \frac{1}{n} \sum_{r=1}^n W_1(r) \quad (29.1a)$$

(We note the very real possibility that *considerable selection on the focal trait may have already occurred prior to the life-cycle stages being examined*; Example 29.1.) Following this first episode, the new fitness-weighted frequency of the r th individual is $w_1(r)/n$, implying that the mean fitness for the second episode of selection is calculated by

$$\bar{W}_2 = \sum_{r=1}^n W_2(r) \cdot w_1(r) \cdot \left(\frac{1}{n}\right) \quad (29.1b)$$

In general, for the j th episode of selection,

$$\bar{W}_j = \sum_{r=1}^n W_j(r) \cdot w_{j-1}(r) \cdot w_{j-2}(r) \cdots w_1(r) \cdot \left(\frac{1}{n}\right) \quad (29.1c)$$

Note that if $W_j(r) = 0$, further fitness components for r are unmeasured. If we let $p_j(r)$ be the fitness-weighted frequency of individual r after j episodes of selection, it follows that $p_0(r) = 1/n$ and

$$p_j(r) = w_j(r) \cdot p_{j-1}(r) = \frac{1}{n} \prod_{i=1}^j w_i(r), \quad \text{where} \quad \sum_{r=1}^n p_j(r) = 1 \quad (29.2a)$$

The $1/n$ term represents the initial frequency of individual r , while the product is the total relative fitness for individual r following the j episodes of selection. It immediately follows that Equation 29.1c can be expressed as $\bar{W}_j = \sum W_j(r) \cdot p_{j-1}(r)$. Using these weights allows fitness-weighted moments to be calculated. For example, the fitness-weighted mean of a particular character following the j th episode is given by

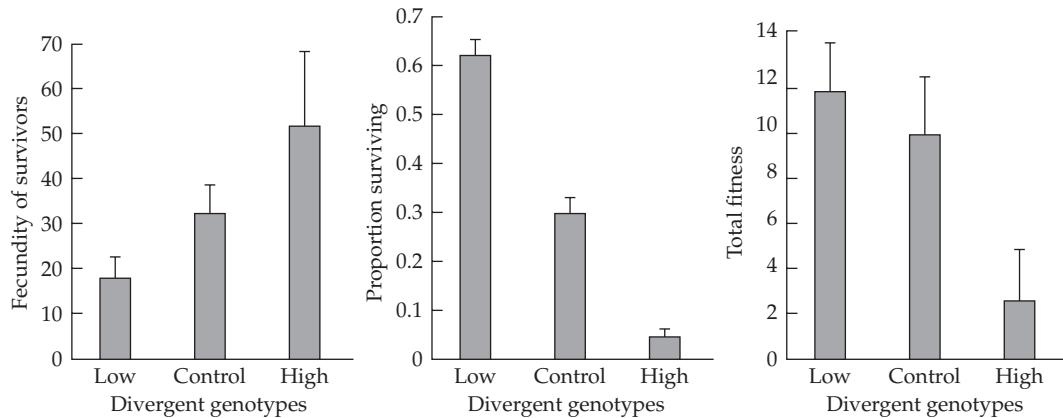

$$\bar{z}_j = \sum_{r=1}^n z(r) \cdot p_j(r) \quad (29.2b)$$

where $z(r)$ is the value of the character in individual r . Likewise, the sample variance is

$$\text{Var}(z_j) = \frac{n}{n-1} \left[\sum_{r=1}^n z^2(r) \cdot p_j(r) - (\bar{z}_j)^2 \right] \quad (29.2c)$$

As discussed later in the chapter, the fitness distribution over a particular episode (or component) may closely correspond to a standard distribution, such as a Bernoulli random variable (with a value of zero or one) for survival or mating status, or a Poisson for the number of offspring or mates. However, the resulting compound distribution of fitness over several episodes is generally very complex. In particular, we usually expect a large probability mass at zero, representing individuals that did not reproduce. The resulting distribution generally does not correspond to any standard one, nor can it easily be transformed into one. As discussed at the end of the chapter, the aster-model approach can be used to construct the full unconditional distribution of total fitness.

Example 29.1. Mojica and Kelly (2010) presented an important cautionary study regarding the interpretation of fitness components. They reviewed a number of studies showing a distinct fitness advantage for larger flower size. To test this association, they planted seedlings of three distinct flower-size genotypes (High, Low, and Control) of yellow monkey flower (*Mimulus guttatus*) in the wild. These lines were the result of selection experiments for increased (High) and decreased (Low) flower size from the starting control population.

As the left-most figure shows, surviving individuals of the larger-flower (High) genotype had significantly higher fecundity than did the control or the small-flower (Low) genotype,

consistent with the literature pattern of larger flowers having a selective advantage. However, the authors also found a massive (over tenfold) difference in survival (middle panel). The large-flower genotype required significantly more time to mature (flower) during a period when water stress becomes increasingly important. Total fitness (fecundity times survival; right panel) shows a very large advantage for the small-flower over the large-flower genotypes, which would be entirely missed in the absence of these transplant experiments. Note also that there is not a significant difference in total fitness between the control and small-flower genotypes, although the control genotype had significantly higher fecundity and significantly lower survival than the small-flower genotype, illustrating tradeoffs between life-history components.

Example 29.2. Total reproductive success ($W = W_1 \cdot W_2$) and its components, mating success (W_1) and fertility (W_2 ; eggs per successful mating), were measured in 38 male bullfrogs (*Rana catesbeiana*) in a longitudinal study conducted by Howard (1979). For illustrative purposes, we use part of this dataset to examine these fitness components in five males, along with their body size, z (in mm):

Male	z	W_1	W_2	w_1	p_1	w_2	p_2
1	145	1	25,820	0.714	0.143	1.628	0.233
2	128	1	22,670	0.714	0.143	1.429	0.204
3	148	0	0	0	0	0	0
4	138	2	7,230	1.429	0.286	0.456	0.130
5	141	3	15,986	2.143	0.428	1.008	0.433

Before selection, each male has frequency of $1/5$, resulting in

$$\bar{W}_1 = \frac{1}{5} (1 + 1 + 0 + 2 + 3) = \frac{7}{5} = 1.4 \quad \text{and} \quad w_1 = \frac{W_1}{1.4}$$

While the *observed* frequencies of individuals have not changed after the first episode of selection (all are still present in the population), their *fitness-weighted* frequencies change due to differences in acquiring mates. For male 2, $p_1(2) = 0.714/5 = 0.143$ (e.g., 14.3% of the seven matings in the population involved this male), and the values for the other adults were similarly obtained. The mean fertility *per mating* is

$$\begin{aligned} \bar{W}_2 &= \sum_{r=1}^n W_2(r) \cdot p_1(r) \\ &= (25,820 \cdot 0.143) + (22,670 \cdot 0.143) + (7230 \cdot 0.286) + (15,986 \cdot 0.429) = 15,860 \end{aligned}$$

If each reproducing male were weighted equally, average total fertility per individual (independent of the number of times each mates) would be $(1/4) \cdot (25,820 + 22,670 + 7230 + 15,986) = 17,927$. The actual mean fertility *per mating*, $\bar{W}_2 = 15,860$, is lower because males 4 and 5 had much lower fertility than the other (successful) males. Using $w_2(r) = W_2(r)/(15,860)$ and recalling Equation 29.2a, the final fitness weighting for male 1 is $(1/5) \cdot 0.714 \cdot 1.628 = 0.233$ (namely, 23.3% of all eggs produced by these five males were sired by this male). The remaining p_2 values in the table are similarly computed.

Using the body sizes for the males given above, the preselection mean and variance are $\bar{z}_0 = 140.0$ and $\text{Var}(z_0) = 59.5$. From Equation 29.2b, the fitness-weighted mean following the first episode of selection is

$$\bar{z}_1 = (145 \cdot 0.143) + (128 \cdot 0.143) + (148 \cdot 0) + (138 \cdot 0.286) + (141 \cdot 0.429) = 138.86$$

Thus, if we take a hypothetical offspring following the first episode of selection, the mean size of the adult that produced this randomly chosen offspring is 139. Similarly, we find that $\text{Var}(z_1) = 30.51$, $\bar{z}_2 = 138.88$, and $\text{Var}(z_2) = 43.7$.

Potential Issues With Assigning Discrete Fitness Values

In many studies, fitness cleanly falls into discrete categories. Often these are simply binary, such as alive/dead or mated/unmated. Zuk (1988) and Blanckenhorn et al. (1999) noted that biased sampling is not uncommon in such situations, with a tendency to oversample the rarer class. While such sampling can improve hypothesis testing (increasing the power to test whether a trait is a target of selection), if the investigator is careless in the weighting of the estimates from these two samples, such biased sampling generates biased estimates of phenotypic selection (Example 29.3).

Example 29.3. Suppose that 10% mortality occurs during an episode of selection and one is examining whether a focal trait influences fitness. The trait may be somewhat difficult to measure, making it tempting to oversample dead individuals in order to gain more power for testing whether a difference in trait value occurs between groups. Suppose the mean of the trait is 100 in surviving individuals and 50 in those showing mortality. With 10% mortality, the mean (before selection) is just $0.1 \cdot 50 + 0.9 \cdot 100 = 95$, giving a selection differential of $S = 100 - 95 = 5$. However, if one oversampled dead individuals to gain more precision in the mean of the trait in this group, say with 25% of the sample being dead individuals, then the (before-selection) sample mean becomes $0.25 \cdot 50 + 0.75 \cdot 100 = 87.5$, and the resulting selection differential is overestimated, with $S = 100 - 87.5 = 12.5$. If the investigator neglects to standardize the weights for these classes when computing the before-selection mean, oversampling of a rare class that is favored (survives or mates) relative to a more common unfavored class (dies or does not mate) results in an *underestimation* of selection differentials. Conversely, oversampling the rare class that is unfavored results in an *overestimation* of the selection differential.

A second, more subtle, issue with assigning fitness values to discrete classes was noted by Brodie and Janzen (1996). The absolute value of fitness assigned to a class can, in some cases, influence measures of selection. In the binary (Bernoulli) case, where fitness is scored as 0 and x (such as dead/living or unmated/mated), any (strictly positive) value can be chosen for x , as the relative fitnesses are independent of the choice of x . However, with three (or more) discrete fitness classes, this is no longer true. Brodie and Janzen presented an example in which laboratory survivorship was followed over a four-year period in turtles. One could code these data as simply 0 (do not survive) or 1 (survive). However, the data could also be scored as 0 through 4, depending on the latest year of survival. They also noted that it might make sense to double the assigned fitness value in year 4, as this is when reproduction typically starts in nature. These different weighting schemes give different relative fitness values for the surviving age classes, and hence different measures of selection. This problem arises because only one component of selection (viability) is measured while reproduction is also occurring, and the different proposed fitness-weighting schemes attempt to accommodate for this unmeasured component. As discussed later, using an aster-model approach with the appropriate life-history graph avoids this problem.

Assigning Components of Offspring Fitness to Their Mothers

When assigning a parent's reproductive fitness, offspring generally should be counted at the zygote (newly fertilized egg) stage. If counted later in life, offspring may have experienced selection based on their own, as opposed to their parents', phenotypes, thus confounding the targets of selection (Lande and Arnold 1983; Cheverud and Moore 1994). However, it is not uncommon for avian and mammalian evolutionary geneticists to count only "successful" offspring. For example, although eggs in the nest is a close measure of number of zygotes produced, the number of offspring from a parent is often scored as **hatchlings** (eggs that successfully hatch), **fledglings** (offspring that successfully leave the nest), or **recruits** (offspring recorded as breeding later in life). These measures move increasingly away from

number of zygotes and can reflect selection on features of the offspring, rather than its parent. Many biologists counter that maternal care is critical, and thus the success of the offspring is a maternal, rather than offspring, trait (Grafen 1988). Where indeed does one draw the line? The strict barrier that is set at zygotes is formally correct *provided* parental phenotypes have no influence on offspring fitness. However, it is also clear that in species with significant parental investment in offspring care (such as birds and mammals, as well as seeds with significant endosperm contribution), the genotype and phenotype of the mother can influence the fitness of her offspring *independently* of the offspring phenotype.

Much of this apparent confusion arises from thinking about how to partition fitness over parents and offspring as a univariate selection problem. In reality, however, this assignment is a multiple-trait problem, with offspring survival potentially involving both the **direct** effect of an offspring on its own fitness and an **indirect** effect from the genotype/phenotype of the mother (Kirkpatrick and Lande 1989), see Figure 15.5. Recall that we have visited this issue before in Chapter 22, wherein the fitness of an individual is influenced by its own phenotype (its direct effect) and the **associative effects** of individuals (potentially parents, other relatives, or even unrelated individuals) around it. From the standpoint of assigning fitnesses, when the maternal phenotype has no effect on offspring fitness, assigning the fitness of the mother by counting her offspring *after* they may have experienced one or more episodes of selection (such as viability selection) is misleading.

Conversely, if the maternal phenotype *does* impact the survival of her offspring independent of their own direct effects, failure to include this also creates a misleading picture (Wolf and Wade 2001; Thomson and Hadfield 2017). In terms of correlated traits, one can view maternal performance as one trait and offspring performance as another. Both can influence the fitness of an offspring. If these are uncorrelated (i.e., there is no genetic or phenotypic correlation between the direct and maternal effects), maternal fitness should be assigned as the number of offspring *following* the episodes of selection in the offspring that are influenced by the maternal performance trait. For example, a trait may influence survival to the fledging or weaned stage but then have no future impact. Simply counting the number of eggs laid misses the maternal contribution. Conversely, even if the maternal contribution is important, if there are correlations between direct and maternal traits, then a misleading picture of selection can arise unless we uncouple them.

Given this uncertainty, how should one proceed? One suggestion is to perform separate analyses with several measures of reproductive success (based on counting offspring at different stages) and examine their consistency. Alternatively, as we saw with Equations 15.39a and 15.40, one can use a multiple-regression approach, including both offspring- and maternal-trait values (Kirkpatrick and Lande 1989; Thomson and Hadfield 2017). The limitation of this latter approach is that it is trait-based (one has to specify, and measure, maternal features influencing offspring fitness). We return to this issue in Chapter 30.

Concurrent Selective Episodes, Reproductive Timing, and Individual Fitness, λ_{ind}

The partitioning of selection into discrete episodes is, of course, an abstraction of the real world. Often this partitioning is simply done for the convenience of a researcher who wishes to measure individual fitness by considering just one or two episodes, potentially looking for tradeoffs between them. Selection episodes (e.g., viability and reproduction) often occur *concurrently*, rather than sequentially. For example, in the turtle data of Brodie and Janzen (1996), one has only information about viability (in the laboratory), and how to weight this information to account for the translation of viability into the timing of reproductive success raised issues in assigning fitness values. While methods to partition concurrent episodes of selection into their components have been proposed (e.g., Hamon 2005), the more general problem is assigning an appropriate measure of fitness that accounts for reproductive timing.

We have been stressing the use of **lifetime reproductive success (LRS)**, but this is a *rate-insensitive* measure, which counts only the total number of offspring and not the actual *timing* of when offspring are produced. If reproduction occurs in a discrete window and

the generations do not overlap, LRS provides a good measure of fitness. However, when generations do overlap, the actual timing of reproductive events can be more important than the total number of offspring, as earlier-produced offspring have a head start on contributing their own offspring to the population (Lande 1982). Consider three individuals, all of which produce 40 offspring during their lifespan, and hence each has the same fitness when measured by LRS. However, suppose individual 1 has 10 offspring each at ages 2, 3, 4, and 5; individual 2 has 20 offspring at both ages 4 and 5; and individual 3 has 20 offspring at ages 2 and 3. Clearly, individual 3 has a higher *rate* of offspring production than individuals 1 or 2 on an absolute time basis, even though it has the same LRS as the other two individuals. How do we account for this?

One solution is based on **age-projection** (or **Leslie**) **matrices** (Leslie 1945, 1948; Caswell 1989, 2001), an approach first proposed by Lenski and Service (1982). McGraw and Caswell (1996) forcefully argued for this approach as a measure of individual fitness in age-structured populations. The growth rate of an age-structured population can be determined from ℓ_x , the probability of surviving from age (or class/stage) x to $x + 1$, and b_x , the birth rate (fecundity) in class x (the ℓ_x and b_x are collectively referred to as the **vital rates**). This information is expressed in a $k \times k$ matrix, where k is the upper age limit on reproduction. The first row of the Leslie matrix contains the fecundities, while the below-diagonal line consists of the survival values, ℓ_x ,

$$\mathbf{L} = \begin{pmatrix} b_1 & b_2 & \cdots & b_{k-1} & b_k \\ \ell_1 & 0 & \cdots & 0 & 0 \\ 0 & \ell_2 & \cdots & 0 & 0 \\ \vdots & & \ddots & 0 & 0 \\ 0 & 0 & \cdots & \ell_{k-1} & 0 \end{pmatrix} \quad (29.3a)$$

If $\mathbf{n}(t)$ is a vector of the number of individuals in each age/stage class at time t , then $\mathbf{n}(t+1) = \mathbf{Ln}(t)$. The **asymptotic growth rate**, λ , for this population is the largest eigenvalue of \mathbf{L} , while its associated eigenvector is the stable age distribution. The Leslie matrix is just one type of life-history projection matrix. More generally, the life history of a species may be more accurately defined by **stages**, rather than **ages**. For example, a perennial plant could spend many years in a rosette stage before flowering. Life-history graphs are a more general approach for categorizing such stage-structured organisms. In an age-structured model, individuals increase in age at each step, but in a stage-structured model, an individual can *remain* in the same stage on the next step (e.g., stays as a rosette), generating a loop in the graph (an arrow that circles back to itself), and hence a nonzero diagonal element, L_{ii} , representing the chance of remaining in stage i in the next step (Caswell 1989, 2001).

Now consider a particular individual that last reproduced at age m . The resulting Leslie matrix for *this individual* is

$$\mathbf{L}_{ind} = \begin{pmatrix} f_1 & f_2 & \cdots & f_{m-1} & f_m \\ 1 & 0 & \cdots & 0 & 0 \\ 0 & 1 & \cdots & 0 & 0 \\ \vdots & & \ddots & 0 & 0 \\ 0 & 0 & \cdots & 1 & 0 \end{pmatrix} \quad (29.3b)$$

where $f_x = b_x/2$ is half the number of offspring that the individual produced at age x (using half accounts for both males and females contributing to the population, to avoid double-counting of the offspring). Note that $\text{LRS} = 2 \sum_j^k f_j$. The individual-specific matrix, \mathbf{L}_{ind} , is very similar to a population growth matrix (\mathbf{L}), but in \mathbf{L}_{ind} , the fecundities are those that were *observed* for the focal individual (as opposed to *population averages* for each age class). In addition, because this individual survives to (at least) age m , we replace the ℓ_x elements in \mathbf{L} (the average survival per age class) by ones, indicating the actual survival of the focal individual. The “growth” rate, λ_{ind} , for this individual is given by the largest

eigenvalue of \mathbf{L}_{ind} , which can be obtained by solving the modified **Euler-Lokta equation**

$$\sum_{i=1}^m f_i \lambda_{ind}^{-i} = 1 \quad (29.3c)$$

Note from this equation that λ_{ind} can be thought of as an **age-discounted LRS**, a rate-sensitive measure of fitness, as opposed the rate-insensitive measure given by LRS.

McGraw and Caswell (1996) noted two sources of bias in using λ_{ind} . First, for any given phenotypic class, the particular realization of the matrix of vital rates (\mathbf{L}_{ind}) for an individual in that class (i.e., the expected survival, $\ell_x(z)$, and fecundity, $b_x(z)$, values for phenotype z) is a biased estimator of the matrix for that class. The reason is that random death prevents a proper estimation of the values of b_x , especially at later ages. The second source of bias, which was also a concern for Lenski and Service (1982), was that the average of the leading eigenvalue for each realization of \mathbf{L}_{ind} does not generally equal the leading eigenvalue for the average matrix (i.e., the average of the values of λ_{ind} does not equal the population growth rate, λ). Despite these issues, McGraw and Caswell (1996) still favored the use of λ_{ind} , while Lenski and Service (1982) developed a resampled measure (based on \mathbf{L}_{ind}) with less bias. Alternatively, if the mean population growth rate (λ) is known, then an unbiased estimator for the relative fitness for individual j is

$$w(j) = \sum_{i=1}^k f_i(j) \lambda^{-i} \quad (29.3d)$$

where $f_i(j)$ denotes half of j 's fecundity at age i (Lenski and Service 1982).

Example 29.4. In the case of overlapping generations, the timing of when reproduction occurs can be at least as important as the lifetime reproductive success (LRS). Consider the three hypothetical individuals mentioned previously, each with an LRS of 40 but with differences in the timing of reproduction. Recalling that the values of f_i in Equation 29.3b represent half the number of offspring, the Leslie matrices for these three individuals become

$$\mathbf{L}_1 = \begin{pmatrix} 0 & 5 & 5 & 5 & 5 \\ 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \end{pmatrix}, \quad \mathbf{L}_2 = \begin{pmatrix} 0 & 0 & 0 & 10 & 10 \\ 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \end{pmatrix}, \quad \mathbf{L}_3 = \begin{pmatrix} 0 & 10 & 10 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}$$

The leading eigenvalues for these three matrices are $\lambda_1 = 2.77$, $\lambda_2 = 1.97$, and $\lambda_3 = 3.58$. Under this metric, individuals 1 and 2 are, respectively, 77% and 55% as fit as individual 3.

Example 29.4 shows that individuals with the same LRS can have very different λ_{ind} values. Indeed, the rankings of individuals based on LRS versus λ_{ind} can be rather nonconcordant. Hence, it should not be surprising that Brommer et al. (2002) noted several cases where inferences on selection were altered when λ_{ind} was used in place of LRS. An especially telling example is shown in Figure 29.1, which plots these two measures of fitness for female Ural owls (*Strix uralensis*). As the figure shows, there is a diminishing return in λ_{ind} with increasing values of LRS. This occurs because reproductive contributions later in life are increasingly down-weighted by λ_{ind} (Equation 29.3c).

While there are strengths to using λ_{ind} , it is not without problems. Brommer et al. (2002) made the important point that the stages when offspring are scored (e.g., eggs vs. hatchlings) is critical. Although LRS can also change given differences in the stage of scoring,

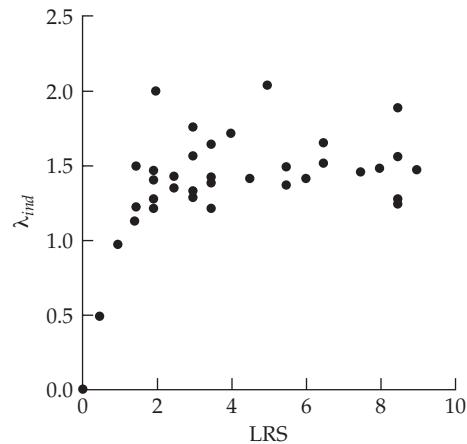

Figure 29.1 Lifetime reproductive success (LRS) versus λ_{ind} in 56 Ural owls (*Strix uralensis*) where offspring were measured as fledglings. Increasing LRS results in diminishing returns in λ_{ind} , which occurs because additional reproduction later in life is increasingly down-weighted by this rate-sensitive measure. (After Brommer et al. 2002.)

the effects can be much more dramatic for λ_{ind} , which differentially weights offspring produced at different ages. An interesting discussion on the merits of LRS versus λ_{ind} was given by Brommer et al. (2004), who compared these single-generation measures of fitness with the long-term genetic contribution of an individual. Using multigenerational population studies on Ural owls (a long-lived species) and shorter-lived collard flycatchers (*Ficedula albicollis*), they examined the correlation of both measures (LRS and λ_{ind}) with the long-term genetic contribution of an individual to future generations. The latter was assessed from known pedigrees as the expected number of gene copies left after more than two generations. Following the standard practice of ornithologists, the number of offspring from a parent was counted using two different measures of success: number of fledglings and number of recruits. This resulted in fitnesses measured by lifetime fledgling production (LFP) and lifetime recruit production (LRP) as the LRS analogs, and their rate-sensitive counterparts, $\lambda_{ind}(fp)$ and $\lambda_{ind}(rp)$. LFP had a higher correlation with the number of descendants (gene copies left after at least two generations) than did $\lambda_{ind}(fp)$. For flycatchers, the correlation between LFP and number of descendants was 0.35, while it was only 0.20 for $\lambda_{ind}(fp)$. In owls, these correlations were 0.54 for LFP and 0.19 for $\lambda_{ind}(fp)$. When fitness was based on recruits, LRS and $\lambda_{ind}(rp)$ performed equally well in both species in predicting the long-term contribution. Brommer et al. expressed concern that rate-sensitive measures such as λ_{ind} discounted later reproduction too harshly, and that rate-insensitive measures (such as LRS) might be a more robust choice.

In closing, we remark that there is a robust discussion in the literature on the appropriate measures of selection in age-structured populations (a partial list includes Charlesworth 1980, 1983, 1994a; Lande 1982; Lenski and Service 1982; Travis and Henrich 1986; Partridge and Harvey 1988; Henle 1991; Metz et al. 1992; Kozlowski 1993; de Jong 1994; Benton and Grant 1996, 2000; McGraw and Caswell 1996; Brommer 2000; Link et al. 2002; Brommer et al. 2003; Coulson et al. 2005; Metcalf and Pavard 2007; Horvitz et al. 2010; and Engen et al. 2011, 2012). Indeed, Stearns (1976) said it best: “Fitness: something everyone understands but no one can define precisely,” and later (1992) noted that “all fitness definitions are tools invented by scientists to analyze natural selection.” In part, this debate arises because different questions (e.g., whether a new phenotype can invade a population vs. determining the change in a trait value following selection) can result in different appropriate definitions of fitness.

Sensitivities and Elasticities of the Elements of L

Measures of how a small change in a vital rate (one of the elements of L) impact λ provide

a connection between selection on particular traits and demography (van Tienderen 2000). An introduction to these metrics was offered by de Kroon et al (2000), with a more detailed treatment by Caswell (1989, 2001). The **sensitivity**, s_{ij} , of an element, L_{ij} , of a Leslie matrix is defined as the impact of a small change in that element on the total growth rate,

$$s_{ij} = \frac{\partial \lambda}{\partial L_{ij}} = \frac{v_i \cdot w_j}{\mathbf{v}^T \mathbf{w}} \quad (29.4a)$$

where \mathbf{v} and \mathbf{w} are the left and right eigenvectors associated with the dominant eigenvalue (λ) of \mathbf{L} (Caswell 1978). The right-most identity follows from the spectral decomposition (Equation A5.9a) of \mathbf{L} . The right eigenvector is the familiar $\mathbf{L}\mathbf{w} = \lambda\mathbf{w}$, while the **left eigenvector** satisfies $\mathbf{v}^T \mathbf{L} = \lambda\mathbf{v}^T$. Taking transposes on both sides shows that $\mathbf{L}^T \mathbf{v} = \lambda\mathbf{v}$, which means that \mathbf{v} is the right eigenvector of \mathbf{L}^T . Sensitivity provides the *absolute* change in the growth rate, λ , given an infinitesimal change in L_{ij} .

In contrast, the **elasticity**, e_{ij} , of element L_{ij} is the *proportional* change in λ given a *proportional* change in L_{ij} ,

$$e_{ij} = \frac{\partial \lambda / \lambda}{\partial L_{ij} / L_{ij}} = \frac{L_{ij}}{\lambda} \frac{\partial \lambda}{\partial L_{ij}} = \frac{L_{ij}}{\lambda} s_{ij} \quad (29.4b)$$

Recalling from the chain rule of calculus that $\partial \ln[f(x)]/\partial x = [1/f(x)] \cdot [\partial f(x)/\partial x]$ shows that elasticities can also be expressed as

$$e_{ij} = \frac{\partial \lambda / \lambda}{\partial L_{ij} / L_{ij}} = \frac{\partial \ln(\lambda)}{\partial \ln(L_{ij})} \quad (29.4c)$$

Caswell (1984) and de Kroon et al. (1986) showed that the elasticities of all of the elements of \mathbf{L} sum to one, giving the result of de Kroon et al. (2000), namely, that

$$\lambda = \lambda \cdot 1 = \lambda \sum_{ij} e_{ij} = \lambda \sum_{ij} \frac{L_{ij}}{\lambda} s_{ij} = \sum_{ij} L_{ij} s_{ij} \quad (29.4d)$$

As will be discussed later in the chapter, elasticities provide a link between the impact of a trait on fitness components and the impact of those components on the growth rate (van Tienderen 2000). Volume 3 examines selection in age-structured populations in more detail.

VARIANCE IN INDIVIDUAL FITNESS

How do we compare the amount of selection acting on different populations? At first glance, one might consider using the variance-standardized selection differential (the selection intensity), $\bar{i} = S/\sigma$, to compare the relative strengths of individual selection between populations (Chapter 13). The limitation with \bar{i} as a measure of *overall* selection on populations is that it is *character specific*. Hence, \bar{i} may be appropriate when comparing the strength of selection on a particular *character* (one could also use mean-standardization, S/μ , instead; Chapters 13 and 30), but it is inappropriate for comparing the overall strength of selection in a *population*. This is because two populations may have the same \bar{i} value for a given character, but if that character is tightly correlated with fitness in one population and only weakly correlated in the other, selection will be much stronger in the latter population.

Another issue with using \bar{i} is that considerable selection can occur without changing the mean (e.g., stabilizing selection). Haldane (1954) and Van Valen (1965) proposed measures of the intensity of selection, which is suitable for stabilizing selection. Both contrast the mean fitness, \bar{W} , with W_o , the fitness of the optimal phenotype (usually estimated as the value of the mode of a stabilizing selection function, e.g., θ in Equation 28.3). Haldane suggested

$$I_H = \ln(W_o) - \ln(\bar{W})$$

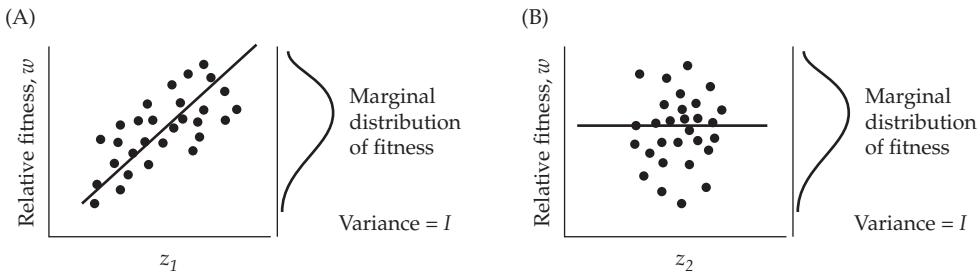

Figure 29.2 The fraction of I (the opportunity for selection) that is translated into a change in the mean depends on the correlation, $\rho(z, w)$, between relative fitness and the trait value. Traits z_1 and z_2 have the same marginal distribution of fitness, but only the regression of w on z_1 is significant. Thus, within a generation, selection changes the mean of z_1 , but not of z_2 .

while Van Valen proposed

$$I_{VV} = \frac{W_o - \bar{W}}{W_o} = 1 - \exp(-I_H)$$

For small values, note that $I_{VV} \simeq I_H$ (as $e^{-x} \simeq 1 - x$ for small x). These measures, however, also have limitations as comparative measures of the strength of selection. First, the value of W_o when selection is strictly directional is unclear, and second, like \bar{t} , these metrics are also trait-specific.

A much cleaner measure (which requires no assumptions about which traits are under selection or on the nature of that selection) is I , the **opportunity for selection**, which is defined as the variance in *relative* fitness

$$I = \sigma_w^2 = \frac{\sigma_W^2}{\bar{W}^2} \quad (29.5a)$$

This measure was introduced by Crow (1958; reviewed in 1989), who referred to it as the **index of total selection**, and was independently developed by O'Donald (1970). I is estimated by

$$\hat{I} = \text{Var}(w) = \frac{n}{n-1} (\bar{w}^2 - 1) \quad (29.5b)$$

Crow noted that if fitness is perfectly heritable ($h_W^2 = 1$), then $I = \Delta\bar{w}$, namely, the expected selection response in relative fitness. This follows from the Robertson-Price identity (Equation 6.10), $S = \sigma(z, w)$. When $z = W$, then (applying the breeder's equation with $h_W^2 = 1$) we have

$$R_W = h_W^2 S_W = S_W = \sigma(W, w) = \bar{W} \sigma(W/\bar{W}, w) = \bar{W} \sigma_w^2$$

implying that $R_W/\bar{W} = \Delta\bar{w} = \sigma_w^2 = I$. Following Arnold and Wade (1984a, 1984b), I is called the opportunity for selection, as any variation in individual fitness represents an *opportunity* for a within-generation change in a trait. The opportunity for selection provides an upper bound on \bar{t} . This follows by using: (i) the definition of a correlation, ρ , (ii) the Price-Robertson identity, $S = \sigma(z, w)$, and (iii) the fact that $|\rho| \leq 1$, to yield

$$|\rho_{z,w}| = \frac{|\sigma(z, w)|}{\sigma_z \sigma_w} = \frac{|S|}{\sigma_z \sqrt{I}} \leq 1 \quad (29.6a)$$

implying that

$$|\bar{t}| \leq \sqrt{I} \quad (29.6b)$$

Thus, the most that the mean of any trait can be shifted within a generation is \sqrt{I} phenotypic standard deviations.

The usefulness of I as a bound of \bar{I} depends on the correlation between relative fitness and the character being considered. From Equation 29.6a,

$$|\bar{I}| = |\rho(z, w)| \sqrt{I} \quad (29.6c)$$

Figure 29.2 shows scatterplots of relative fitness versus two characters (z_1 and z_2) measured in the same set of individuals. The marginal distributions of fitness are identical for both characters (because the same set of individuals, and hence the same set of fitnesses, were measured for each trait), and thus both have the same opportunity for selection. The association between relative fitness and z_1 is fairly strong, while there is no relationship between relative fitness and z_2 , which means that z_1 realizes much of the opportunity for change, while z_2 realizes none of it.

Example 29.5. To estimate I for the bullfrog data used in Example 29.2, we first compute lifetime relative fitnesses, $w = w_1 \cdot w_2$, which yields values of 1.162, 1.020, 0, 0.652, and 2.160 for the five chosen males. Hence,

$$\overline{w^2} = (1/5) [1.162^2 + 1.020^2 + 0^2 + 0.652^2 + 2.160^2] = 1.496$$

giving

$$\hat{I} = \frac{5}{4}(1.496 - 1) = 0.62$$

From Equation 29.6b, the most that selection can change the mean of any character within a generation is $\sqrt{\hat{I}} \simeq 0.79$ standard deviations. The observed change in male body size (in standard deviations) from Example 29.2 is $(138.9 - 140)/\sqrt{59.5} = -0.143$, which is less than one-fifth of the maximum absolute change of 0.79.

Example 29.6. In many cases individual fitnesses are not recorded, and the average fitness for each phenotypic class is simply estimated. O'Donald (1970, 1971) analyzed the data of Dowdeswell (1961), who searched for signs of selection on hindwing eyespot number in the meadow brown butterfly (*Maniola jurtina*; see Brakefield 1984 for a review of the biology of this character). Dowdeswell compared the population distributions of eyespot number between a series of 471 wild-collected females (field) and a series of 237 females reared from larvae (lab). Presumably, any difference in distributions was due to selection on adults in nature. If p_i and p'_i denote the laboratory and field proportions for spot-class i , respectively, then from Equation 5.7a, the relative fitness of class i follows because $p'_i = w_i p_i$, and hence $w_i = p'_i/p_i$, assuming that the laboratory frequencies match the field frequencies before selection. The resulting data were as follows:

Eyespot No.	Number		Proportion		$w_i = p'_i/p_i$
	Lab	Field	Lab	Field	
0	124	294	0.523	0.624	1.1930
1	67	111	0.283	0.236	0.8336
2	34	53	0.143	0.113	0.7844
3	10	13	0.042	0.028	0.6541
4	2	0	0.008	0	0

Because the eyespot frequencies in the laboratory sample presumably represent the frequencies before selection, these are the ones we use, which yields

$$\overline{w^2} = \frac{1}{237} [(1.1930^2 \cdot 124) + (0.8336^2 \cdot 67) + (0.7844^2 \cdot 34) + (0.6541^2 \cdot 10)] \simeq 1.0475$$

and hence

$$\hat{I} = \frac{237}{236} (1.0475 - 1^2) \simeq 0.0477$$

This is an *underestimate* of I , as to properly estimate I the distribution of *individual* fitnesses, rather than mean fitness for each phenotypic class (*class* fitnesses), is required. The Dowdeswell data only allow us to estimate the between-group variance in fitness (the variance in average fitness for the different eyespot classes) and neglects the additional within-group variance (the variance in fitness among individuals with the same number of eyespots).

Partitioning I Across Episodes of Selection

The total opportunity for selection can be partitioned into opportunities associated with each episode. Such a partitioning allows for comparisons of the relative strength of selection across episodes, as well as bounding the change in means and variances due to selection during any particular episode. Denote the opportunity of selection associated with the j th episode by I_j . By analogy with the definition of I , Arnold and Wade (1984a) suggested that the appropriate definition is the variance in the relative fitnesses of the j th fitness component

$$I_j = \sigma^2(w_j) = E(w_j^2) - 1 \quad (29.7a)$$

which is estimated by

$$\begin{aligned} \hat{I}_j &= \text{Var}(w_j) = \frac{n}{n-1} (\overline{w_j^2} - 1) \\ &= \frac{n}{n-1} \left(\sum_{r=1}^n w_j^2(r) p_{j-1}(r) - 1 \right) \end{aligned} \quad (29.7b)$$

where $p_j(r)$ is the fitness-weighted frequency of individual r after j episodes of selection (Equation 29.2a). Arnold and Wade showed that the partition for I over k episodes of selection is given by

$$I = \sum_{j=1}^k I_j + R \quad (29.8)$$

where the remainder term, R , represents a complex sum of covariances between fitness components (see Arnold and Wade 1984a for details). Webster et al. (1995) examined partitions of I involving both multiplicative and additive components of fitness. The latter can arise when fitness is influenced through two (or more) distinct paths, for example, mating success through both bonded-pair and extra-pair matings (see Whittingham and Dunn 2005 and Webster et al. 2007 for applications of the Webster approach).

Example 29.7. Compute the estimates of I_1 and I_2 using the data from Example 29.2. Using the relative fitnesses given in the table with $p_0(r) = 1/5$ yields

$$\overline{w_1^2} = \frac{1}{5} (0.714^2 + 0.714^2 + 0^2 + 1.429^2 + 2.143^2) \simeq 1.531$$

Likewise,

$$\begin{aligned} \overline{w_2^2} &= \sum_{r=1}^5 w_2^2(r) p_1(r) = (1.628^2 \cdot 0.143) + 0 + (1.429^2 \cdot 0.143) \\ &\quad + (0.456^2 \cdot 0.286) + (1.008^2 \cdot 0.429) \simeq 1.165 \end{aligned}$$

Hence,

$$\widehat{I}_1 = \frac{5}{4} (1.531 - 1) \simeq 0.664 \quad \text{and} \quad \widehat{I}_2 = \frac{5}{4} (1.165 - 1) \simeq 0.206$$

Because $\widehat{I} = 0.62$ (Example 29.5), $\widehat{I}_1 + \widehat{I}_2 = 0.87 \neq \widehat{I}$. From Equation 29.8,

$$\widehat{R} = 0.62 - 0.87 = -0.25$$

which reflects the strong negative covariance within individuals between the first and second fitness components (in this dataset, individuals with high w_1 tend to have a low w_2 , and vice versa).

Correcting Lifetime Reproductive Success for Random Offspring Mortality

As noted by Clutton-Brock (1988b), the variance in female lifetime reproductive success tends to increase with the age at which the offspring are counted. For example, in birds, I typically increases as we measure reproductive success by offspring at increasing ages: from eggs to hatchlings and finally to fledglings. One might expect to see this pattern when maternal care is important, but it can also arise simply from random offspring mortality. Cabana and Kramer (1991) noted that a correction proposed by Crow and Morton (1955), originally suggested for allele-frequency change, can be used to adjust for random mortality. Suppose that the mean family size before an episode of selection is μ with a variance of σ_1^2 . If offspring mortality is entirely random, with s being the probability of survival of a random individual, then the mean family size after selection is $s\mu$ and (from Crow and Morton) the variance σ_2^2 satisfies the relationship

$$\frac{\sigma_2^2/(s\mu) - 1}{s\mu} = \frac{\sigma_1^2/\mu - 1}{\mu} \quad (29.9a)$$

Because $s\mu$ and μ are the mean fitnesses, $\sigma_2^2/(s\mu)^2 = I_2$ and $\sigma_1^2/\mu^2 = I_1$, which yields

$$I_2 - \frac{1}{s\mu} = I_1 - \frac{1}{\mu}$$

which Cabana and Kramer rearrange to find that the opportunity for selection generated entirely from random offspring mortality is given by

$$I_2 = I_1 + \frac{1/s - 1}{\mu} \quad (29.9b)$$

Random offspring mortality always inflates the variance in reproductive success, and its effect is inversely proportional to the survival probability, s , and the mean family size, μ . Cabana and Kramer applied Equation 29.6b to 43 case studies of vertebrate reproductive success. In all cases, the mean decreased and the variance increased with the age at which the offspring were counted. They found that the predicted value of I_2 from random mortality alone (Equation 29.9b) was roughly 45% of the observed value of I_2 for a dataset of 16 bird species (measuring fitness as the number of fledglings per nesting attempt), while the predicted random-mortality value of I_2 was around 85% of the observed I_2 for a dataset of lifetime fledging and weaning success in a set of 8 birds and mammals. Thus, in many cases a large fraction of I can often be accounted for by this simple model of random mortality.

Caveats in Using the Opportunity for Selection

There are several subtle issues in the interpretation of I . To begin with, even though this variable appears to remove scaling effects due to different types of fitnesses, for estimates of I to

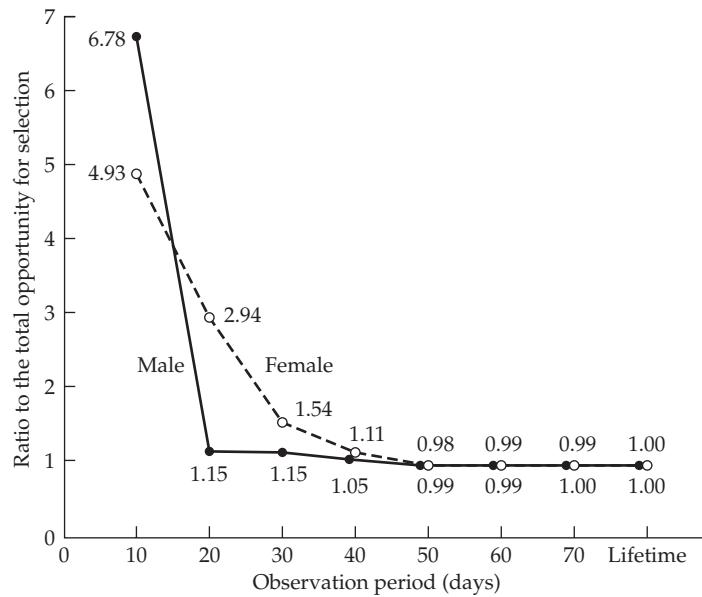

Figure 29.3 The ratio of the opportunity for selection on reproductive success to the lifetime opportunity for the coreid bug, *Colpula lativentris*, as a function of observation period. Males are given by the filled circles and females by the open circles. Note the inflation in I when very short time intervals are considered. (After Nishida 1989.)

be truly comparable, they must be based on consistent measures of fitness (Trial 1985). Consider the opportunity for selection based on number of *mates* per male (sexual selection), I_s , versus the opportunity for selection based on total male reproductive success (the number of *offspring* per male), I_{rs} . Total male reproductive success depends on both the number of mates and the fertility per mating. Recalling Equation 29.8, $I_{rs} = I_s + I_f + R$, where I_f is the opportunity for selection based on differences in male fertility per mating. Hence, I_{rs} is expected to exceed I_s unless there is sufficient negative covariance between the mating success and fertility components ($R < -I_f$).

A second point is that if the variance in fitness is not independent of \bar{W} , comparisons of I values between populations will be compromised. This dependency occurs in cross-sectional studies that measure sexual selection by simply counting the number of mating pairs (in such studies, an unequal sex ratio further biases comparisons of I between the sexes). If the time scale is such that only single matings are observed, the fitness of any individual is either 1 (mating) or 0 (not mating). The resulting fitnesses of randomly drawn individuals are binomially distributed with a mean of p (the mean copulatory success for the sex being considered) and variance $p(1-p)$, hence

$$I = \frac{p(1-p)}{p^2} \simeq \frac{1}{p} \quad \text{if } p \ll 1 \quad (29.10)$$

In this case, the mean and variance in individual fitness are not independent, and the opportunity for selection depends entirely on mean population fitness. As the time window for observing mating pairs decreases, fewer matings are seen and p decreases, which increases I . As the data plotted in Figure 29.3 illustrate, the opportunity for selection is often inflated if the observation period is short relative to the total mating period. Exactly the same problem occurs for viability selection (where p is now the probability of survival), but here p is expected to *decrease* (increasing I) as the window becomes longer.

Another example of the lack of independence between \bar{W} and σ_W^2 was given by Downhower et al. (1987). The Poisson distribution is a reasonable initial model for the number of mates under random mating. Indeed, Joshi et al. (1999) found that it provides an excellent

fit for male mating success in laboratory populations of *Drosophila melanogaster*. Assuming that the number of mates for any given male follows a Poisson distribution, the variance in number of mates equals the mean number of mates, resulting in

$$I = \frac{\overline{W}}{\overline{W}^2} = \overline{W}^{-1}$$

where \overline{W} is the mean number of mates per male. Thus, differences in I between populations do not necessarily indicate *biological* differences in male mating ability. For example, in a population of 100 males, if only 5 females mate, average male mating success is $\overline{W} = 0.05$, while if 50 females mate, $\overline{W} = 0.5$. For this example, differences in I come solely from variation in the number of mating females, *not* biological differences between males in their ability to acquire mates. Downhower et al. concluded from this example that comparing I values with the Poisson prediction ($I = 1/\overline{W}$), or some other appropriate random distribution, may help clarify the interpretation of I . Values of I less than the Poisson prediction indicate a more uniform distribution of fitness than expected if mate choice is random, while values in excess of this expectation indicate disproportionately high fitness among a limited set of individuals. In a study of four species with lek mating systems (where matings typically occur only in a specified area), Mackenzie et al. (1995) found that the combination of random mating and variation in male attendance at the lek accounted for ~40% of the total variation in male mating success. Thus, the variance in mating success was inflated by random factors, but still contains a substantial fraction of unexplained variance.

This comparison of I to the value expected under a Poisson distribution of individual fitness is an attempt to account for differences in opportunities for selection due to differences in mean fitness. In effect, this is a problem of stabilizing the variances (LW Chapter 11). Because I is the squared coefficient of variation in fitness, it is plagued by the same statistical problems as the Roginskii-Yablokov effect: a negative correlation is often expected between x/y and y , even when x and y are independent (LW Chapter 11). Thus, in most cases we expect I to be somewhat dependent on \overline{W} .

The Poisson mating example highlights that random variation (differences in individual fitness not attributable to intrinsic differences between individuals) reduces the correlation between phenotypic value and relative fitness. Although carefully controlled studies can reduce the error variance induced by chance (e.g., Houck et al. 1985), accounting for the inflation in the opportunity for selection by random effects remains problematic. It should be stressed that, despite these concerns, I still provides an upper bound on the strength of selection on any trait (over the measured episodes of selection). Accounting for random sources of variation that inflate I can tighten this limit.

MEASURING SEXUAL SELECTION

The idea of sexual selection, differences in reproductive success arising by differential mating success (**premating selection** or, in animals, **precopulatory selection**) and differential fertilization following mating (**postmating selection** or, in animals, **postcopulatory selection**) began with Darwin's (1959) *Origins* and was more fully examined in his *The Descent of Man, and Selection in Relation to Sex* (Darwin 1872). As a product of his times, Darwin viewed females as essentially monogamous, and thus never considered postmating selection. He also assumed that sexual selection was mainly restricted to animals, because (as quaintly noted by Moore and Pannel 2011) organisms outside of animals "could surely not appreciate each other's beauty." Modern evolutionary biologists ascribe a much broader role (both across genders and across phyla) to Darwin's original concept. For example, starting with David Lloyd, many botanists have viewed sexual selection for increased siring ability (i.e., pollen dissemination) as one of the major evolutionary forces shaping floral evolution (Moore and Pannel 2011). Likewise, Darwin's original views on gender roles in sexual selection have been replaced with a more gender-neutral one, allowing for either, or both,

males and females to be under strong sexual selection, depending on the biology of their situation.

Premating selection can be **intrasexual** (male-male or female-female competition for access to mates) or **intersexual** (female, or more rarely, male choice of mates). Postmating selection is possible when a female has mated multiple times. **Sperm competition** (or more generally, **gamete competition**) among the donations from different males within a single female is an example of intrasexual postmating selection, and **cryptic female choice** (preferential selection among male gametes by a female) is an example of intersexual postmating selection. By the nature of their reproductive biology, postmating selection may be rather common in the flowering plants. The growth of a pollen tube from a pollen grain down to the ovule of a flower has the potential for considerable selection (especially in the case of self-incompatible species). Given that a large fraction (often over 50%) of the genome is expressed during pollen tube growth (Mascarenhas 1990), such selection has underappreciated evolutionary implications. Our focus here is mainly concerned with premating selection and assessing which traits (if any) are under sexual selection. However, with the rise of molecular markers, the ability to examine the hidden postmating selection that may be ongoing within a female's reproductive system has now become accessible.

Sexual selection, and the evolution of mate choice, is an enormous (and growing) area of evolutionary biology, especially with the realization that sexual selection may be just as, if not more, intense as natural selection in some species (Hoekstra et al. 2001; Siepielski et al 2001; Kingsolver et. al. 2012). Jones and Ratterman (2009) provided a nice overview. A very incomplete list of more general reviews include those examining: the entire field (Arnold 1983a; Bradbury and Andersson 1987; Andersson 1994; Andersson and Iwasa 1996; Murphy 1998; Mead and Arnold 2004; Arnqvist and Rowe 2005; Kokko et al. 2006; Clutton-Brock 2007, 2009; Hunt et al. 2009; Tobias et al. 2012; Reid 2014), the evolution of mate choice and mating systems (Bateson 1983; Kokko et al. 2003; Shuster and Wade 2003; Neff and Pitcher 2005; Andersson and Simmons 2006; Kotiaho and Puurtinen 2007; Shuster 2009), postmating selection (Parker 1970, 2006; Smith 1984; Birkhead and Møller 1998; Birkhead and Pizzari 2002; Eberhard 2009), and sexual selection in plants (Willson and Burley 1983; Ashman and Morgan 2004; Delph and Ashman 2006; Moore and Pannell 2011).

Roughgarden et al. (2006) ignited a bit of a firestorm when they proclaimed that the notion of sexual selection is “always mistaken” and that it “needs to be replaced.” One foundation for their argument was, as noted by Shuker (2010), that “various societal biases associated with gender have detrimentally influenced how scientists have thought about sexual selection.” It is always appropriate to examine how societal biases may warp one’s scientific viewpoint, but given that 40 prominent evolutionary biologists immediately, and vehemently, disagreed with Roughgarden et al. (Kavanagh 2006), there seems to be little traction for their radical reassessment. Additional debate on this issue can be found in Roughgarden and Akçay (2010a, 2010b), Clutton-Brock (2010), and Shuker (2010).

Bateman’s Principles

In a classic paper, overlooked for many years (until it was rediscovered by Trivers 1972, who allegedly was directed to it by Ernst Mayr), Bateman (1948) used data from mating success and fecundity in laboratory populations of *Drosophila* to propose several principles regarding sexual selection. As much of the debate on the measure (and potential mismeasure) of sexual selection is centered around these principles, we discuss them here before considering how to quantify sexual selection. Ironically, Gowaty et al. (2012) recently suggested that Bateman’s experimental design had a critical flaw (the genetic markers that were used influenced viability), producing a systematic bias in the estimates of number of offspring by sex. Despite this potential issue, Bateman’s ideas have shaped most of the attempts to describe sexual selection, in large part due to Arnold’s (1994) framing of the three principles from Bateman’s experiment:

1. *Males show a greater variance in the number of offspring than do females.* The opportunity for selection, when measured by reproductive success (a composite measure of both

- sexual and natural selection), is greater for males than females.
2. *Males show a greater variance in number of mates than do females.* The opportunity for selection, when measured by number of mates, is larger in males than in females. This suggests that variance in number of mates is a potential measure of sexual selection.
 3. *The total number of offspring for males is an increasing function of the number of mates, but is largely independent of the number of mates in females.* Provided females have mated, their fecundity is largely independent of their number of mates. Thus, in females, the average fecundity per mating should be a *decreasing* function of number of mates, as their total fecundity, (number of mates) \times (fecundity per mating), is largely independent of the number of mates (provided she has mated at least once).

The essence of Bateman's observations was that female fitness is not increased by additional matings, while male fitness is, meaning that the third principle drives the first two. While these three principles served as a useful baseline for thinking about sexual selection, Arnold (1994) and Arnold and Duvall (1994) showed that each can be violated in different mating systems. If female fecundity increases with the number of matings (such as can occur when males provide nuptial gifts), we expect sex-specific differences in the opportunity for selection (based on either total reproductive success or the number of mates) to decrease. For example, Rodríguez-Muñoz et al. (2010) showed that female field crickets (*Gryllus campestris*), like their male counterparts, leave more offspring when they have more mates. A hypothetical (extreme) example arises in some mantids, wherein the female eats her mate, accruing additional nutrition. In such cases, "successful" males mate just once, while female fecundity could easily (in theory) be an increasing function of number of mates (or, in this case, meals).

It is well known that there are numerous exceptions to Bateman's assumed male-dominated sexual selection (e.g., Brown et al. 2009), but the focus on this issue misses the point that Arnold was trying to make. He stressed that the utility of Bateman's principles is that they *codify what needs to be measured in order to show that the opportunity for sexual selection exists*: variance in total fitness (reproductive success [RS]), variance in mating success (MS), and a relationship between increased MS and increased RS. Following Jones et al. (2002), we can restate Bateman's principles in a more gender-neutral fashion as follows:

1. *The sex experiencing the strongest sexual selection has a higher variance in reproductive success (RS).*
2. *The sex experiencing the strongest sexual selection has a higher variance in mating success (MS).*
3. *The slope of the RS-on-MS regression is larger for the sex experiencing the strongest sexual selection.*

It needs to be stressed that neither, or both, sexes could be experiencing strong sexual selection. The metric of the first principle is just the opportunity for selection (I) and the variance in mating success is the corresponding metric for the second principle. The critical principle is the third, which provides a direct connection between the number of matings and reproductive success. If both sexes experience strong sexual selection, both will show significant regressions of reproductive success on mating success.

Variance in Mating Success

The gender-neutral version of Bateman's second principle suggests that a natural measure for the *potential* of sexual selection is variance in mating success. Further, in many (but certainly not all) species, a higher variance is expected in males because some will fail to mate whereas essentially all females are (generally) assumed to have mated. This led Wade (1979) to suggest that the variance in male mating success was a measure of the potential for

sexual selection. Arnold (1994, Arnold and Duvall 1994) codified this idea by considering the **opportunity for sexual selection**,

$$I_s = \frac{\sigma^2(MS)}{\overline{MS}^2} \quad (29.11a)$$

which is the variance in mating success (MS = number of mates per individual), scaled by the square of the average number of mates per male (with a corresponding definition for females). As this is just the variance, σ_{ms}^2 , in **relative mating success** ($ms = MS/\overline{MS}$ being the mean-standardized mating success), it is the logical extension of the opportunity for selection ($I = \sigma_w^2$), which is based on relative fitness (Equation 29.5a). The importance of this measure is that if I_s (which also appears in the literature as I_{mates}) is nearly zero, there is little chance of sexual selection acting on any trait. However, a large value of I_s , by itself, does not guarantee that *any* sexual selection is occurring (i.e., it is a *necessary*, but not *sufficient*, condition). As we have seen above, chance variation in mating success can generate significant values of I_s without any sexual selection occurring. Likewise, even if specific traits result in a strong mating advantage, if this does not translate into increased reproductive success (increased numbers of offspring), no sexual selection occurs.

For this reason, measures of sexual selection based entirely on I_s have been criticized (Banks and Thompson 1985; Sutherland 1985a, 1985b; Koenig and Albano 1986; Hubbell and Johnson 1987; Klug et al. 2010a; Jennions et al. 2012; Henshaw et al. 2016), and a number of alternative metrics have been suggested (reviewed by Kokko et al. 1999; Mills et al. 2007; Klug et al. 2010a; Henshaw et al. 2016). These attempt to adjust for the impact that sample size and mean mating success can have on I_s under random mating. The two metrics most widely appearing in the literature have their roots in ecological measures of competition and resource allocation. The use of **Morisita's index** (Morisita 1962),

$$I_\delta = N \left(\frac{\sum_{i=1}^N m_i^2 - \sum_{i=1}^N m_i}{(\sum_{i=1}^N m_i)^2 - \sum_{i=1}^N m_i} \right) \quad (29.11b)$$

where m_i is the number of mates for individual i ($1 \leq i \leq N$), was recommended by Fairbairn and Wilby (2001), as it adjusts the variance in mating success by the variance generated when all individuals have an equal chance of mating. An alternative measure is **Green's index of resource monopolization** (Green 1966),

$$Q = \frac{\sigma_m^2 - \mu_m}{N\mu_m^2 - \mu_m} \quad (29.11c)$$

where μ_m and σ_m^2 are the mean and variance in number of mates. Q adjusts the observed variance in mating success with its maximal possible value, and was used by Ruzzante et al. (1996) and Blanckenhorn et al. (1998). These alternative indices are both attempts to generate a **null model**, namely, the variance expected under the mating system when there is no systematic mating bias, but rather only random encounters within the parameters set by the biology, such as the sex ratio or the “handling time” of a mating.

The **operational sex ratio (ORS)** of Emlen and Oring (1977), which is the ratio of sexually active males to fertilizable females, is also used as a metric for the potential for sexual selection (Kvarnemo and Ahnesjö 1996). A male-biased ORS (>1) offers the *possibility* of sexual selection on males, and a female-biased ORS (<1) offers the opportunity for sexual selection on females. One important issue with *any* measure is that sexual selection can be very context-specific (e.g., Fitze and Le Galliard 2011). For example, if there is a large pool of males, but only a small fraction have the capacity to mate, then an *observed* male-biased sex ratio could actually mask a female-biased *operational* sex ratio. As Klug et al. (2010b) stressed, it is not trivial deciding whom to include in measures of sexual selection. Finally, there is a density component to mate choice as well. When both sexes are scarce, individuals may be far less choosy about mates.

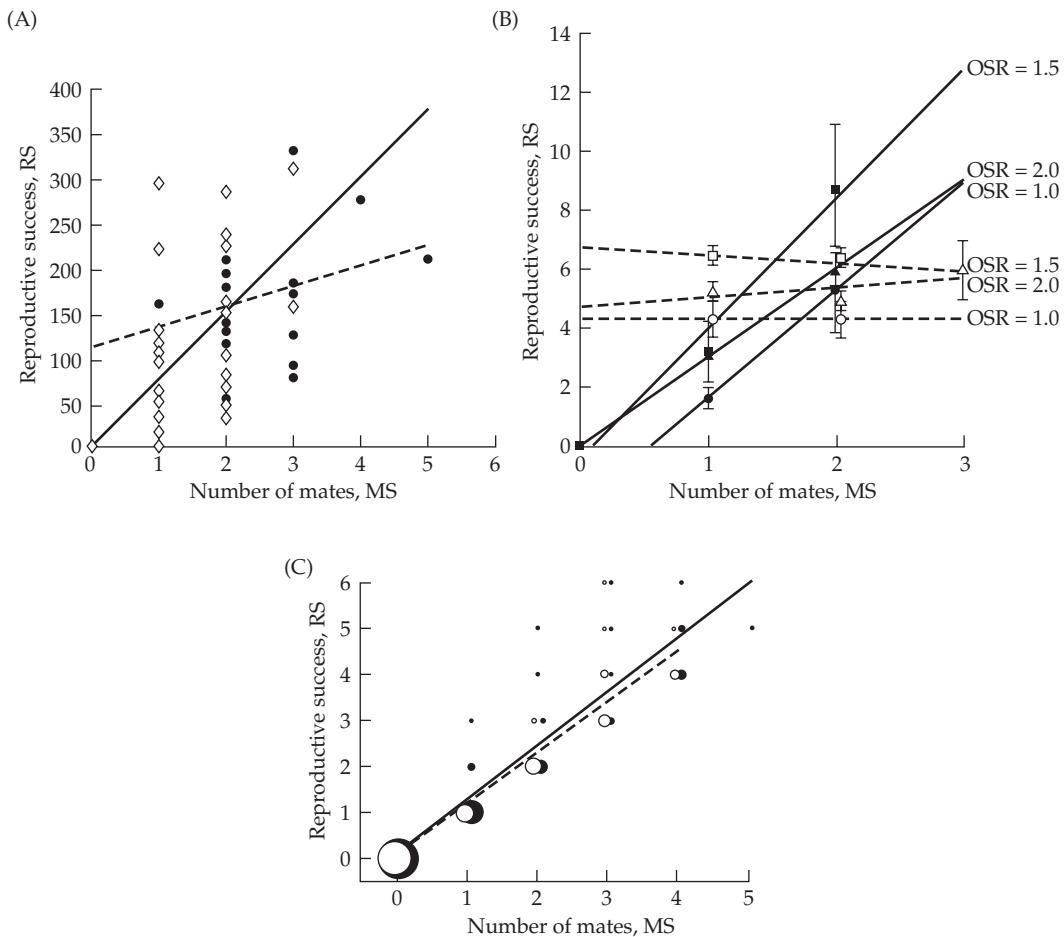

Figure 29.4 Examples of Bateman gradients, the regression of total offspring number (reproductive success [RS]) as a function of number of mates (mating success [MS]). **A:** Data for male (open diamonds and solid line) and female (filled circles and dashed line) rough-skinned newts (*Taricha granulosa*). The slope for males is significantly different from zero while the slope for females is not, and the sex-specific slopes are significantly different from each other. (After Jones et al. 2002.) **B:** Data for male (filled symbols and solid lines) and female (open symbols and dashed lines) bank voles (*Clethrionomys glareolus*), for three different operational sex ratios (ORS), indicated by squares, circles, and triangles. Again, the male slopes (at all three values of ORS) are significantly positive, while none of the female slopes are. (After Mills et al. 2007.) **C:** Gradients for a Québec population of eastern chipmunks (*Tamias striatus*). Males are open circles (regression given by the dashed line), and females are filled circles (solid line). The gradients on both sexes are positive and very similar, allowing for the possibility of strong sexual selection in both males and females. (After Bergeron et al. 2012.)

While the above alternative measures (I_δ , Q , ORS) may contain information to better inform a behavioral ecologist, the advantage of I_s is that it bounds the opportunity for sexual selection, no matter what the cause. It must be measured over an appropriate time window and in an appropriate setting, which are legitimate concerns. However, a dispassionate reading of the literature that is critical of the use of I_s shows that concern centers more around the reasonable objection that an investigator might be sloppy and directly relate I_s with *actual* sexual selection (rather than as a measure of its *opportunity*). From an evolutionary standpoint, I_s and two other measures to be introduced shortly—the Bateman gradient (Equation 29.12) and Jones index (Equation 29.14a)—are the most natural measures of the *potential* for sexual selection (Jones et al. 2000, 2002; Wade and Shuster 2005; Mills et al. 2007;

Jones 2009; Krakauer et al. 2011). Nonetheless, as stressed by Croshaw (2010), while I_s is a natural measure of sexual selection potential, it should always be contrasted with its value under a null model. Croshaw observed high values of both I and I_s in marbled salamanders (*Ambystoma opacum*), but only I was significantly greater than its expected value under a null model.

The Sexual Selection, or Bateman, Gradient

Bateman's first two principles, by themselves, do not guarantee that sexual selection is occurring. Rather, it is his third principle, relating total reproductive success (RS) with mating success (MS), that indicates the potential for sexual selection to exist. Arnold and Duvall (1994) quantified this relationship by regressing total fecundity on number of mates,

$$RS_s = \text{const} + \beta_{ss} MS_s + e_s \quad (29.12)$$

where s indexes the sex (m for male or f for female), with the regression coefficient (β_{ss}), which they termed the **sexual selection gradient**, indicating the potential for sexual selection in that sex. Biologically, β_{ss} is the additional number of offspring gained per mating. As noted by Jones et al. (2002), the gradient is the final statistical path to fitness from all sources of sexual selection. One can have large variances in both RS and MS for a particular sex, but if the two variables are uncorrelated over individuals, there is no sexual selection. Andersson and Iwasa (1996) used the term **Bateman gradient** for β_{ss} , and this has generally replaced Arnold and Duvall's term in the literature. Examples of Bateman gradients are given in Figure 29.4. Bateman's original expectation was that males will show a positive slope, while females will show little to no slope (provided they have been mated at least once). The former (a positive male Bateman gradient; $\beta_{mm} > 0$) is routinely seen, but the assumption of a small female Bateman gradient ($\beta_{ff} \approx 0$) is often incorrect. Gerlach et al. (2012) reviewed a wide range of species (ranging from invertebrates to fish, birds, reptiles, amphibians, and mammals) in which females showed a positive Bateman gradient, indicating the potential for sexual selection.

Although Bateman gradients are widely used for demonstrating the potential of sexual selection in one or both sexes (Jones et al. 2000, 2002; Mills et al. 2007), Kokko et al. (2012) made the point that the operational sex ratio (ORS) and Bateman gradients are complementary measures. The latter describes the fitness gain with increasing number of mates, while the former measures the potential difficulty in obtaining such matings. If one has a strong Bateman gradient on males (for example, estimated under controlled settings) but females are very scarce in nature (i.e., the ORS is small), much of this gain is never realized.

While least-squares linear regressions are typically used to model the RS-to-MS relationship, Arnold (1994) noted that the functional nature of this relationship may be one of four general forms. First, there could be **single-mating saturation**, as when a single mating allows a female to acquire sufficient male gametes to fertilize all of her eggs (females in Figure 29.4B). Alternatively, this relationship could be linear, with total reproductive output increasing linearly with the number of mates (as shown for all males in Figure 29.4 and for females in Figures 29.4A and 29.4C). More generally, because of additional costs and benefits of mating, the RS-to-MS functional relationship could show a **diminishing-returns** shape (e.g., increased mating yields more offspring but also puts the mating individual at additional risk). Finally, this relationship could exhibit an **intermediate optimum** number of matings. Given that most studies have insufficient numbers of individuals that have mated three or more times, attempts to fit nonlinear regressions are typically not performed.
